2. discuss basic and comprehensible metadata requirements,
3. train members of the research community from students to journal editors and reviewers.

In the future, machine learning tools will further broaden the benefits of standardized tephra sample data collection, analysis, and visualization that are not invasive to the end user. Assisted by advances in field and laboratory data collection software, digital checklists should ultimately take correlation and identification of tephra across geographically large areas to a new level that will clearly benefit all collaborative tephra research fields.

This project is partially supported by NSF and USGS.

P-1613

Identifying environmental records held within tephra layer morphology

Polly Thompson

The University of Edinburgh , Edinburgh, United Kingdom

Abstract

This PhD project aims to develop the use of tephra layer morphology as a proxy for past environments and as a tool for environmental reconstruction. Tephra layers that are incorporated into the surface stratigraphy form isochrones which can be used to define a moment in time. Based on this, tephrochronology has made significant contributions to understanding the timing of change in past environments. This project seeks to develop aspects of direct environmental reconstruction from tephra layers themselves because variation in the thickness and morphology of tephra layers reflect Earth surface processes and the surface vegetation communities present at the time the tephra was deposited and stabilised as an enduring stratigraphic layer. Therefore, the morphology of the tephra layer itself can provide valuable insights into past land surface conditions, environmental processes and land management activities. Using tephra layers as a proxy in this way can provide a novel means for interpreting past environments and allows long-term human-environment interactions to be assessed, thus further developing uses of tephra layers in a stratigraphic context.

However, post depositional alterations by surface processes, for example cryoturbation or solifluction are also captured in the morphology of tephra layers, highlighting areas in the landscape that are dynamic, less resilient and sensitive to environmental change. Such processes can erase the initial form and thickness of the tephra layer created as it was deposited and incorporated into the stratigraphy, making both traditional tephrochronological studies and novel interpretations of layer morphology more challenging. Field-based study and experimentation in Iceland are used to assess these alternative sources of environmental information held within tephra layers, in order to create a new approach to the application of tephra layers in environmental research. This will both contribute to proxy development for past environments and also improve the interpretation of tephra layers to better understand volcanic eruptions, creating more accurate eruption parameter reconstructions and isopach maps of past tephra eruption volumes.

Abstract

The investigation of tephra layers in terrestrial sediment sections such as loess-paleosol-sequences is frequently used to temporally correlate archives on a regional, supra-regional or even continental scale. This study, however, concentrates on other aspects of tephrostratigraphy, such as the depositional milieu and the post-depositional alteration of the volcanic ashes. In that sense, the polygenetic sediment sequence of Bodoc north of Sfântu Gheorghe (Transylvania, Romania) at the bank of the Olt River was investigated. In this 15 m long section volcanic ashes are intercalated by sediments of fluvial, aeolian, and colluvial origin. The sequence covers the last glacial cycle, and the several, partly thick tephra layers originate from the dacitic Ciomadul (Csomád) volcanic dome complex (CVDC). The CVDC is known to host the youngest volcanic eruptions during the late Quaternary in the Carpathian-Pannonian region, occurring ca. 29 ka BP. Due to the polygenetic characteristics of the Bodoc section, the deposition of tephra differs between subaqueous and subaerial. In the course of this study, granulometric, geochemical and spectrophotometric analyses were conducted as proxies for the paleoenvironment. Additionally, magnetic parameters were measured in order to investigate diagenetic alterations, pedogenesis and to detect cryptotephra. The chronostratigraphy is based on OSL dating as well as stratigraphic correlation and geochemical comparison of tephra deposits. Field observations and preliminary results show that the tephra deposits were altered by redoximorphic and soil forming processes. Most striking are periglacial features such as block rotations at the contact between solifluction layers and persistent permafrost as well as ice-wedge casts. These features rank among the first reported strongly developed permafrost features in the Transylvanian Basin and indicate a harsh periglacial environment following the tephra fall out. The investigations about the post-depositional alterations of the tephra is presented within the context of the sedimentation dynamics controlled by the Late Pleistocene environmental evolution.

Abstract

Sumatra hosts at least 30 active or potentially active volcanoes close to highly populated areas and lies in close proximity to global transportation and trade routes. Despite these facts and the high humanitarian and economical hazard potential of these volcanoes, very little is known about the eruptive history of the Sumatran Volcanoes.

The Sumatephra Project aims to establish a tephrostratigraphic framework for Sumatra's volcanic activity during the Quaternary, which will help to quantify the eruptive activity and to identify the sources of these eruptions. To address this task, we are combining tephra and cryptotephra records from marine, lake and peat sediments, with classical on-land records. Combining proximal, medial and distal archives provides the opportunity to not only reveal the history of highly explosive eruptions in the region, but also to reconstruct the volcanic activity within certain areas in more detail. Which will lead to a better understanding of the eruption frequencies and their spatial distribution.

Within this project we adapted methods typically used to identify cryptotephras of highly explosive eruptions in distal to ultra-distal settings at higher latitudes to tropical peat swamps located within the volcanic arc in Central Sumatra. Given the sampling locations the clastic proportions within the peat is dominated by volcaniclastic material. This requires additional characterization of the glass shards to distinguish between primary (cryptotephra) and secondary deposits (background sediment input).

The goal is to not only identify deposits of widespread highly explosive eruptions, but also evaluate the potential of using these methods to reconstruct the eruptive history of volcanoes or volcanic areas including smaller explosive eruptions (\leq VEI 4). This is of particular interest in a highly vegetated tropical region with low preservation potential for moderate to small eruptions on land and limited historical record like Sumatra.

We will present peat core data from the vicinity of active and potentially active volcanoes from Central Sumatra.

The Avellino event: a Bronze Age environmental reconstruction from the Pontine plain and the Fondi basin, southern Lazio, central Italy.

Wouter van Gorp¹, Marieke Doorenbosch², Jan Sevink³, Michael Field², Luca Alessandri¹

¹Groningen Institute of Archaeology, University of Groningen, Groningen, Netherlands. ²Faculty of Archaeology, Leiden University, Leiden, Netherlands. ³Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Amsterdam, Netherlands

Abstract

The major Early Bronze Age (EBA, about 2000-1650 BC) Avellino eruption of the Monte Somma Vesuvius has had an enormous impact on the landscape and inhabitants of the Campania region. This eruption buried the EBA landscape to the north and south of the volcano in a deep layer of volcanic ash. However, a small initial eruption had probably allowed the population to flee the area before this devastating event, heading inland rather than towards the sea. A multi-disciplinary research involving geology, palaeo-botany and archaeology has been set up to unravel the hypothesis, that a significant percentage of the refugees must have decided to resettle in the nearest coastal plains to the north - the Pontine Plain and Fondi Basin of South Lazio, and that it should therefore be possible to prove this by tracing the ecological, demographic and cultural impacts that this immigrant population must have had. This was further encouraged by the already established presence of distal AV-tephra within Holocene stratigraphy of these basins. This paper discusses the palaeogeographical and –ecological results needed to be able test the hypothesis. A detailed palaeogeographical reconstruction was made of these coastal plains to identify the AV-tephra layer within diverse EBA lake-marsh settings. Results show termination of marine influence, the presence of multiple lacustrine basins with different genesis and diachronous terrestrialization around the time of AV-tephra deposition. The palaeobotanical research has focused on reconstructing the vegetation in this area before and after the AV eruption, to detect the environmental impacts that should have been brought about by the influx of possible immigrants from Campania. High quality profiles of eight peat locations in the Pontine plain and the Fondi basin have been chosen. In addition, macro botanical research has been conducted in four of these case studies, to provide information on the local vegetation and environment around the profile locations. Where possible, plant macrofossils from terrestrial plants were extracted to obtain accurate radiocarbon dates allowing the construction of a precise chronology for the profiles. Palaeo-ecological analysis of peat in the Fondi basin shows that tephra deposition might have had a local effect on vegetation, but a limited effect on regional vegetation, while the overall human signal in the pollen record is weak. This suggests that the area was thinly populated during and directly after the Avellino event. During the project, an unexpected discovery was the presence of more than one tephra layer within the Holocene peaty sediments, opening the potential for an even more detailed palaeogeographical and –botanical analysis. New tephra characterisation studies have disclosed their origin and new radiocarbon datings have improved age control.

Establishing a tephra- and luminescence-based chronology for glacial lake outburst flood deposits in the Channelled Scablands of North America

Svenja Riedesel¹, Nicholas J G Pearce¹, Helen M Roberts¹, Geoff A T Duller¹, Britta Jensen², Jim E O'Connor³, Victor R Baker⁴

¹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom. ²Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada. ³United States Geological Survey, Portland, USA. ⁴Department of Hydrology and Atmospheric Sciences, University of Arizona, Tucson, USA

Abstract

The largest known freshwater floods in Earth's history scoured the north-western USA from the late Pleistocene catastrophic drainage of ice-dammed glacial Lake Missoula. The resulting floods covered more than 7500 km², leaving behind an impressive and dramatic landscape. Besides large-scale erosional features, the floods also deposited extensive sediment sequences. During these floods, eruptions from the Cascade volcanoes Mt St Helens (MSH) and Glacier Peak deposited volcanic ash over large areas of the Pacific Northwest, some of which, remarkably, were preserved as tephra layers within and overlying the flood sediment sequences.

The aim of this project is to develop a clear understanding of the nature, frequency, and timing of the cataclysmic glacial lake outburst floods by establishing a high-resolution chronology of these deposits by both optically stimulated luminescence (OSL) dating and tephrochronology. The magnitude of these floods, high sediment loads, and the depth of the water column diminish the likelihood that the OSL signals from the suspended sediment load were fully reset ('bleached') on deposition, making OSL dating challenging. Robust, independent age control is therefore of key importance. In this study, tephrochronology will serve as the independent age control for OSL dating; additionally, in some settings the OSL dating of sediment bracketing a tephra layer may be able to further constrain the timing of the corresponding eruption.

We use a combination of major and trace element chemistry to chemically fingerprint the tephra layers preserved in the flood deposits by comparison to reference samples of proximal deposits from Mt St Helens and well-characterised Glacier Peak deposits. Forty tephra samples collected from ten sites in Washington State were prepared and examined in the laboratory. This sample suite includes several occurrences of two closely spaced tephra layers, referred to as a couplet, and generally assigned to MSH set S on the basis of their stratigraphic position, field characteristics and major element chemistry. The clear geochemical correlation provided by this study of these distal tephra deposits preserved in flood deposits and the link to those of source-proximal tephra deposits offer a more robust correlation of different flood deposits across the region and greater insight into flood magnitude and frequency. When combined with OSL dating, the tephra-based evidence from these flood deposits provides insight into the timing of the deposition of flood sediments in the Channelled Scabland and potential links to loess deposits in the Palouse.

P-1618

Determining possible controls on Icelandic volcanism during the last glacial period: an examination of the Greenland Ice-core tephra framework

Anna Bourne¹, Siwan Davies², Peter Abbott^{3,4}

¹Queen Mary University of London, London, United Kingdom. ²Swansea University, Swansea, United Kingdom.

³Cardiff University, Cardiff, United Kingdom. ⁴University of Bern, Bern, Switzerland

Abstract

A link between increased volcanic activity in Iceland following the deglaciation has been suggested for some time ([Sigvaldason et al., 1992](#); [MacLennan et al., 2002](#), Kutterolf et al., 2019) and more recently studies have suggested a possible climatic control on Icelandic volcanism during the Holocene (Swindles et al., 2018). This poster will examine the relationship between Icelandic volcanism and climatic controls over a section of the last glacial period (25-50ka BP) using tephra data from the Greenland ice-cores. The Greenland ice-core records provide a master record of past climate changes through the last glacial period and also act as a repository of past volcanism with both volcanic aerosol (ice acidity and sulphate records) and tephra particulate matter (or glass shards) preserved in the ice. However, only the volcanic glass shards allows a geochemical link to specific Icelandic volcanic sources. The majority of deposits are preserved in cryptotephra form and continuous sampling of the NGRIP ice-core between 25-50ka allows an initial assessment of volcanic frequency during the last glacial period. A total of 88 individual volcanic events are recorded during this time period. Basaltic composition tephtras dominate the records and indicate frequent eruptions from the Grimsvötn, Katla and Kverkfjöll volcanoes in Iceland. An assessment of the eruptive frequency of different volcanic centres will be presented and links to any climatic forcing discussed.

Finding source: Integrating proximal and distal tephra records to obtain more complete volcanic histories, examples from the Cascade arc

Stephen Kuehn, James Frye, Eric Arrington, Jared Rose, Donna Kalteyer, Cameron McNeely, Addison Hostetler, Savannah Hostetler
Concord University, Athens, USA

Abstract

At Summer Lake, Oregon, USA, an ~200 kyr outcrop record contains at least 90 tephra beds (Kuehn & Negrini, 2010) yielding an average frequency of one tephra per 2,200 years. Surprisingly, less than one quarter of these beds have been correlated to proximal deposits in the Cascade arc. This indicates that our understanding of the frequency and impacts of pyroclastic volcanism from Cascade arc volcanoes based on proximal records is woefully incomplete. By integrating proximal and distal records, this situation may be improved. Recent work in the Three-Sisters–Tumalo volcanic region, associated with a relatively active segment of the Cascade volcanic arc, has obtained stratigraphic and geochemical information on numerous proximal tephra and silicic lavas. To date, more than 50 field locations have been studied, yielding more than 180 samples. Statistical clustering suggests at least 30 and perhaps more than 40 geochemically and stratigraphically distinct populations. This adds substantially to a known catalog of several small late Holocene (e.g. ~2.2 ka Rock Mesa tephra) to much larger late Pleistocene (e.g. ~0.4 Ma Bend Pumice/Tumalo tuff, and ~0.65 Ma Desert Springs tuff) eruptions from this area. At least six tephra beds (II1, JJ, JJ0.2, G, F, and E1) at Summer Lake are newly correlated with their proximal equivalents near Three Sisters. Summer Lake bed F is the ~30-35 ka Wono tephra, a key regional time marker in Oregon, California, and Nevada, which forms a visible tephra bed as much as 500 km distant. The ~200 ka bed JJ has previously been correlated (Coleman et al., 2006) to Bear Lake, Utah/Idaho about 850 km distant. At least two Three Sisters tephra correlate to Carp Lake, Washington, about 200 km to the north-northeast. Carp Lake also contains an excellent record of the early (pre set C) tephra history of Mount Saint Helens. Geochemical and age relations suggest that Summer Lake beds I (~80 ka) and W (~190 ka) correlate with coarser deposits at Carp Lake and thus likely originate from Mount Saint Helens.

The importance of grain size and shape in controlling the dispersion of the Vedde cryptotephra

Jennifer Saxby¹, Katharine Cashman¹, Alison Rust¹, Frances Beckett²

¹University of Bristol, Bristol, United Kingdom. ²Met Office, Exeter, United Kingdom

Abstract

Volcanic ash is dispersed in the atmosphere after a large eruption according to meteorology and the physical properties of the particles, including size and shape. However, there are multiple definitions of size and shape for non-spherical volcanic ash particles. This affects our ability to use physical particle properties to understand tephra transport. It is generally assumed that large particles ($> 100 \mu\text{m}$) fall out close enough to the volcano to be excluded from ash dispersion models. However, ash in tephra deposits that are hundreds, and even $>1000 \text{ km}$, from source can exceed $100 \mu\text{m}$ in size, and its transport distance is often difficult to explain using numerical models of ash dispersion. Here, using X-ray computed tomography (CT) and optical microscopy, we measure the shape and size of samples of the Vedde ash from Iceland, an exceptionally widespread tephra layer in northern Europe. We find that ash that travelled further is lower sphericity, showing that shape is an important control on tephra dispersion. Shape also impacts particle size measurements, as size for non-spherical particles can be defined in several ways. We find that particle long axis, the parameter often reported by the cryptotephra community, is on average $2.3 \times$ greater than geometric size, used by dispersion modellers. By using geometric size and quantifying shape, we can explain how Vedde ash particles of up to $190 \mu\text{m}$ were transported $> 1200 \text{ km}$ from source. We define a set of best practices for measuring the size and shape of cryptotephra shards and discuss the benefits and limitations of using physical particle properties to understand cryptotephra transport.

The origin of ocean-rafted pumice found in Mesolithic to Medieval archaeological sites across the North Atlantic

Anke Verena Zernack^{1,2}, Erlend Kirkeng Jørgensen³, Anthony Newton⁴, Felix Riede²

¹Massey University, Palmerston North, New Zealand. ²Aarhus University, Aarhus, Denmark. ³UiT Norges Arktiske Universitet, Tromsø, Norway. ⁴University of Edinburgh, Edinburgh, United Kingdom

Abstract

Ocean-rafted pumice has been found at sites across the North Atlantic, from Arctic Canada, Greenland, Iceland, the British Isles, Scandinavia and Svalbard. The majority of finds were reported from Scottish archaeological sites dated from early Holocene to the second millennium CE, representing Mesolithic, through Neolithic, Bronze and Iron Age to Norse-medieval contexts.

We have investigated frequently found, yet hitherto largely unexamined, pumice pieces from archaeological sites along the North Atlantic and Barents Sea coasts of Northern Norway. The overall aim of the study was to explore spatiotemporal patterns of pumice deposition at a distal coastline and its prehistoric human use. This paper focuses specifically on establishing the origin of the pumice and on comparing the results to other North Atlantic finds. A set of 38 new samples were selected from 19 well-controlled, spatiotemporally diverse archaeological contexts dated to between 10,100 to 587 cal. years BP, and crucially, from sites of variable isostatic uplift. The samples were subjected to geochemical and use-wear analysis. The pumice pieces exhibit high variability in kinds of use-wear; most show evidence of being used as an abrasive tool on wood, bone, antler, or hide, with marks ranging from one or more grooves and furrows to flattened, polished surfaces, some of which created a faceted appearance. The shape of the largest piece suggests use as net floater for fishing. From a volcanological perspective, the pumice samples vary macroscopically in colour, vesicularity, phenocryst assemblage and proportion, roundness and degree of alteration.

Microprobe glass analyses conducted to identify the source of the pumice revealed that most are dacitic in composition with some being rhyolitic and two plotting in the field of trachyandesite. Similar to most of the pumice found in Scottish archaeological sites and on raised shorelines in Southern Norway, the majority of pumice from Northern Norwegian sites was produced by silicic eruptions of the Katla Volcanic System in Iceland. While some could be correlated to distinct, well-dated eruptions such as the 7,000-7,200 BP SILK-B tephras and the early Holocene Vikurholl pumice, the bulk displayed a compositional range that overlaps with the SILK-A tephras. These tephras were produced by several eruptions from Katla between 6,600 and 1,676 BP and show similar major element concentrations, although further trace element analyses might allow correlation to specific eruptions.

Our pilot study provides additional albeit mostly coarse-grained age control for pumice-bearing archaeological context in the North Atlantic and sheds new light on the availability, use and curation of natural pumice resources throughout the Holocene. Furthermore, these results contribute to a better understanding of ocean-circulation patterns and the nature and frequency of Holocene silicic eruptions from Katla with implications for the potential distal impact by ocean-rafted pumice from future Icelandic eruptions.

P-1622

Holocene tephrochronology of west Iceland

David Harning^{1,2}, Thor Thordarson¹, Áslaug Geirsdóttir¹, Gifford Miller^{2,1}

¹Faculty of Earth Sciences, University of Iceland, Reykjavík, Iceland. ²INSTAAR and Department of Geological Sciences, University of Colorado Boulder, Boulder, USA

Abstract

Emerging lake sediment records are rapidly improving Iceland's Holocene tephra stratigraphy and chronology. Here, we expand upon these recent developments with a securely-dated tephrochronological record from the lake Haukadalsvatn in west Iceland. We capitalize on the existing paleomagnetic secular variation (PSV) age model, which uses 54 tie points to synchronize Haukadalsvatn's high-resolution lake sediment record to a well-dated PSV master chronology from marine core MD99-2269 on the North Iceland Shelf. Major element composition permits the identification of 38 tephra layers over the last 10,500 years. Of these total 38 tephra, 13 can be traced to tephra found on the Vestfirðir peninsula and represent a series of well-dated key tephra markers for western and northwestern Iceland. By comparing Haukadalsvatn's tephra record to other well-dated lake sediment tephra records across Iceland, we hypothesize that the early Holocene demise and mid-late Holocene nucleation of ice caps over the most productive volcanos may have at least partially controlled the tephra layer frequency in Icelandic records. We argue that Haukadalsvatn serves as an important template for the tephrochronology of western Iceland and for future studies investigating the tephra records in more distal regions of the northwestern North Atlantic, such as Greenland.

The effect of volcanism on the submontane rainforest vegetation composition: palaeoecological evidence from Danau Njalau, Sumatra (Indonesia)

Christina Setyaningsih¹, Siria Biagioni¹, Asmadi Saad², Yudhi Achnopa², Supiandi Sabiham³, Hermann Behling¹
¹Georg-August University of Goettingen, Goettingen, Germany. ²University of Jambi, Jambi, Indonesia. ³Bogor Agriculture University, Bogor, Indonesia

Abstract

Volcanic processes might have played an important role in the vegetation history of Sumatra, one of the largest and most tectonically active region in Southeast Asia. Palynological and macro-charcoal analysis results from Lake Njalau in the Kerinci Seblat National Park (KSNP) in Sumatra (Indonesia) provide an understanding of interactions between the volcanic deposition and vegetation in the past 5000 years. The deposition of volcanic material in the depression of the Lake Njalau (5100–4400 cal. yr BP) led to the dominance of pioneer species of *Casuarina* and *Myrica*, which grow in deforested land and volcano slopes (volcanophile taxa). The formation of the modern forest composition took several centuries after the volcanic deposition in the soil ended (ca. 900 years at ca. 2400 cal. yr BP). This suggests that the vegetation changes were not driven by a successional pattern, and soil formation was the most important environmental factor explaining this slow change in composition. The palynological records show no evidence for prehistoric human–landscape interactions in the area despite the close proximity to known megalith sites. The local fire regime reconstructed using macro-charcoal analysis indicates that fire was rare for the last 5000 years, and the average fire return interval was ca. 500 years. Phases of increased fire frequency could not be linked to either any of the vegetation phases or regional climatic changes, suggesting that fire occurrences were stochastic events. Our results overall suggest that volcanism has acted as one important driver of changes in the rainforests of the KSNP

P-1624

An important sedimentary archive adjacent to the Taupo Volcanic Zone, New Zealand: Volcanic activity and landscape evolution

Alan Palmer, Callum Rees, Julie Palmer

School of Agriculture and Environment (SAE), Massey University, Palmerston North, New Zealand

Abstract

Large caldera-forming rhyolite eruptions from the Central Volcanic Region have shaped New Zealand over the last c. 12 Ma. During the Quaternary the Taupo Volcanic Zone (TVZ) has been the most frequently active and productive Quaternary silicic system on Earth. Voluminous ignimbrites, many exceeding 100 km³, and at least two exceeding 1000 km³, have periodically spread over hundreds of km² of New Zealand's North Island, whilst related airfall deposits can be found over 3000 km from source.

Deposition and subsequent long-term remobilisation of vast volumes of pyroclastic material from these mega-eruptions cause abrupt, dramatic environmental changes. In adjacent river and coastal systems, the sudden influx of volcanic sediment result in valley aggradation, river avulsion, infilling of coastal embayments and coastal progradation. These large-scale sedimentary processes represent some of the most catastrophic, landscape-altering mechanisms in the world, particularly well preserved in the Whanganui Basin, in the southwest North Island of New Zealand.

Whanganui Basin is a 40,000 km², Late Miocene-Pleistocene sedimentary basin located 200 km south of the active TVZ. It occupies a back-arc position with respect to the current Pacific-Australia plate boundary, located west of the main axial range composed of Mesozoic greywacke-argillite. Subsidence migrated southeast through time, facilitating preservation of a 4.5 km dominantly marine succession. Throughout the Quaternary, sedimentation has broadly matched subsidence resulting in deposition of shelf muds through to nearshore or coastal sands and occasional terrestrial deposits on a low-lying, broad coastal plain. The sedimentary record is preserved as 58 cyclothem resulting from Quaternary climatic fluctuation on 41 k (2.58 – 1Ma) and then 100 k timescales (1Ma – 0.125Ma). Late Quaternary uplift has exposed magnificent coastal and river valley sections through the basin fill, revealing one of the most complete Quaternary stratigraphic records of climate change exposed onland anywhere in the world.

Silicic volcanism and associated volcanoclastic processes are key drivers in the landscape evolution due to their magnitude and thus extensive, long-term impact. Ignimbrites from the TVZ flowed into the catchment areas draining into the Whanganui and other peripheral sedimentary basins. The unwelded parts of these ignimbrites were easily eroded and only fragmentary records remain. However, volcanoclastics preserved as river alluvium, coastal progradation fills, deltas and nearshore deposits are conspicuous. Silicic tephras are also common in both terrestrial and marine environments.

By 1 Ma, the coastline was moving rapidly south-west towards its present position, punctuated by glacial periods of low sea-level. By 0.5 Ma, preserved marine terraces were forming in interglacials and river aggradation terraces in glacials as uplift and subsequent dissection ensued.

P-1625

A refined chronology of the Biały Kościół loess key section (Silesia, Poland) and comparison with other sections in European Lowlands

Ludwig Zoeller¹, Zdzisław Jary², Marcin Krawczyk²

¹University of Bayreuth, Geomorphology Chair, Bayreuth, Germany. ²University of Wrocław, Department of Physical Geography, Wrocław, Poland

Abstract

The loess-paleosol sequence (LPS) at Biały Kościół (Silesia, Poland) has been recognized since many years as a regional key section in the northern branch of the European loess belt, spanning the last glacial-interglacial cycle. In spring 2017, a new and more complete profile was excavated immediately adjacent to the former section, and was sampled for several sedimentological and pedological investigations. 12 well-selected samples for optical dating (OSL, pIR-IRSL) were taken from the bottom of the section to the top.

From the previous section 21 OSL ages from coarse grains of quartz (90-125µm) were published by Moska et al. (2012), but for loess older than the Upper Pleniglacial results showed some inconsistencies and problems such as apparent age underestimates which were supposed to be induced by saturation effects. Some preliminary OSL ages from the previous profile on quartz fine grains (Zoeller, unpublished) partly agree with the ages by Moska et al. (2012) but tend towards somewhat higher ages ($\geq 10\%$).

The present study tries to overcome these problems by applying the pIR-IR method using polymineral fine grains, complementary to OSL of quartz. The suitability of the pIR-IR method to avoid OSL age underestimates due to saturation effects was basically demonstrated by Moska et al. (2015) at the Złota LPS near Sandomierz. The optical sensitivity of the pIR-IRSL signal is, however, much less than of the OSL signal from quartz, eventually leading to significant age overestimates for young loess. We therefore intend to check the risk and the amount of pIR-IR age overestimation for young loess samples from Biały Kościół (<30 ka) for which quartz OSL ages are regarded reliable. As a pIR-IR age overestimation derives from a residual dose unbleached at deposition and is a numerical value expected in the range of very few ka only we expect that it becomes insignificant (<10%) for Middle or Lower Pleniglacial loess. Luminescence ages which are reliable within error bars will improve the chronostratigraphy of at least the complete last glacial cycle in Silesia.

Latest results from the ongoing research into the new profile will be presented and serve as a base for well-founded correlations with other key sections on a regional and continental scale.

Local, regional or global climatic signal? A multiproxy analysis of complex loess-palaeosol sequences from the Bulgarian Middle Danube

Kaja Fenn¹, David Thomas^{1,2,3}, Julie Durcan¹, Daniel Veres⁴

¹University of Oxford, Oxford, United Kingdom. ²University of Witwatersrand, Johannesburg, South Africa. ³East China Normal University, Shanghai, China. ⁴Romanian Academy, Oxford, Romania

Abstract

Due to their completeness and location loess-palaeosol sequences in Europe provide an opportunity to investigate in detail the last glacial-interglacial cycle. Most of the investigated records in Central and Eastern Europe fall into the typical “loess” sequence, with thick glacial loess units, broken up by a small number of well-developed interglacial and/or interstadial palaeosols. Despite a number of studies investigating short-term pedogenesis and embryonic soils in Western European loess belts, not many of these features have been described in Central and Eastern Europe. Yet these sequences have the potential to provide a detailed picture of short-term local, environmental, geomorphological or climatic conditions.

Here we present the results of a multi-proxy examination of two nearby loess-palaeosol sequences in northern Bulgaria. These sites differ from other sites investigated in the region as they preserve many embryonic soil horizons. We present the results of magnetic susceptibility, grain size, luminescence dating, and tephrochronology. The results show that sediment accumulation at the sites during the Last Glacial Maximum is almost equivalent to a full glacial-interglacial cycle recorded at sites further downstream, further highlighting the differences between the upper and lower reaches of the Lower Danube. Additionally, this work uses single grain provenance as a new tool to help understand and reconcile complex sedimentary histories. The results of U-Pb zircon dating combined with sedimentological analysis show that the two sites either experienced different depositional histories or there was a switch in the sediment delivery mechanism to the sites. We suggest that these complex loess-palaeosol sequences may hold the key to a better understanding of the Quaternary in Central Europe.

Abstract

Loess-paleosol sequences (LPS) are sensitive terrestrial archives of past aeolian dynamics and paleoclimatic change. Numerous paleoenvironmental reconstructions from loess records have traditionally depended on the analysis of grain size (GS) distributions. A number of GS based statistical approaches are widely used. However, the GS distribution of a loess sample is not solely a function of aeolian dynamics, but rather of complex polygenetic depositional and post-depositional processes.

At the well-differentiated LPS Duesseldorf Grafenberg (Lower Rhine Embayment, Germany), the $\Delta\text{GSD}_{\text{clr}}$ was identified as promising indicator for post-depositional alteration processes in LPS (Schulte and Lehmkuhl 2018). It is based on two different optical models to calculate GS distributions from laser diffraction data. We apply the $\Delta\text{GSD}_{\text{clr}}$ on the weakly differentiated last glacial LPS Krems-Wachtberg (Lower Austria) in order to evaluate its use in a loess record without distinct paleosols. The 8 m thick LPS records paleoenvironmental fluctuations between 40-20 ka in a sequence of loess sediments, reworked horizons and incipient paleosols, mainly of tundra gley type. A Beckmann Coulter LS 13320 measured GS from samples taken in 2.5 cm resolution along the whole LPS.

$\Delta\text{GSD}_{\text{clr}}$ values range around zero in the entire dataset. Nevertheless, the vertical variation of the $\Delta\text{GSD}_{\text{clr}}$ signature is directly related to post-sedimentary processes and reflect zones alternated by chemical weathering processes. The degree of pedogenesis detected by the $\Delta\text{GSD}_{\text{clr}}$ is markedly lower than suggested by colorimetric data.

We conclude that detailed grain size information (e.g. $\Delta\text{GSD}_{\text{clr}}$ values) can be used as a reliable proxy for past aeolian dynamics. In combination with a robust color-based stratigraphy the comparison of LPS Krems-Wachtberg to the LPS Nussloch and the NGRIP dust and oxygen isotope records is possible.

Abstract

Loess deposits in Europe extend from the maritime North Atlantic-influenced climatic zone of northwest Europe, to the Mediterranean-influenced southeast and the long, thick deposits influenced by Eurasian continental climate in the East. Western Central Europe sits at the core of these deposits; its location has ensured variable influence through time by both maritime and continental climate subsystems, as well as experiencing strong climatic gradients between glaciated areas in the north, and the Alps in the south. In this context, the Schwalbenberg in the Middle Rhine valley in Germany is a key area for understanding terrestrial system response to North Atlantic Climate Oscillations within the western part of Central Europe.

Previous studies indicate that loess deposits in the Schwalbenberg area are particularly thick, resolving especially the interpleniglacial period (OIS 3) in detail. However, these studies were bound to one available outcrop located in slope position enabling the creation of a local stratigraphy, which was used for a correlation to regional and supra-regional records of environmental and climate change.

Following the catena principle from downslope to interfluvial position, we conducted systematic non-invasive geophysical prospection, followed by the application of Direct Sensing techniques using the Hydraulic Profiling Tool (HPT) and Cone Penetration Testing (CPT) and subsequent sediment coring in order to obtain detailed information on the variability of the sedimentary composition along the transect. Stratigraphical data were complemented by sedimentological and geochemical analyses and the determination of rock magnetic parameters. The chronostratigraphical framework is based on radiocarbon dating of earthworm calcite granules, luminescence dating using the quartz OSL and feldspar pIR IRSL signals, palaeomagnetic time series and intercalated volcanic ashes.

We are able to demonstrate that investigated novel Loess-Palaeosol-Sequences from the Schwalbenberg area yield the thickest and most complete non-aquatic record of environmental change in Western and Central Europe for the entire Last Glacial Cycle. Furthermore, the combination of direct sensing techniques and geophysical measurements allows for accurate mapping of stratigraphical marker horizons (e.g. soil horizons, tephra layers), significant layer

boundaries (e.g. transition from loess deposits to fluvial and colluvial sediments) and erosional events along the geomorphological transect. Thus, the combined approach allows for the detection of variations between different coring and sensing locations, which enables us to decouple local, regional and supra-regional processes acting on the deposits and to elucidate the nature of loess deposition and formation through the Last Glacial Cycle.

Abstract

Abstract

A multi-proxy analysis, including grain size, magnetic susceptibility, diffuse reflectance and soil geochemistry, the examination of stable isotopes of hypocoatings, was performed on the loess-paleosol succession at Hévízgyörk (Hungary). Field investigations suggested a continuous record of sedimentation and pedogenesis at first sight. However, after the identification of the Bag Tephra (Horváth, 2001), a characteristic late Middle Pleistocene marker horizon in the Pannonian Basin, it was getting clear that paleosols and loesses are missing from the section. In contrast to the field observations, fluctuations were identified in the measured proxies in the upper paleosol, potentially indicating the presence of more than one paleosol, merging into a single paleosol.

Presumably, paleogeomorphological processes supposed to be responsible for the superposition of the paleosols, alongside of the differences between the paleoenvironment and local geomorphological position. Erosional processes could be more intensive during the beginning of interglacials along the slope, when vegetation was sparse but precipitation increased. On the other hand, it is presumed that sedimentation decreased locally, during dry, cold glacial periods, because the strong winds carried away the deposited dust. These paleoenvironmental features may well have led to the partial erosion of paleosol horizons and the lack of or entire alteration of thin loess formed during the glacials, therefore the superpositioning development of successive paleosols.

Based on their pedogenic characteristics, the investigated paleosols presumably developed during intensive interglacials and thus can be correlated to global interglacial intensities (Past Interglacials Working Group of PAGES, 2016), and gives an opportunity to define key units of the Hungarian loess stratigraphy (Thiel et al., 2014; Újvári et al., 2014).

According to the interpretation about the superpositioning, the upper paleosol could contain the MIS 7e, the MIS 7a and the MIS 5 paleosols or at least two of them, while the intercalated loess (MIS 6), and possibly the MIS 7a paleosol, were totally eroded.

The case study shows that although the superposition of paleosols disrupts the clear chronostratigraphical subdivision of the section, it can nonetheless provide valuable information about the sequence evolution.

Abstract

Introduction:

Loess-paleosol sequences often record information useful for the reconstruction of paleoenvironmental processes such as periods of increased dust accumulation, erosion or landscape stability (soil formation) triggered by climate changes. This study is focused on a loess-paleosol sequence exposed in Dejvice, located near downtown Prague, Czech Republic, which was investigated during a rescue research.

Methodology: The loess-paleosol sequence was studied using a multi proxy approach. Magnetic susceptibility and magnetic fabric (anisotropy of magnetic susceptibility) methods and geochemical approaches (total organic carbon, XRF elemental analyses, XRD mineralogy, ¹³C and ¹⁸O stable isotopes) were used to interpret the paleoenvironmental record. Optically stimulated luminescence (OSL) dating was used to determine the chronology of the section which is essential for understanding the link between climatic shifts and depositional and post-depositional regimes.

Results and Preliminary Conclusions: The loess-paleosol sequence is 15 m thick and includes loess and colluvial deposits, representing cold stages, and at least 4 different paleosol horizons, developed during warmer periods. The section records the climatic oscillations during the last two glacial stages. The Dejvice sequence contains a partly eroded weakly developed paleosol classified as PK I (MIS 3), a Chernozem and a Luvisol of PK III (MIS 5e). The oldest detected paleosol is a Luvisol of PK IV. The Dejvice sequence was highly affected by several erosion events. There is a hiatus of approximately 50 ka corresponding to the Early Weichselian. Gravel and colluvial deposits are present in a number of layers in the section. The record preserved in the section corresponds well to other sections exposed in central Bohemia and shows significant paleoclimate changes.

Mineral analysis (QEMSCAN® method) of the loess-palaeosol sequence in Złota (Sandomierz Upland, Poland) – preliminary results

Jacek Skurzyński¹, Piotr Kenis^{2,1}, Zdzisław Jary¹

¹Department of Physical Geography, University of Wrocław, Wrocław, Poland. ²PORT Sp. z o.o., Wrocław, Poland

Abstract

The mineralogy of the five loess samples from the Złota loess-palaeosol sequence (LPS) was analysed by the QEMSCAN® - Quantitative Evaluation of Minerals by Scanning Electron Microscopy. Each sample was placed into silicon cup and covered by Epofix (cold mounting). Samples were then treated by a low vacuum to remove air vesicles. The hardened surface was grinded, polished and carbon-coated. The final samples were transferred to the sample holder dedicated to the QEMSCAN® analysis.

The used QEMSCAN® combines an automated scanning electron microscope (SEM) with two energy-dispersive X-ray spectrometers (EDS). The backscattered scanning electron signal (BSE) controls the acquisition of EDS spectra identifying the chemical composition of the sample surface. The measurements are compared against a database of known mineral phases and classified into hierarchically-grouped mineral list. Mineral identification, mapping and data analysis are performed by the iDiscover® software.

In Złota LPS the dominant rock-forming mineral components are quartz, feldspars, carbonates (calcite and dolomite) and micas. In heavy minerals group there are zircons, tourmalines, garnets, pyroxenes, automorphic titanium-rich minerals (ilmenite, titanite, and polymorphic forms of TiO₂ e.g. rutile), etc. Furthermore, gold and electrum were found. The preliminary results reveal also that in Złota there are present rare REE-bearing heavy minerals e.g. Allanite-(Ce) and Xenotime-(Y), which are characteristic for "NYF" granitic pegmatites. For each sample QEMSCAN® provided quantitative mineralogy data, textural information in form of mineral maps of the scanned sample surface, and mineral-specific size and shape attributes. The mineralogical analyses confirmed earlier results of chemical composition analyses e.g. clear distinction between L1LL1 and L1LL2 loess units.

Grain size variation of loess in Poland

Marcin Krawczyk¹, Małgorzata Wieczorek², Zdzisław Jary¹

¹Department of Physical Geography, University of Wrocław, Wrocław, Poland. ²Department of Geoinformatics and Cartography, University of Wrocław, Wrocław, Poland

Abstract

Loess in Poland occupies the central area of the northern zone of occurrence of loess in Europe - one of the largest loess areas in the world. Because of their characteristic transitional location, they are among the most interesting on the continent. Their granulometric diversity is the main subject of this study.

The analysis was based on the grain size distribution of L1LL1 loess units of three loess-soil sequences that represent the three most important loess areas in Poland. Loess-soil sequences are well suited for studying past changes, although in most cases sediment properties can't be associated with only one process. An important condition for pre-separation of signals coming from sediments and further reconstruction of parameters is to examine the contemporary spatial variability of sediment characteristics and apply appropriate models. Observable sediment properties are the result of the interaction of many processes. Several statistical methods have been used to diagnose them well. One of them is the flexible end-member modeling algorithm (EMMA). This algorithm calculates the so-called "end members" which represent sources and processes affecting the lithological features of loess. The statistical *k*-median method was also used in the granulometric analysis. This method allowed the separation of several groups in the L1LL1 loess structure.

These groups were characterized by different grain characteristics and suggest different features of the loess sedimentation environment between western and eastern Poland. The western part of Poland has many features related to the loess of Western Europe deposited in the marine climate. Loess in eastern Poland had more features related to the deposit in the continental climate. The results of the analysis show the dissimilarity of granulometric features of SW Poland loess represented by the sequence in Biały Kościół (Strzelin Hills) in relation to the loess of the eastern part of the country. Loess at this place is characterized by a different composition and structure, which is confirmed by the results of *k*-median analysis. It is confirmed by enrichment of fine dust fractions. The results of grain-size analysis of Złota and Tyszowce sections show a lot of similarities and differ to a small extent. Within all analyzed L1LL1 units *k*-median analysis suggests the presence of three different subpopulations which may suggest a differentiation of the loess formation processes. Subpopulations are reflected in the number of calculated particle-based "end members".

The obtained results confirm that the process of forming the L1LL1 unit was not continuous. The subpopulations separated by statistical methods indirectly inform about climatic conditions prevailing in the sedimentation environment, i.e. with different sedimentation coefficient, as well as factors affecting the pollination from various sources.

P-1633

Colorimetric variations of loess-paleosol sequences in SW Poland

Marcin Krawczyk¹, Tobias Sprafke², Kamila Ryzner¹, Zdzisław Jary¹

¹Department of Physical Geography, University of Wrocław, Wrocław, Poland. ²Institute of Geography (GIUB) - Unit Paleo-Geoecology, University of Bern, Bern, Swaziland

Abstract

Loess-paleosol sequences (LPS) are terrestrial records of paleoenvironmental changes in the Pleistocene, which develop in the interplay of aeolian sedimentation, pedogenesis, slope processes and erosion. Color variations along the stratigraphic sequence of LPS result mainly from pedogenic overprinting during sedimentary pauses. Brownish to reddish colors reflect different degrees and conditions of oxidation, whereas grey colors can be attributed to reduction (tundra gleys). Color variations are complex, indirect proxies for paleoclimatic changes and increasingly recognized in loess research.

This poster studies the colorimetric variations of two last glacial LPS in SW Poland. The LPS Zaprężyn is located at 165 m a.s.l. at the southern margin of the Trzebnickie Hills, where loess sediments have a thickness of about 4-6 m. The LPS Biały Kościół is located 60 km further south on the west slope of the Oława river valley at an altitude of approximately 185 m a.s.l. The profile is located in an old loam pit and exposes 9 m interfluvial and slope loess.

An overall number of 1500 samples were collected with 1 cm intervals from both profiles. A Konica Minolta 600d spectrophotometer quantified their color variations objectively, reproducibly and non-destructively. The results are presented in the CIELAB color space and then converted to the RGB color scale. The measured color values were the basis for the differentiation and classification of profile units using widely established pedological standards (e.g. A, B, C master horizons). This classification has sufficient sensitivity in detecting stratigraphically significant changes in the intensity of pedogenesis processes.

The analysis of colorimetric variation of the loess-soil sequences in SW Poland allowed for several conclusions:

- * Colorimetric studies confirm the presence of major lithostratigraphic units.
- * Color measurement and their vertical differentiation allowed to separate new subunits even in seemingly homogeneous loess units.
- * High resolution colorimetric studies play a significant role in clarifying the stratigraphic division of LPS.

Chronostratigraphy of Late Pleistocene loess-palaeosol sequences in Poland – record of discontinuous sedimentation

Zdzisław Jary¹, Piotr Moska², Grzegorz Adamiec², Andrzej Bluszcz², Ludwig Zoeller³, Pierre Antoine⁴, Marcin Krawczyk¹, Jerzy Raczek¹, Jacek Skurzyński¹

¹Department of Physical Geography, University of Wrocław, Wrocław, Poland. ²Institute of Physics – Center for Science and Education, Silesian University of Technology, Gliwice, Poland. ³Chair of Geomorphology, University of Bayreuth, Bayreuth, Germany. ⁴Laboratoire de Géographie Physique Environnements quaternaires et actuels (UMR 8591, CNRS-Universités Paris I & Paris XII), Meudon, France

Abstract

Loess covers in Poland are situated in the southern part of the country, along the northern margin of the central part of the European loess belt. Their location and origin are clearly connected with the Pleistocene glaciations.

In the 1991 book entitled “Main Sections of Loesses in Poland” about 50 loess profiles were characterized that represented all loess areas in Poland. According to Maruszczak’s chronostratigraphic scheme, the Late Pleistocene loess-palaeosol sequences (LPS) consists of four main loess deposition stages: Early Weichselian and lower, middle and upper Pleniveichselian age (Marine Isotope Stage - MIS 5b, 4, 3 and 2). Maruszczak claimed that the Late Pleistocene loess sedimentation process in Poland was almost continuous and very well correlated with the marine record. At the end of the 20th century most of the questions concerning Late Pleistocene loess in Poland (stratigraphy, age by means of the TL method, rate of deposition, periglacial record and others) seemed to be well explained and documented.

To verify previous chronostratigraphic scheme of the Late Pleistocene LPS in Poland new research was performed during the last 10 years, using a new methodological approach. Several representative loess successions were chosen along the latitudinal transect from western to eastern Poland. These LPS were sampled in vertical continuous sections at close intervals (5 cm) and comprehensively documented. Grain-size distribution, carbonate and organic carbon contents, geochemical composition and magnetic susceptibility were determined.

To emphasize the global nature of loess sedimentation a slightly modified labelling system elaborated for the Chinese Loess Plateau was used. High resolution optically stimulated luminescence (OSL) dating was performed: Post-IR IRSL method for the polymineral fraction (4-11 μm) and OSL method for medium quartz fraction (45-63 μm). Radiocarbon dating was conducted for chronostratigraphic modelling.

The results of the investigations allow drawing some conclusions. The research results obtained to date, indicate that Late Pleistocene loess sedimentation in Poland was not a continuous process. Aeolian dust was deposited mainly during MIS 4 and 2. No evidence was found to confirm the significant deposition of loess in the middle Pleniveichselian (MIS 3). In warmer Late Pleistocene stages (MIS 5 and 3) the rate of loess deposition was reduced almost to zero. The results of high resolution dating indicate short but very intensive processes of aeolian dust deposition which took place in very harsh climatic conditions with very sparse plant cover. Confirmation of this interpretation is the common occurrence of the primary loess lamination - especially characteristic for L1L1 loess.

The research was performed under the National Science Centre project No. 2011/01/D/ST10/06049 entitled “Establishing the chronology of Late Pleistocene loess formation in Poland on the basis of high resolution luminescence dating and litho-pedological studies of selected loess-soil sequences”.

¹University of Cologne, Institute of Geography, Cologne, Germany. ²RWTH Aachen University, Institute of Geography, Aachen, Germany. ³University of Cologne, Institute of Geology, Cologne, Germany. ⁴Romanian Academy, Institute of Speleology, Cluj-Napoca, Romania. ⁵University of Bayreuth, Department of Geography, Bayreuth, Germany

Abstract

The loess-palaeosol sequence of the Balta Alba Kurgan profile is located in the steppe landscape of the Lower Danube Basin (Romania). The stratigraphic sequence encompasses an interglacial soil complex at the base, as well as interstadial soil horizons and a tephra layer as chronological markers. The latter has been identified as the 39-40 ka old Campanian Ignimbrite (Y5) tephra. The flank of a Neolithic to Bronze Age tumulus intercalated in the Holocene soil which developed during continuous dust input forms the top of the sequence.

Optically stimulated luminescence (OSL) dating has frequently been used to date loess deposits. This method is well suited, because it directly determines the time of sediment deposition. For this study we compared sand-sized quartz and potassium feldspar samples as well as polymineral fine-grained samples using blue stimulation for quartz minerals and infrared stimulation (IRSL) as well as post-infrared infrared stimulation (p-IR IRSL) for potassium feldspar and polymineral samples, for a comprehensive luminescence chronology and to identify the best dating technique for these sediments. However, luminescence age estimates are limited, when investigating short term palaeoenvironmental fluctuations. Therefore, we apply a multi-method dating approach to refine the chronology of the Balta Alba Kurgan profile. This approach includes investigating the potential of radiocarbon dating of earthworm calcite granules in the sediment and palaeomagnetic dating of the section.

Environmental magnetic and colorimetric screening of a last glacial loess profile from Lower Silesia: evidence for a harsh periglacial environment

Christian Laag¹, Ulrich Hambach^{1,2}, Marcin Krawczyk³, Jerzy Raczek³, Zdzisław Jary³, Ludwig Zöller^{1,2}

¹Chair of Geomorphology, University of Bayreuth, Bayreuth, Germany. ²BayCEER, University of Bayreuth, Bayreuth, Germany. ³Chair of Physical Geography, University of Wrocław, Wrocław, Poland

Abstract

Central European loess-palaeosol sequences (LPS) are valuable recorders of Late Pleistocene climatic change, especially in areas where other geoarchives are rare or absent. However, in the vicinity of the ice margins mid latitude last glacial loess sequences are strongly influenced by periglacially controlled humidity variations. Deep seasonal frost and permafrost cause periodic waterlogging, which in turn is responsible for pervasive redoximorphy, leading to reduction and mobilisation of iron (Fe) and re-precipitation of Fe-minerals. These processes alter colour and magnetic properties in LPS. Here we present preliminary results from a multidisciplinary study on a Late Pleistocene LPS from Lower Silesia (Poland), strongly effected by redoximorphy.

The Biały Kościół (BK) section is situated in Lower Silesia, approximately 130 km south of the last glacial maximum ice extent. The profile is considered as one of the most complete LPS in SW-Poland covering the last glacial cycle. Previous studies provide numerical ages by optical stimulated luminescence and radiocarbon dating, as well as grain size analysis, pointing to a time-span ranging from the latest Pleistocene down to the last interglacial.

Preliminary environmental magnetic and colorimetric data show the strong influence of secondary alteration, largely caused by redoximorphy of variable degree. In general, in the dry steppe loess of Eurasia, pedogenesis leads usually to brunification and to so-called magnetic enhancement which is caused by the neoformation of superfine magnetic minerals in the course of silicate weathering. At BK, magnetic enhancement is only realized in the Holocene soil, whereas the remaining sediments show solely a strong depletion of magnetic signals.

Quantitative magnetic susceptibility measurements display distinct and consistent units, with their highest values in the Holocene soil and in the lower third of the sequence, whereas qualitative parameters detect increasing alternation of the materials' magnetic composition with increasing depth. In contrast to most Eurasian dry loess areas, BK does not display any magnetic enhancement except for the Holocene soil. We assume, that the primary detrital signal is overprinted by early diagenesis and simultaneously modulated by complex redoximorphic processes. Interestingly and so far not explainable by physics, but stratigraphically consistent, intervals of negative frequency dependence of magnetic susceptibility are restricted to intervals of most intense redoximorphy. It is telling, that this phenomenon has already been observed in southern Siberian LPS.

Combined environmental magnetic and colorimetric results show distinct features of a profile close to the last glacial ice margin with fundamental differences to characteristic steppe loess of Eurasia. Based on the completeness of the profile, its geographic location, previous analyses, and newly obtained results, the loess profile of BK has great potential to become a key profile for periglacial loess in Silesia and beyond, hopefully improving our understanding of the impact of harsh periglacial environments on LPS.

Late Pleistocene loess deposits and palaeoenvironmental conditions in Iskitim district, Novosibirsk Ob region, West Siberia

Anna Olegovna Volvakh, Nikolay Evgenevich Volvakh

Sobolev Institute of Geology and Mineralogy Siberian Branch Russian Academy of Sciences, Novosibirsk, Russian Federation

Abstract

Late Pleistocene loess deposits are widespread in the Iskitim region. Its thickness varies from 1 to 10 meters mostly depending on geomorphological settings. Loess and loess-like deposits of MIS-2 and MIS-3 are most common. The farther from Ob Loess Plateau (up to 8-9 m; Lozhok section) to the east to the foothills of the Salair (Prisalair plain), the lower the cover thickness (up to 4-5 m, Ust'-Chem and Koen sections, MIS2-MIS4). The fullest and the most representative sections are Lozhok (MIS2-MIS-6) and Mramornyi (MIS-2-MIS-4). Sand quartz grain morphoscopy of all studied sections revealed the aeolian processes during the sedimentation and traces of cryogenic processes. As it was shown by high-resolution grain size distribution (interval 5 cm and 2 cm) the dynamics activity increased from the Tulino loess (MIS-4) to the Bagan loess (2nd half of MIS-2). Frequency-dependent magnetic susceptibility increases in paleosol horizons, while in loess layers its value is lower. Detailed bulk chemical composition (Sizikova, Zykina, 2015) and elemental ratios (Ba/Sr, Sr/Ca, Mg/Sr, Mg/Ca, with interval of 5 cm in Lozhok section) determine several peaks that seems to indicate paleoclimate humidification. During the latest field investigations of the Lozhok profile, some traces of weekly developed soil formation were noted, which had not previously distinguished as a separate horizon. They are marked above two horizons of paleosols (MIS-5e and MIS-5c) of Berdsk pedocomplex. At this stage of the study, we cannot unambiguously attribute this layer with soil formation of the substage MIS-5a, which is practically not found in this area before. Further research will help to understand whether there is a connection between its formation and the events of MIS-5a.

Multi-method data show that in the second half of the Sartan Glaciation (MIS-2), the environmental conditions in the area was apparently the driest and the coldest, being favorable for aeolian processes.

The work is done on state assignment of IGM SB RAS. The reported research was funded by Russian Foundation for Basic Research and the government of the Novosibirsk region of the Russian Federation, grant № 18-45-543007 and RFBR grant №19-05-00513.

Cryogenic features in loess of Pleistocene periglacial zone (Volga region, Russia)

Natalia Taratunina^{1,2}, Victor Rogov³, Redzhep Kurbanov³, Irina Streletskaya³, Tamara Yanina³

¹Institute of Geography of the Russian Academy of Sciences, Moscow, Russian Federation. ²Skolkovo Institute of Science and Technology, Moscow, Russian Federation. ³Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

Loess-soil formations within the Pleistocene periglacial zone are widely spread. Most researchers believe that cyclical climate variations in the Pleistocene are fixed in the structure of loess-soil formations. This work presents the results of complex cryolithological analysis for sediments of sections of the left bank of the Akhtuba River (the southern periphery of the loess European area, Russia).

A cryolithological analysis of mineral matter was conducted to assess the paleogeographic conditions of their formation. The analysis was performed by using scanning electron microscope (SEM), particle size analyzer and X-Ray diffractometer to assess the degree of influence of cryogenic processes on the formation of loess lithological features.

It was shown that processes of cryogenic transformation of deposits took place in the conditions of seasonal freezing in the Pleistocene, which contributed to the formation of the high thickness loess. Researches showed prospects of the cryolithological analysis of mineral matter to estimate the paleogeographic conditions.

This study has been supported by Russian Foundation for Basic Research (Grant №18-35-00619).

Abstract

Paleogeographic development of the Caspian Sea in the Late Pleisocene is characterized by alternation of transgressive and regressive stages. Unlike transgressive periods, the paleogeographical environment during regressive periods is less understood. The main reason is the lack of paleontological and paleobotanical remains (fauna and pollen) in continental deposits of various genesis.

The longest period of a Caspian Sea low level stand in the Late Pleistocene is the Atelian regression. During this period a thick sequence of continental deposits was formed. This formation is widespread within the Northern Caspian Depression and represented by subaqueous and subaerial deposits, including alluvial and aeolian. In the southern part of Lower Volga most of this strata is eroded by more active abrasion during Caspian sea minor transgressions of Hirkanian time and the first part of Khvalynian period. But in the north, in the series of sections around the Volgograd city, Atelian strata reach up to 10-12 m in thickness. In this area continental sedimentation was longer, the abrasion during the high-stand of Early Khvalynian transgression was relatively small (~1-3 m, depending on the geomorphological position) due to very rapid sea-level rise in a short time (Kurbanov et al., 2018). Four sections reveal the structure of Atelian formation: Srednyaya Akhtuba, Leninsk and Batayevka on the left side of the Volga valley and Raigorod on the right side.

Described stratigraphy and chronology of the loess-paleosol sequence of the Atelian formation allows us to better understand the main stages of environmental evolution of the Lower Volga region and the whole Northern Caspian lowland during the Late Quaternary.

Characteristics of black carbon in the topsoil of the central and southeastern Qinghai-Tibetan Plateau, China, and their environmental significance

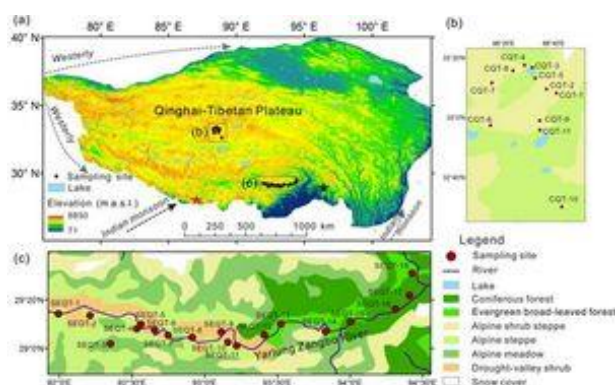

lian liu¹, Quan Li², Min Huang¹, Yan Yang¹

¹Chinese Academy of Geological Sciences, Beijing, China. ²Institute of Geographic Sciences and Natural Resources Research, Chinese , Beijing, China

Abstract

Abstract: The Qinghai-Tibetan Plateau (QTP), known as the ‘roof of the world’, is the largest elevated landscape in the world with an average altitude of over 4000m above sea level (m a.s.l.). To date there is still a lack of investigation into topsoil BC at the high-altitude regions of the QTP, where alpine vegetation changes dramatically with the altitude gradient and responds sensitively to climate changes. In order to establish the relationship between BC, contemporary vegetation and climate at the high altitudes of the QTP, we investigated the carbon concentration and carbon isotope composition of BC and soil organic carbon (SOC) (%BC, %SOC, $\delta^{13}C_{BC}$ and $\delta^{13}C_{SOC}$) in 29 topsoil samples from the central QTP (CQTP) and southeastern QTP (SQTP) (Fig. 1). In general, the %SOC (CQTP: 0.20%-1.58%; SQTP: 0.35%-13.07%) and %BC (CQTP: 0.02%-0.14%; SQTP: 0.03%-0.74%) of topsoil show generally similar variations, indicating a common controlling factor for SOC and BC production, i.e., vegetation. The relatively small BC/SOC ratios (CQTP: 4.75%-19.29%; SQTP: 5.62%-18.77%) fall in the range of BC/OC for pyrogenic particles from biomass burning, indicating a minor contribution of BC from fossil fuel combustion. The $\delta^{13}C_{SOC}$ of topsoil (CQTP: -24.1‰ to -21.5‰ ; SQTP: -26.5‰ to -17.4‰) can effectively indicate local vegetation in the QTP. The $\delta^{13}C_{BC}$ and $\delta^{13}C_{SOC}$ are positively correlated, whereas the $\delta^{13}C_{BC}$ values (CQTP: -27.5‰ to -25.3‰ ; SQTP: -29.7‰ to -20.7‰) are more negative than those of $\delta^{13}C_{SOC}$ ($\Delta^{13}C_{SOC-BC}$ of -0.3‰ to $+5.1\text{‰}$). This could due to fire season and fractionation processes during post-deposition, but not carbon isotope fractionation during combustion or exogenous BC input. Therefore, BC in topsoil of the QTP mainly records ‘local’ environmental information, and the $\delta^{13}C_{BC}$ can be used in paleovegetation reconstruction in combination with the local climate.

Abstract

Projected warming scenarios suggest fire risk increases in certain regions, in particular in the Mediterranean region. However, large uncertainties remain because fire is a complex process, which is difficult to integrate into global modelling. Moreover, because climate is changing rapidly, models must be tested not only with modern observations, but also with observations from climate conditions very different from today. Marine sediments are a source of past fire history data that can provide such information. However, charcoal (the fire proxy) in marine sediments must be calibrated, i.e. linking the amount of charcoal found in sediments to fire regime metrics in order to benchmark quantitative models. Microcharcoal concentration was quantified in several interface sediment samples from the Atlantic Ocean margin off the Iberian Peninsula. Microcharcoal concentration was compared with parameters linked to the microcharcoal production source area (burnt area, net primary productivity, type of burnt plants, watershed size), and to the transport/deposition (wind, currents, bathymetry, distance to the river's mouth, sedimentary discharge). Our results show a great heterogeneity in the spatial distribution of microcharcoal concentrations. However, the south of the Iberian margin is characterized by higher mean concentration than the northern region. Burnt area and the numbers of fires partially explain this pattern. Our results suggest that the high winter net primary productivity of grassland and dry shrubland and the hot and dry climate observed in the southern region explain high microcharcoal concentration values in the south of the Iberian margin. Additionally, the bathymetry and the distance from the river's mouth influence the distribution of concentration within this area.

Holocene fire history in the forest zone of European Russia: climate change or human impact?

Elena Novenko^{1,2}, Dmitry Kupriyanov¹

¹Faculty of Geography, Lomonosov Moscow State University, Moscow, Russian Federation. ²Institute of Geography Russian Academy of Science, Moscow, Russian Federation

Abstract

Fire frequency was reconstructed on the base of macro- and micro-charcoal concentration in peat cores from five key areas, located in different landscape zone of European Russia: Ustyanskoe plateau in Archangelsk region (middle taiga), southern part of Valdai Upland (the Central Forest Biosphere Reserve, south taiga), Meshchera lowlands and Mordovia State Natural Reserve (Polesie-type landscape, mixed coniferous-broadleaf forests) and Mid-Russian Upland (Kaluzhskie Zaseki State Natural Reserve, broadleaf forests). The obtained results showed that the beginning of human occupation of the areas is clearly marked by increased fire activity. Medieval time (at about 1000 cal yr BP) and Modern Period (the last 300 years) were marked by high fire frequencies allover the East European Plain. In the model area "Kaluzhskie Zaseki" a significant increase in fire frequency was revealed around 2000 cal yr BP (Early Iron Age) and the maximum frequency of fires (8 fires per 1000 years) was reconstructed for the last millennium. However, periods of increased fire activity occurred prior to the occupation of these areas by human. The highest frequency of fire in all model areas was determined for the periods 9000-6000 cal yr BP and 3500 – 2500 cal yr BP. According to data available, the influence of anthropogenic factor during these time interval was low. Archeological findings were not revealed in vicinity of the peat cores and no pollen or plant macrofossil indicators of human impact were detected. Evidently forest fires were caused by climatic reason. According to regional climatic reconstruction inferred from pollen and testate amoebae data these periods were characterized by high temperatures and dry summer conditions. Even in the areas of spruce taiga forests (Ustyanskoe plateau and Valdai Upland) where fire events were rare entire the Holocene until the Modern Period, most of them occurred in 9000-6000 and 3500-2500 cal yr BP. In contrast to the taiga area the Polesie-type landscapes (Meshchera lowlands, Mordovia, vast fluvio-glacial plains with pine forests) were affected by repeated fires throughout the Holocene, nevertheless fire frequencies increased during the same periods as in other model areas. Fire-free interval determined for the periods 9000-6000 cal yr BP and 3500 – 2500 cal yr BP ranged from 15- 20 to 120 years.

Abstract

Fire provides an important indicator of paleoclimatic change. However, little information of late Cenozoic fire history has been gathered in mid-latitude Asia (including Inner Asia and East Asia), a key region for understanding the development of the arid-monsoon climate system as well as the driving forces behind it. Here we first report the records of microcharcoal concentrations (MC) covering the Holocene (10-0 ka) and late Pleistocene (0.8-0 Ma), which we use to analyze the fire patterns in orbital time scale; then we compile the late Cenozoic MC record to investigate the long-term fire history by analyzing four cores from the Yangtze River Delta (YRD) area, East Asia (coupled with 8-0 Ma) and three sites in the Inner Asia (coupled with 18-2 Ma). The results show that the MC (i) remained higher during the relatively dry late Holocene/glacial stages than during the humid middle Holocene/interglacial stages at individual sites; (ii) became denser with time in both Inner Asia and East Asia after 18 and 8 Ma, respectively; and (iii) always remained higher in the dry Inner Asia than in the contemporaneous wet East Asia. All these characteristics imply that late Cenozoic fire in mid-latitude Asia experienced a gradual increasing trend along with the global temperature/ice volume change, and represented a continuous aridification trend across the mid-latitude Asia. The global cooling rather than the Tibetan Plateau uplift might have played a key role in it.

P-1805

The impact of climate and vegetation on fire activity over the past 2000 years in the Daxing'an Mountains, China

Yiyin Li

Peking University, Beijing, China

Abstract

It is very important to understand the causes and consequences of fire activity as global warming is likely to increase the risk of fire. The region around the Daxing'an Mountains known as a high incidence area of fire in China is an ideal sites to explore the fire history and the interactions between fire, vegetation and climate change. Four peat profiles in the Daxing'an Mountains was sampled for pollen and charcoal analyses. Compared with the synthesis charcoal records of Global and Northern Hemisphere¹, four peat profiles in the Daxing'an Mountains showed that regional fire activity had obvious fluctuation characteristics during the past 2000 years. Three periods of greater frequency of fire with different climates were detected over the past 2000 years: MWP (AD 680-1300, warm and dry), early LIA (AD 1300-1500) and late LIA (AD 1700-1900) (cold and dry). Our results confirm that the occurrence of fire depends on both fuel availability and climate conditions. More intensive fire activities coincide with phases of drier climate demonstrated by drought-tolerant pioneer taxa, such as *Pinus*, *Betula* and *Quercus*. Fewer fires have been identified in the middle LIA (AD 1500-1700) due to the cold and wet climate evidenced by *Sphagnum* spore. Warm climate related to the higher total PAR² (pollen accumulation rate) is suitable for the growth of vegetation, which would produce abundant fuel accumulation for burning. However cold climate with the lower PAR restrains litter decomposition and increases the combustible loads on the surface litter layer, which provides sufficient fuel for burning. Wet climate would promote plant growth, but could also restrain the break-out of fires. Our study suggest that temperature is less important than humidity in determining whether there is frequent fire activity in our study area.

Abstract

Compared to other areas of Europe (e.g. Mediterranean, Alps or Carpathians), fire activity in central European lowlands is not well recognized and only few new charcoal records have been published from palaeo-archives in this region in the recent years. The poster will present a summary of microscopic charcoal records based on seven Sphagnum-dominated peatlands located in northern Poland along the oceanic-continental climatic gradient (from west to east): Pawski Ług, Bagno Kusowo, Głębozec, Linje, Gązwa, Mechacz Wielki and Jaczno. The records cover up to the last 6000 years. We recognized a general trend of increasing fire activity along the gradient from west to east, with significantly higher charcoal influxes recorded in peatlands influenced mainly by continental climatic conditions. Charcoal peaks recorded in the last 2000 years were often connected with increased human activity, including agricultural activity (decrease in arboreal pollen and higher number of open land and agricultural indicators), drainage, and military events (for example higher charcoal influxes during the Thirty Years' War in western Pomerania). As fire activity is predicted to increase in the near future also in central and eastern Europe, the information about long-term fire activity and biomass burning in European lowlands is essential for further predictions.

Late-Holocene fire activity in the New Jersey Pine Barrens and correlation with historical fire records of a managed ecosystem

Mark Grosvenor^{1,2}, Michael Gallagher³, Claire Belcher²

¹King's College London, London, United Kingdom. ²University of Exeter, Exeter, United Kingdom. ³United States Forest Service, New Lisbon, USA

Abstract

The New Jersey Pine Barrens is the largest area of pine-oak forest on the Atlantic Coastal Plain and is located in one of the most densely populated areas of the United States. The Pine Barrens are a fire dependant ecosystem, and prescribed burning has been routinely used as a tool to manage the landscape in order to protect local communities, and reduce wildfire related impacts (such as air quality) upon nearby centres of habitation including Philadelphia and New York City. When evaluating the impact of management, it is important to consider the long-term fire regime of the landscape. Our research presents the first regional charcoal dataset from a sedimentary record in order to reconstruct fire activity prior to historical records of fire and the more intensive ecosystem management of the 20th Century.

A ~ 3400 year sediment core from a wetland basin within the central Pine Barrens was dated using ²¹⁰Pb and ¹⁴C. Charcoal concentrations for macro (>125 µm) and micro (15 – 125 µm) particles were determined on contiguous samples at up to 0.5 cm intervals providing a sub-decadal sampling resolution on historical timescales. Alongside charcoal data, pollen was analysed from the same samples to identify long term vegetation change.

Whilst our evidence shows correlation between recorded fires during the 20th Century and peaks in charcoal concentration, there is also evidence to show far greater levels of fire activity prior to historical records. We identify a substantial increase in charcoal concentrations around 1800 years BP. Following this increase, there is evidence to suggest a ~400 year cyclicity in micro-charcoal concentrations and a ~300 year cyclicity in macro-charcoal. Furthermore, there is an apparent increase in regularity of peaks in macro-charcoal concentration following European settlement of the region (last ~400 years).

Holocene paleofire history and responses to climate change in the northern Greater Khingan Range

Chao Zhao^{1,2}, Xiaoqiang Li^{3,4,5}, Xinying Zhou^{3,4,5}

¹Beijing Senior Expert Technology Center Chinese Academy of Sciences, Beijing, China. ²Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China. ³Institute of Vertebrate Paleontology and Palaeoanthropology, Chinese Academy of Sciences, Beijing, China. ⁴University of Chinese Academy of Sciences, Beijing, China. ⁵Center for Excellence in Life and Palaeoenvironment, Chinese Academy of Sciences, Beijing, China

Abstract

Natural fire is one of the important indicators of climate and environment change. The northern Greater Khingan Range (GKR), in the northernmost part of northeast China, is located on the eastern margin of the Eurasian continent and contains cold-temperate coniferous forest. It lies on the margins of the East Asian Summer Monsoon region and is extremely sensitive to changes in temperature and moisture. It accounts for 29.9% of the total forest and is a concentrated major forest fire distribution area in China.

Over the past decades, temperatures in the GKR region have increased, while precipitation has decreased, profoundly affecting the vegetation type and the forest fires. However, the prediction of short-term fire evolution simulation has relatively large uncertainty. Therefore, a longer paleofire history is needed to verify the natural fire responses to climate change in this area. The Holocene environment in this area has been principally affected by natural factors, with relatively weak human influence. Therefore, it is the ideal area to study paleofire succession and its response to climate change.

Sediment pollen and charcoal samples from the Huola Basin in the northern GKR were analyzed to reconstruct accurately the historical response of paleofire and vegetation to climate change during the Holocene. AMS¹⁴C dating and Bayesian chronological method-Bacon age-depth model were conducted. CharAnalysis technique was used to reconstruct fire regimes. Results indicated that vegetation experienced a transformation from early-mid Holocene warm-cold mixed vegetation to late Holocene cold-temperate vegetation. The paleofire succession showed a changing trend: mean fire frequency (MFF) was very low during the relatively warm period in 10000-3000 cal yr BP; however, after 3000 cal yr BP, the MFF increased markedly. Besides, the fire activity has a quasi-500 year period according to Redfit spectrum analysis. Based on the comparison of paleofire history with the vegetation succession and other paleoclimate proxy records, we found that the cooling events at high latitude might lead to the increase of fire frequency and intensity during the Holocene in this area. Consequently, the warm period in northeast China could have resulted in a strengthening of precipitation in northern GKR and encourage the development of broadleaved forests, with the fire events falling down.

P-1809

Did recent wildfires increase metal deposition to lakes of the Canadian Shield and Taiga ecoregions, Northwest Territories, Canada?

Nicolas Pelletier¹, John Chételat², Olivier Blarquez³, Jesse C. Vermaire¹

¹Carleton University, Ottawa, Canada. ²Environment and Climate Change Canada, Ottawa, Canada. ³Université de Montréal, Montréal, Canada

Abstract

Wildfires are a natural part of Boreal ecosystems but severity and frequency of wildfires is increasing in northwestern Canada, with possible links to climate warming. Wildfires have the potential to release metal(oids) stored in plant biomass, organic soils and upper mineral soils and gaseous and particulate emissions from wildfires are recognised as a major source of certain metal(oids) to the atmosphere on a global scale (e.g. mercury). Depending on atmospheric transport and smoke plume strength, a fraction of atmospheric emissions will be redeposited at close distance to the fire area. These elements can reach freshwater ecosystems via direct deposition or watershed transport following deposition. The extent to which wildfires contribute to the metal(oid) loading of aquatic ecosystems has yet to be accurately quantified.

We sampled sediment and peat from 10 small lakes and 5 peatlands in the Canadian Shield and Taiga Regions of the Northwest Territories. We used lake sediment and peat cores to evaluate the impact of the atmospheric deposition of metal(oid) from wildfires on the flux of mercury, lead, arsenic, cadmium and antimony to these environments. Cores were dated using lead-210, wildfire occurrences were identified macroscopic charcoal analysis, and metal concentrations were analyzed by ICP-MS and DMA. The impact of wildfires was evaluated by measuring the synchronicity between metal fluxes and charcoal particle fluxes using paired statistical testing and Superposed Epoch Analysis.

The impact of wildfire on metal(loid) deposition was generally low and dependent on the metal(loid). Mercury fluxes in lakes were largely unaffected by wildfires. Sediment concentrations of lead, arsenic, cadmium and antimony were also not significantly greater following most fire events. Sedimentation rates were largely unaffected by the deposition of wildfire ash in most lakes. However, some fire events were associated with higher sedimentation rates, indicative of large ash input in the lakes from direct deposition and catchment transport. These fire events were also associated with increased concentrations of arsenic, antimony and cadmium in the sediments, leading to a higher flux of these elements for a brief period following fire events. Events that did cause a significant increase in metal(oid) concentration and flux could be related to particularly severe fires or fires occurring in areas polluted by point-sources of metal(oids) from local gold mining in the nearby City of Yellowknife. These results suggest that overall wildfires play a minimal role in metal(loid) loading to lakes but large wildfires that deposit substantial ash to a lake can increase metal(loid) input to aquatic ecosystems.

Fire-vegetation dynamics during the Holocene in the Central Pyrenees (Spain)

Maria Leunda¹, Graciela Gil-Romera^{1,2}, Anne-Laure Daniiau³, Penélope González-Sampériz¹

¹Department of Geoenvironmental Processes and Global Change, Pyrenean Institute of Ecology (IPE-CSIC), Zaragoza, Spain. ²Department of Geography and Earth Sciences, Aberystwyth University, Penglais Campus, Aberystwyth, United Kingdom. ³Environnements et Paléoenvironnements Océaniques et Continentaux, UMR CNRS 5805 EPOC University of Bordeaux, Pessac, France

Abstract

Landscapes are dynamic entities, exposed to continuous changes as a result of long-term climatic and human processes which have been shaping them through time. Particularly, alpine ecosystems have been proved to be extremely sensitive to past environmental changes and are currently facing important transformations due to current global change. The long-term relationship between vegetation changes and fire activity is one of the most critical features transforming mountain ecosystems, and as fire risk is expected to increase in the future, understanding the long-term fire-vegetation dynamics is essential for current conservation of forests in alpine areas.

Over the last few years, several records of Holocene vegetation change in the Central Pyrenees have provided important results in relation to vegetation dynamics and treeline fluctuations. There is still a lack of knowledge in understanding the role of fire as a disturbance agent in mountain landscapes and whether fires were naturally or anthropogenically produced over the Holocene.

We present here two Holocene high-mountain lake sequences; Marboré (2612 m a.s.l.) and Basa de la Mora (1914 m a.s.l.) both located at the Central Pyrenees. We have characterized fire activity and vegetation dynamics on both of them, identifying and quantifying sedimentary microcharcoal using automated image analysis and comparing it with pollen data.

The results show an increasing fire activity during the mid-Holocene (ca. 7000-6000 cal yr BP), concurring with the highest recorded summer temperatures over the Holocene and well-developed deciduous forests. We suggest that increasing fuel availability would have fostered more active fires. Burning agency decreased as shown in both sequences, concurring with the Neoglacial period and the expansion of a nearby glacier, indicative of a cooler period, which suggests that climatic control is still dominant in promoting fire occurrence during the mid-to late Holocene transition. Interestingly fire activity increases quite abruptly at the beginning of the late-Holocene (ca. 4000-3000 cal yr BP), coinciding with an increase in herbaceous taxa, showing an opening of the landscape. This could be related to both increasing human impact and an aridity trend observed in other Pyrenean sequences. From 3000 cal yr BP until very recent times, fire activity remains low but a remarkable Holocene maximum over the last 200 years in both sequences is observed, likely related to increasing human pressure.

P-1811

Holocene savanna fire history in the seasonal tropics of northern Australia

Christopher Wurster¹, Cassandra Rowe¹, Rainy Comley¹, Michael Brand¹, Costijn Zwart¹, Vlad Levchenko², Lindsay Hutely³, Michael Bird¹

¹James Cook University, Cairns, Australia. ²Australian Nuclear Science and Technology, Kirrawee, Australia. ³Charles Darwin University, Darwin, Australia

Abstract

Savannas are environmentally and socioeconomically important environments, and fire is an important agent of disturbance in savanna ecosystems. North Australia consists largely of relatively intact savanna ecosystems, with high plant diversity. Understanding Australian savanna dynamics requires a long-term perspective, however very few records are available from which to gain insight on long-term change. We present a pyrogenic carbon record from a 5-meter sediment core from Girraween Lagoon, Darwin region of the Northern Territory, Australia, spanning the last 12,700 cal BP. We compare a novel technique for the isolation of pyrogenic carbon, hydrogen pyrolysis (hypy), with more traditional charcoal counting method. Hypy uses catalyst-assisted pyrolysis under high hydrogen pressures (> 10 MPa) to remove labile organic matter leaving only 'stable polycyclic aromatic carbon' (SPAC) derived from biomass burning. Quantification yields robust interpretation of fire history, and the stable carbon isotope composition indicates what source material has burnt.

In general, charcoal counts compare well with SPAC accumulation rates where highest values occur between 4000 and 10,000 cal BP, with lower values before and after this time period. However, some differences are apparent. SPAC accumulation is highest at the top of the core and rapidly decreases to lowest values between 2,000 and 3,000 years, whereas charcoal values start low and generally increase to peak values from 0 to 4000 years. Moreover, the charcoal counts indicate rapid changes occurred, whereas SPAC indicates more gradual change to fire regimes in this region, although this observation might change with increased sample resolution. If such a difference holds, it might be that charcoal counts incorporate more local burning, whereas SPAC may be representative of a larger area, and more representative of trends associated with regional climate change. It may also be that some differences reflect changes in fire intensity, as this is a key variable controlling SPAC production. Stable carbon isotope values indicate the source of the burning was largely tropical grasses from early in our record until about 4,000 BP, when a gradual increase in woody sourced pyrogenic carbon is evident. This is also consistent with an increase in grass pollen evident at Girraween over this time frame.

Understanding the long-term dynamics of Australia's extensive tropical savannas are key to defining appropriate management of these ecosystems. The past has played a major role in shaping savanna systems, and the historical role of fire, as a major driver of disturbance, needs to be understood on a longer than observational timescale. As one of a handful of records from this region, our data will serve to fill a current gap in our understanding of savanna dynamics in Australia.

The Mid- and late Holocene fire history at the southern boundary of the forest vegetation zone (European Russia)

Dmitry Kupriyanov¹, Elena Novenko^{1,2}, Maxim Bobrovsky³

¹Lomonosov Moscow State University, Moscow, Russian Federation. ²Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation. ³Institute of Physicochemical and Biological Problems of Soil Science, Russian Academy of Sciences, Pushino, Russian Federation

Abstract

The present study aimed to the reconstruction of forest fire history for the area of the Mordovia State Nature Reserve (European Russia). This area is located at the border between mixed forest and forest-steppe vegetation zones and particularly sensitive to environmental changes including forest fires. The Quaternary deposits in the study area is represented by fluvioglacial sands which contribute to the increasing the role of pine in the forest composition due to the edaphic factor. High pine abundance determines the relatively high activity of forest fires. Two main methods were used for reconstructions of the fire history: analysis of the macrocharcoal (particle size >125 µm) concentration in the peat and pedoanthracological analysis. The rate of macrocharcoal accumulation and identified peaks of fire activity were calculated on the base of macrocharcoal analysis and radiocarbon dating of 3 peatbogs using the CharAnalysis software. Also we compare this data with results of other proxy methods (pollen analysis, LOI, peat humification). Pedoanthracology analysis included radiocarbon dating of charcoal fragments from soil (70 samples), their species identification and the study of anthropogenic impact traces in the soil morphology.

The obtained results show that the frequency of fires was caused by both climatic and anthropogenic factors. The study area was characterized high-fire activity during the in the first half of Holocene thermal maximum (9–7 ka BP), obviously due to the relative warmer and drier climatic conditions. No evidences of human impact were detected for this period. Frequent fires (4-5 local fire events per 1 ky for each peatbog) during the Holocene thermal maximum may have led to the persistence of birch and pine forests in the study area. The subsequent decreasing of the forest fire frequency could contribute the expansion of broadleaved forests (*Quercus*, *Tilia* and *Ulmus*) and *Picea*, which reached their maximal role between 2.3 and 1.5 ka BP. The second peak (2-3 local fire events per 1 ky) of increased forest fires activity occurred in 1.2 – 0.2 ka BP and probably coincided with the beginning of intensive human-induced change of the area. Most of the charcoal fragments from soil are dated in the range of 0,2-1.5 ka BP. The presence of plowing traces in the most soil pits also confirms the fact of active human impact during the last 1.5 ka BP. The identification of species composition of the soil charcoal showed that more than 80% of all charcoals fragments are represented by *Pinus*. Remains of *Picea*, *Quercus* and *Betula* were also found. The evidences of active human influence during the last 1.5 ka BP are consistent with the data on archaeological findings and historical studies in this region.

This study was supported by Russian Foundation for Basic Research (Grant 18-04-01329).

Holocene fire history of the British Isles

Claire Jones¹, Jennifer Clear²

¹Edge Hill University, Ormskirk, United Kingdom. ²Liverpool Hope University, Liverpool, United Kingdom

Abstract

Fire is part of the natural disturbance dynamics of many systems. Understanding of fire history and the key drivers of fire are increasingly important for those involved in conservation and management, including sites in the British Isles. There are many records from across the British Isles which record fire activity throughout the Holocene, however limited work has been done to assess if there are any spatio-temporal trends and the implications these may have for our understanding of fire as a natural disturbance mechanism. This study uses existing sedimentary charcoal records from across the British Isles to reconstruct Holocene fire history. This reconstruction will seek to address a key question asked by palaeoecologists and archaeologists about the nature of fire in the Holocene environment, specifically whether it is driven by anthropogenic activity or climatic change. Spatio-temporal analysis of this data provides evidence of a changing fire regime, with limited burning in the early Holocene, likely to have been driven by climate. The mid- to late Holocene reveals an increase in burning across much of the British Isles, followed by a marked decline in the last 500 years, indicative of anthropogenic influence.

The interaction between climate, vegetation and fire history during the last 250 ka at Lake Van, Turkey

Nadine Pickarski¹, Arne Kappenberg², Eva Lehndorff³, Thomas Litt¹

¹University of Bonn, Institute of Geosciences and Meteorology, Bonn, Germany. ²University of Bonn, Institute of Crop Science and Resource Conservation – Soil Science and Soil Ecology, Bonn, Germany. ³University of Bayreuth, Department of Soil Ecology, Bayreuth, Germany

Abstract

Regionally variable interaction between climate, composition of vegetation and the non-neglected role of natural fire is not yet fully understood. The investigation of the last two interglacial-glacial cycles at Lake Van (ca. 0-250 ka, MIS 1-7) contributes significantly to the picture of long-term climate variability, vegetation changes and fire history in a climatically sensitive region, which is not influenced by human activity.

A unique multi-proxy study, derived from pollen and microscopic charcoal data, black carbon analysis (BC), stable oxygen isotopes, and XRF measurements, provides the opportunity to examine different paleoenvironmental indicators, e.g., vegetation communities, fire activity, erosion processes, evaporation rates, and moisture availability in the catchment area. We additionally used geochemical traces to reconstruct fire temperature, which relies on the oxidation of fire residues in sediments to benzene polycarboxylic acids (BPCAs). We are able to evaluate how climate triggers the activity of vegetation fires in a long continental sediment record.

The integration of all proxies shows three warm-temperate intervals, the penultimate interglacial complex (MIS 7; ca. 193-242 ka BP), the last interglacial (MIS 5e; ca. 111-131 ka BP), and the current interglacial (MIS 1; present-11.7 ka BP), characterized by the predominance of an oak steppe-forest, higher moisture availability and lower erosion processes in the catchment area. At Lake Van, intensive fire events (max. BC concentration) were recorded mainly during dry summers within temperate/humid climate conditions (large biomass production) rather than within colder/dry periods with overall sparse vegetation (low BC production). Finally, periodic variability in the vegetation composition and fire activity followed climate changes, hence are related globally to orbital forcing, with a cyclicity of ~100.000 years.

P-1815

A 'dates as data' approach to understanding anthropogenic fire trends over multi-millennial timescales; a case study from the British Isles

Mark Hardiman

University of Portsmouth, Portsmouth, United Kingdom

Abstract

Disentangling the roles of human vs climate as primary drivers of fire regimes is one of the biggest conundrums in palaeofire research, and often comparisons between various archives and evidence are hampered by the accidental nature of the archaeological record. This is perhaps one reason why the majority of Quaternary charcoal records that cover multi-millennial timescales come from lake or peat bog sequences, where relatively straight forward depositional histories allow the use of charcoal statistics, such as CHAR alongside regional-to-global syntheses.

Much less attention has been focused on understanding fire occurrence over long multi-millennial timescales directly from archaeological datasets, from which evidence of burning is often manifest. In order to attempt to understand and explore the role of humans as an explanatory factor of fire, here we utilise part of one of the largest amalgamated archaeological radiocarbon databases in existence (taken from Bevan *et al.*, 2017). The data extracted here covers the British Isles from c.10-4 ka BP and contains over 3,500 radiocarbon determinations from material which has directly undergone at least partial charring.

In order to interpret these data, the 'dates as data' approach (Rick, 1987) is utilised, where the frequency and distribution of radiocarbon dates can be used as a proxy of intensity. This method has been most commonly used to assess changes in past human population intensity and demographic trends. A recently published method of kernel density estimation (KDE) plots (KDE_Plot & KDE_Model functions in OxCal; Bronk Ramsey, 2017) is used, which can help retain signal whilst also suppressing noise; a common issue with the more typically used summed probability distribution methods.

The resultant data is presented for 1) the whole of the British Isles, and 2) as national curves for Scotland, Ireland, Wales and England allowing the migration of anthropogenic fire across the Early to mid-Holocene to be assessed and compared to major archaeological cultural shifts (e.g. the Mesolithic-Neolithic transition). Finally, data is also compared from low- and high- habitability areas, based on access to freshwater resources, altitude, and flatness of land (Vahia *et al.*, 2016).

This method is not without a number of caveats, yet despite these, this approach has many advantages; not at least the ability to directly compare anthropogenic 'fire intensity' curves against more traditional lake and peat charcoal records, allowing the formation and testing of new hypotheses.

Abstract

Global warming-induced permafrost thaw is the important source of enormous amounts of organic carbon to the atmosphere. Therefore, it is important to understand the dynamic of the process and controlling factors responsible for permafrost degradation, as well as their variability in time. For this purpose, we studied two peatlands Khar Zurkhonii Khukh Nuur in the Khentii mountain range (Mongolian: Хэнтийн нуруу) in North Eastern Mongolia. This part of Mongolia is characterized by the occurrence of the forest-steppe mosaic in the area of discontinuous permafrost. We aimed to reconstruct dependence between vegetation composition and fire regime shift during the last 1600 years from two peat archive. Two profiles: 36-cm (KH-1) and 55-cm (KH-2) have been extracted from two nearby peatlands, which are only 1 km away. Chronology of the KH-1 core was based on 6 AMS ¹⁴C dates, ¹³⁷Cs, and ²¹⁰Pb analyses, while the second core KH-2 was based on 11 AMS ¹⁴C dates. Respectively, the core KH-1 covers the last 250 years and the core KH-2 covers the last 1600 years. We applied the multi-proxy approach (pollen, plant macrofossils, testate amoebae, Cladocera, macro-charcoal, and geochemistry) to reconstruct changes in the ecosystem. Our first results indicate a strong relation between droughts, vegetation forest-steppe mosaic composition and fire regime shifts, which caused intensified erosion in the catchment. Palaeoecological and geochemical data allowed tracing the dynamics of degradation permafrost and fire regime shifts of the ecosystem triggered by recent and past climate change.

The research was funded by the National Science Centre (Poland) – grant 2017/01/X/ST10/01216

Holocene fire history in a mid-mountain Mediterranean landscape: The Toledo Mountains (central Spain)

Reyes Luelmo-Lautenschlaeger^{1,2}, Sebastián Pérez-Díaz¹, Olivier Blarquez³, César Morales-Molino⁴, José Antonio López-Sáez¹

¹CCHS-CSIC, Madrid, Spain. ²Universidad Autónoma de Madrid, Madrid, Spain. ³Université de Montreal, Montreal, Canada. ⁴Institute of Plant Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland

Abstract

Fire has been a major driver of landscape transformation throughout the Mediterranean basin since at least the early Holocene, modelling its ecosystems, determining species distributions, and conditioning the biodiversity of this territory. Furthermore, humans made fire an essential tool for environmental management long time ago, as it assisted the transformation of the natural landscapes to meet their need for natural resources. Indeed, many studies have shown that the frequency of fire episodes increased linked to anthropic activities such as agriculture and livestock raising and that there was a striking regional variability in human-fire relationships depending on human circumstances and the environmental setting. Eventually, in recent times, not only farming intensification but also land-use abandonment are leading to significant changes in fire regimes.

The Toledo Mountains is a mid-elevation mountain range that separates the Tagus and Guadiana basins in the heart of the Iberian Peninsula. Current climate in this mid-mountain area is mostly mediterranean, with some oceanic influence towards the westernmost section, and the vegetation mainly consists of sclerophyllous evergreen woodlands. The Toledo Mountains have acted as a prominent reservoir of natural resources for human communities, with wood, charcoal or wax as the most important products obtained directly from the local woodland. Additionally, hunting and livestock husbandry have traditionally been the main activities developed in these survival landscapes.

In this study, we reconstruct the fire history of the Toledo Mountains during the mid- to late Holocene by combining several charcoal records (charcoal accumulation rates = CHAR) from peatlands. The obtained CHAR composite curves allow us to understand the relevance of fire in building the landscape across different cultural periods, and to check for differences in the trends observed at the study sites located on the southern and northern slopes of these mid-elevation mountains. Likewise, it will be possible to determine whether fire played a role in the historical development of the landscape for livestock raising and big game hunting.

P-1818

Investigating the effects of different deflocculants on charcoal area

Margarita Tsakiridou, Mark Hardiman, Laura Cunningham
University of Portsmouth, Portsmouth, United Kingdom

Abstract

An increasing need to better understand past wildfire expression, and especially its controls, has, in the recent decades, driven extensive research into the reconstruction of past wildfire regimes. The most commonly employed proxy for this purpose is charcoal, with fragments classified as microscopic ($<125\ \mu\text{m}$) or macroscopic ($>125\ \mu\text{m}$) charcoal. The latter, in particular, is widely used to reconstruct local wildfire frequency. However, no standardized laboratory method currently exists. Various chemical treatments are being used in varying durations/concentrations, both prior and post- wet sieving of the charcoal from unconsolidated sediments, even though the effects on charcoal are not known. Furthermore, variously produced charcoal records are often numerically combined in order to produce regional composites of wildfire activity.

Here we systematically assess the effect of these various treatments on both modern and ancient charcoals. Fresh charcoal was produced from both softwood and hardwood species at $400\ ^\circ\text{C}$ and $800\ ^\circ\text{C}$, as well as grass at $400\ ^\circ\text{C}$. The charcoal was broken down with a mortar and pestle, and waterlogged. Approximately 5 pieces, ranging from $125\text{-}250\ \mu\text{m}$, of each of the five types of charcoal were placed in 90 petri dishes, and then one of the following chemicals was added at the specified concentrations: peroxide (H_2O_2 ; 8% and 33%), Sodium Hypochlorite (NaClO ; 3% and 12.5%), Potassium Hydroxide (KOH ; 10%), Sodium Hexametaphosphate ($\text{Na}_6\text{P}_6\text{O}_{18}$; 20%) and Nitric Acid (HNO_3 , 50%), along with two sets of control treatments (H_2O). The samples were digitally photographed under the microscope as a series of overlapping pictures, instantly after the addition of the chemical and then in four pre-determined time steps (8 hours or 12 hours depending on the chemical). Image analysis software was used to quantify the area of the fragments (cm^{-3}).

Each chemical had a markedly different effect on the area of charcoal, at different time steps. Mixed ANOVA tests showed that the area significantly varied from the water control treatment when submerged in HNO_3 and NaClO . However, significant differences were also found in between the remaining chemicals. These findings have implications for charcoal-based paleofire reconstructions and highlight the need for a standardized methodology in the field. They also suggest that H_2O_2 is probably the most effective chemical whilst use of NaClO should probably be avoided as this was found to markedly decrease the area of the charcoal.

To evaluate these laboratory findings within a “real world” context, a sedimentary sequence, with 9 replicate cores, from Sluggan Bog, Northern Ireland was used. Layers that were known to contain charcoal were treated with H_2O_2 (33%), NaClO (12.5%), and HNO_3 , (50%). The differing effects of these treatments on the fossil charcoal fragments will be outlined and compared to that of the modern charcoal samples.

The Role of Fire in the Late-Glacial Decline of Spruce Forests Across the Great Lakes Region of the United States

Allison Jensen¹, Claire Rubbelke¹, Katherine Hayes², Joe Bevington³, David Fastovich¹, Ben Watson⁴, Jacquelyn Gill⁵, James Russell⁶, Stephen Jackson⁷, Jack Williams¹

¹University of Wisconsin Madison, Madison, USA. ²University of Oregon, Eugene, USA. ³Wisconsin Dept of Natural Resources, Madison, USA. ⁴James River Association, Richmond, USA. ⁵The University of Maine, Orono, USA. ⁶Brown University, Providence, USA. ⁷University of Arizona, Tucson, USA

Abstract

As temperatures rise and the frequency, size, and severity of wildfires increase across North America, there is an increased risk of intensified disturbance regimes driving abrupt ecosystem conversions from forested to open vegetation. A potential model system for understanding these processes is the last deglaciation, when spruce forests and parklands rapidly declined across the Midwest and were replaced by mixed forests. These vegetation changes were primarily driven by rising temperatures (perhaps as high as 6C locally) and increasing seasonality of temperature and insolation. The role of fire during the late-glacial decline of these spruce forests and parklands, however, has not been explored. This study presents a synthesis of deglacial vegetation changes and fire activity using fossil pollen and charcoal records from 5 sites in the Great Lakes Region: Triangle Lake Bog, Bonnett Lake, Stotzel-Leis, Silver Lake, and Appleman Lake. These records have established radiocarbon chronologies, high resolution pollen data, and contiguous charcoal data, enabling a newly-detailed study of the linkages between biome-scale vegetation change and fire dynamics.

Pollen analysis shows a common trajectory of vegetation change across sites, where *Picea* (spruce) experienced a significant decline between 16,000 and 12,000 years ago, which coincided with an increase in *Pinus* (pine) and hardwood taxa like *Fraxinus* (ash), *Ulmus* (elm), and *Ostrya/Carpinus* (hop-hornbeam/hornbeam). This indicates that spruce forests and parklands were replaced by mixed coniferous and deciduous vegetation across the Great Lakes Region. During the deglacial period, the Silver Lake and Stotzel-Leis records show a similar change in fire regime, with significant fire events (top 20th percentile of charcoal peaks identified in analysis) increasing in frequency leading into a rapid spruce decline. The Triangle Lake and Bonnett Lake records show more gradual spruce declines, with one or two significant fire events occurring as spruce starts to decline, though the Triangle Lake record also shows frequent fire events toward the end of the spruce decline. The Appleman Lake record shows no significant fire events before the spruce decline and two significant events at the end of the decline. At all sites, some of the major fire events were followed by spikes in the rate of change in community composition, though the rates of change following fire events were not significantly different from the rates of change in non-fire intervals. Overall, these results suggest that individual fire events alone may not cause a large change in community composition, but increasing frequency of fires may cause communities to reach a tipping point and experience a state-change, as seen in the rapid replacement of spruce by mixed forest at sites like Silver Lake and Stotzel-Leis.

The *paleofire* R package: analyzing charcoal records from the Global Charcoal Database

Olivier Blarquez¹, GPWG Phase 2²

¹University of Montréal, Montréal, Canada. ²PAGES, Bern, Switzerland

Abstract

The analysis of charcoal records stored in the Global Charcoal Database (GCD) has been proven useful for reconstructing millennia trends in regional to global biomass burning. The synthesis of charcoal series poses nonetheless several challenges related to the spatial or temporal representativeness of data or to the various sedimentary charcoal units and associated laboratory methods available within the GCD. In order to provide a set of tools and a common research framework to analyze these records the *paleofire* R package has been developed as an initiative of the Global Paleofire Working Group (<http://paleofire.org>). The *paleofire* package is now in its 1.2.3 version and freely available for the R platform. Since its inception in 2014, numerous methods and tools have populated the initial capabilities of the package. The basic functions embedded within the *paleofire* package enable to: (i) select charcoal records from the GCD, (ii) transform charcoal data in order to produce statistically comparable records, (iii) synthesize temporal charcoal trends to reconstruct biomass burning. In addition to these basic functions, several tools have been incorporated enabling to quantitatively analyze temporal trends in biomass burning or to produce spatial analyses. In this presentation, I will demonstrate the principles of the *paleofire* package and present the latest improvements on spatiotemporal analyses of biomass burning from the GCD. I will also briefly present the latest version of the GCD (v 4.0.4) and how the GCD and the *paleofire* package communicates in order to provide paleofire researchers updated and freely available charcoal data and associated methods.

P-1821

Fire regimes in *Araucaria* forests ecosystem during the last 1800 years in southern South America.

Ana M. Abarzúa, Alejandra Martel-Cea, Leonora Jarpa, Mauro E. González
Universidad Austral de Chile, Valdivia, Chile

Abstract

To understand the climate-vegetation-fire dynamics, associated with anthropic influence, in the millennial scale fire regimes, a large part of the studies have been based on charcoal records. These archives document the magnitude and frequency of local fire events, as well as the fire-free interval for a period. Fire-scarce records have been able to evaluate and refine the detection of fires, which would help to reduce the error in the detection of false events and / or the non-detection of a real event.

In the present work, we present the fire regimes in *Araucaria* forests ecosystem during the last 1500 years in two main areas based on the comparison of pollen, charcoal records and a series of fire-scars records. i) Laguna Escondida (39.5 °S, 71.5 ° W) located in Villarrica National Park, and ii) Laguna Verde from Tolhuaca National Park.

Laguna Escondida covers 2017-1400 CE, while the chronology of fire-scars covers 2000-1696 CE. Both records coincide in an increase in the frequency of fires since 1890 CE, however, the charcoal record detect 4 fire events compared to 13 fire-scars. The low fires detection during the 20th century would be related to lake taphonomic processes (eg. sediment resuspension) and the high frequency of fires associated with greater human activity since 1880 CE, resulting in a relative homogenization in the accumulation of charcoal during the last century. Vegetation is dominated by *Nothofagus* forests, while the last century appears the exotic species and Poaceae taxa, the bamboo *Chusquea* is also associated with fire events recorded in lake sediments.

Laguna Verde covers 2018-150 CE, while the chronology of fire-scars covers 2001-1519 CE. Fire events are not recorded in sediments for the last centuries, however 33 fire-scars are observed between 2001-1800 CE. On the contrary, major peak magnitude and frequency is observed between 150-1500 CE indicating a major fire activity, previous the European colonization. Vegetation is dominated by *Nothofagus* and *Araucaria* forests, while the last century appears the exotic species and Poaceae taxa, the bamboo *Chusquea* shows constants values during the entire pollen record.

Despite the differences on fire regimes observed in both areas, during the settlement of southern Chile, historical fire regimes were often altered by either burning vast areas to create farmland or reducing fire frequencies by suppressing fires or by eliminating aboriginal populations that formerly set fires. These preliminary results suggest a complement between both archives to evaluate fire regimes at higher temporal scales, however, it is necessary that the chronologies are robust in terms of the number of dates used and the number of scars that sustain a fire event.

DiverseK: integrating fire ecology, traditional knowledge and stakeholders

Daniele Colombaroli, Global Paleofire Working Group GPWG
RHUL, Egham, Surrey, United Kingdom

Abstract

Both frequency and intensity of fires are expected to change in many areas under future climate changes, but with different trajectories depending on the biome considered and region-specific land-use changes. Over the last years, The Global Paleofire Working Group (GPWG2) promoted new collaborations and methodological approaches to improve our understanding of fire variability across ecosystems. Central to this mission is the knowledge transfer from palaeofire research to stakeholders and policymakers, with the common goal to implement more sustainable management strategies for conserving biodiversity resources and ecosystem services. The Diverse Knowledge framework (DiverseK), developed within the GPWG community, combines long-term ecology, traditional knowledge and conservation challenges prioritized by stakeholders, and represents a novel and alternative approach to improve existing fire policies counteracting the effects of catastrophic fires in a future warmer world. Integration of ecosystem science and applied research in ecosystem management is a high priority and key challenge for the science-policy interface. The GPWG's will continue to promote the development of community tools for data analyses and new projects across the Quaternary Sciences that merge interdisciplinary ecological knowledge with our understanding of Quaternary climate variability.

The interaction between vegetation, megafauna and fire regimes at Lake George, southeastern Australia.

Susan Rule^{1,2}, Chris Johnson¹, Barry Brook¹, Simon Haberle², Brad Pillans², Janelle Stevenson², Bradley Opdyke², Eva Papp², Phil Roberts²

¹University of Tasmania, Hobart, Australia. ²Australian National University, Canberra, Australia

Abstract

The Lake George basin on the Southern Tablelands of New South Wales, in southeastern Australia, contains the longest known quasi-continuous sedimentary record of any Australian lake basin. The published spore-pollen record of Singh and Geissler (1985), obtained from Lake George, spans the entire Brunhes Palaeomagnetic Chron (ca. 780 000 to the present) and provides a record of glacial-interglacial cycles indicated by altitudinal shifts in vegetation. An ongoing multi-coring campaign funded by an Australian Research Council Linkage Project LP140100911 is examining the tectonic, sedimentary, hydrological, vegetation, climatic and archaeological history of Lake George. A multi-proxy palaeoecological record covering the last 130,000 years is being developed to both refine and provide a more robust chronology of this iconic record with initial results broadly supporting the findings of Singh and Geissler. The presence of dung fungi, *Sporormiella*, indicates that large herbivores were a key component of the environment. Furthermore, unlike more northern Australian sites, such as Lynch's Crater, fire is present prior to 40 ka, suggesting it may be more directly linked to changing vegetation patterns due to climate variation, rather than to human activity. The increased values for both micro- and macrocharcoal across the time-period 30 – 40 ka which also correlates with reduced *Sporormiella* values, suggests that there was a complex interaction between, vegetation, megafauna and fire regimes.

Reconstructions of Fire Activity in North America and Europe over the Past 250 Years

Jennifer Marlon¹, Brian Magi², Anne-Laure Daniau³, Florence Mouillot⁴, Patrick Bartlein⁵

¹Yale University, New Haven, USA. ²University of North Carolina, Charlotte, Charlotte, USA. ³CNRS, Bordeaux, France.

⁴CNRS, Marseille, France. ⁵University of Oregon, Eugene, USA

Abstract

Fire both affects and responds to vegetation changes, climate variability and human activities; a robust understanding of fire thus requires diverse spatiotemporal data and a multidisciplinary approach. This study compares historical fire reconstructions, paleofire records, and simulated land-use changes over the past 250 years to understand the role of fire in North America and Europe during the transition into the Industrial Era. Paleofire data are from the Global Charcoal Database (GCD) and historical fire reconstructions are from diverse sources, including government records and dendrochronological studies. Comparisons of the trends in fire from the GCD and the historical reconstruction show broad agreement, with some regional variations as expected. Western USA and North America show the strongest agreement, with departures in the GCD and historical reconstruction fire trends that may reflect limits in the data itself. Eastern North America shows agreement with an increase in fire from 1750 to 1900, and a strong decreasing trend thereafter. Patterns of burning in both fire history datasets often correlate positively with rates of land-use changes. Through the careful consideration of uncertainties in the data, these results can be used to constrain Earth System Model simulations of both past fires, which explicitly incorporate historical fire emissions, and the pathways of future fire on a warmer planet.

P-1825

Pedoturbations defining charcoal stratigraphy for reconstruction of the forest ecosystem history (the Ryazan region, Russia)

Maxim Bobrovsky¹, Dmitry Kupriaynov²

¹Institute of Physicochemical and Biological Problems of Soil Science, Russian Academy of Sciences, Puschino, Russian Federation. ²Lomonosov Moscow State University, Faculty of Geography, Moscow, Russian Federation

Abstract

Pedoanthracological methods are widely used for analysis of the local ecosystem history. We propose the additional using of analysis of patterns of soil profiles to interpret the data on soil charcoal stratigraphy. We present results of the first study on soil charcoal stratigraphy, taxonomy, and radiocarbon dating combined with morphological analysis of soil profiles performed for sandy soil (Podzols and Arenosols) in the Ryazan region in Russia (55.2N, 40.2E).

Charcoal samples from the specified soil patterns with a visually high concentration of charcoals were taken from 19 soil pits located in four forest sites. Besides charcoal concentration, which has been defined for all samples, taxonomic identification of charcoals was performed for 24 samples and 12 charcoal samples were radiocarbon-dated. We specifically focused on soils that bear marks of pedoturbations, which included three distinct soil patterns: ancient arable layers, root channels, and pits formed after treefalls with uprooting. We compared samples selected from the specified soil patterns with randomly selected samples. For this, we randomly collected 90 soil samples from different soil horizons in 7 soil profiles located in the same sites. Charcoal concentration in randomly selected soil samples was identified. Results of soil charcoal analysis were compared with pollen and microscopic charcoal analysis of the cores taken in the surrounding peats.

Taxonomic composition of trees in charcoal samples was very poor. Pinus charcoals of various age prevailed in all samples. Charcoal of Betula and Sorbus rarely occurred. The oldest charcoals were 2610 cal. BP; the remaining samples were mainly grouped into three clusters: about 2200, about 900–1000, and later 500 cal. BP.

Charcoals were unevenly distributed both horizontally and vertically in the soil profiles. Mean charcoal concentration in randomly selected samples was $1.2 \pm 0.4 \text{ g} \cdot \text{kg}^{-1}$, whereas mean charcoal concentration in ancient root channels originated from artificial tree uprooting (grubbing) was $12.44 \pm 3.48 \text{ g} \cdot \text{kg}^{-1}$ and charcoal concentration was up to $30.92 \text{ g} \cdot \text{kg}^{-1}$ in the ancient arable layer. The largest and most abundant charcoals were located at the greatest depths of ancient pits formed after treefalls with uprooting: mean charcoal concentration was $55.1 \pm 23.15 \text{ g} \cdot \text{kg}^{-1}$ and the highest one was $133.36 \text{ g} \cdot \text{kg}^{-1}$.

Periods of charcoal accumulation in soil and in surrounding peats have not coincided. Since 2000 cal. BP the supply of charcoal in the peats had decreased, but translocation of charcoal into mineral soil had widely started due to the pedoturbations as a result of plowing after tree burning and cutting for clearing. These human activities had provided the upper soil layer (arable layers and sometimes root channels) with charcoal fragments. Analysis of ancient pedoturbations allowed us to explain causes of charcoal stratigraphy in the soil and to interpret history of the local sites.

New perspectives on an old landscape: Utilizing Unmanned Aircraft Systems for rapid high resolution data acquisition to enhance geomorphological research.

Phillip Allen, Matthew Ramspott

Department of Geography, Frostburg State University, Frostburg, USA

Abstract

The increasing availability, relatively low economic expenditure and user-friendly off the shelf capabilities, mean unmanned aircraft systems (UAS) have become a transformational technologic tool for geomorphologists. Over a two-day period UAS were employed to survey a remote upland palaeo-periglacial landscape located within the Bear Rocks Preserve (BRP), Central Appalachians, West Virginia, USA. The preliminary results from the low altitude high resolution aerial survey (LAHRS), when combined with ground based observations, enabled the development of a model of landscape evolution for the BRP. During the aerial survey 2000+ images were captured, and following processing the photogrammetric data, provided a high resolution digital dataset (HRDDS) of the entire BRP. Using the BRP HRDDS a procedure for easier targeting of areas of special interest for ground based data collection, including XRF and clast form analysis was produced. Using the BRP HRDDS lead to improved time and resource management of days spent in the field, which is an ever present pressure for geomorphological researchers. Scrutiny of the LAHRS data aided the identification of landforms and analysis of palaeo-processes that were hitherto unrecognized or published for the BRP. Combining the LAHRS and ground-based investigation of the BRP facilitated the production of a digital map illustrating the variation in the frequencies, compositions, geochemical characteristics and locations of palaeo-periglacial landforms; including but not limited to felsenmeer, tors, ventifacts and patterned ground. The preliminary model for landscape evolution of the BRP site indicates a relative consistently open and exposed environment, with disintegration and accumulation of lithologies being significantly influenced by underlying geologic structural controls. UAS are an exciting and rapidly growing toolkit for future geomorphological mapping and research. Within the USA recent updates to FAA regulations have eased the obstacles for UAS deployment for professional uses, resulting in a more widespread adoption of this technology as an enhancement to remote field-based research activities. An unforeseen positive consequence of UAS technology is the potential and rapidity for engaging and enabling undergraduates, K-12 students and the general public in accessing the geomorphology of their own region. For faculty at institutions with a teaching focus, and available dedicated research time is limited, this emerging technology presents some unique educational challenges and opportunities. The establishment and development of a UAS laboratory at FSU has faced the challenges of integrating specialized new technology into an infrastructure that is oriented toward support of more generalized instructional needs, while under pressure to conform to standards of operational efficiency and cost-effectiveness.

Analysis of Late Quaternary deposits for evaluation of land subsidence in an actively subsiding basin, the Echigo Plain, Japan

Yuka Ito, Tomochika Tokunaga, Seiichi Shimada, Masaatsu Aichi
The university of Tokyo, Kashiwa, Japan

Abstract

The Echigo Plain, central Japan, is an actively subsiding sedimentary basin with its tectonic subsidence rate to be ca. 3 mm/yr at the coastal areas. In addition, anthropogenic activities such as over-abstraction of groundwater accelerate compaction processes, which results in the formation of accommodation space for sedimentation. In this study, we analyzed the latest Pleistocene to Holocene sequences using spatially high-density borehole data. We also estimated the temporal and spatial variations of paleo-water depths based on boreholes with calibrated radiocarbon dates obtained by previous studies to understand the trend of the subsidence. Several geological cross-sections were drawn and analyzed by applying the sequence stratigraphy and new “Shazam stratigraphy” concepts. The depositional sequences of the Echigo plain mainly consist of lower sand and silt deposits (estuary system), middle clay and silt deposits (marine deposits and barrier-lagoon system), sand and silt deposits (dune or bar), and upper sand and silt deposits (modern floodplain, channel, pond deposits). Spatial distribution maps of sediments during the early transgressive stage (ca. 9000 cal y BP), the maximum transgression (ca. 6000-5000 cal y BP), and the high-stand and regression (ca. 3000 cal y BP) were created using GIS based on the analysis results of cross-sections. Paleo-water depth distribution maps of the three time periods were also created based on the estimated paleo-water depth value. In the whole Niigata plain, clay and sandy silt were distributed at ca. 9000 cal y BP. During ca. 6000 cal y BP, the water depths reached a maximum (ca. 10 to 50 m). The clay along the shores and the sand and silt in the inland area were mainly deposited. After ca. 3000 cal y BP, the water depth became shallow. The sand and the silty sand were widely distributed. The variations in paleo-water depth differ regionally. At the river mouth of the modern Shinano River, the water depths were deepest, indicating its environments to be seafloor until very recently. In contrast, the water depth in the region near the western margin fault zone of the Niigata plain was relatively shallow. In the coastal areas and the river mouth where the amount of land subsidence observed by leveling and GNSS is relatively large, thick clay and silt layers, attributed to marine clay during the transgression, are distributed at a depth of ca. -60 to -100 m. While, in the inland area where subsidence is also observed, clay and silt layers attributed to lagoon deposit are also recognized at a depth of ca. -20 to -50 m. In particular, the Shinano river mouth area, where the paleo-water depths were deep and clay and silt layers deposited might be related to the observed land subsidence in the shallow layer through sediment consolidation.

Mapping distinct geomorphic units using a convolutional neural network

Marijn van der Meij¹, Daniel van der Maas², Gilbert Maas¹, Joop Okx¹

¹Wageningen Environmental Research, Wageningen, Netherlands. ²bird'sAI, Amsterdam, Netherlands

Abstract

Accurate geomorphological maps are essential tools for tackling environmental challenges. However, current geomorphic mapping techniques are often time-consuming and difficult to reproduce (e.g. field surveys and manual mapping), or are sensitive to man-made objects such as buildings or roads (e.g. digital terrain analysis). Recent advances in spatial data collection, new software libraries and improved computing power enable the use of more advanced data driven methods such as deep learning, for geomorphic mapping.

We explored the use of convolutional neural networks (CNNs) to map distinct geomorphological units, such as periglacial depressions, drift sand dunes and blowouts, in the north of the Netherlands. CNNs are tools which use pattern recognition to classify input images. In our case, the input consisted of elevation and relief maps of the study area. CNNs often demand large amounts of input data for correct classification. However, the CNN we selected, U-Net, has been shown to be tolerant to a relatively limited amount of data, in the form of manually classified geomorphological units. The training dataset was augmented by deforming and rotating the training data, which ultimately provided a robust model for recognizing the landforms on the input data.

U-Net was successful in locating the periglacial depressions and dune complexes in the study area. The model identified almost all depressions that were manually mapped on the current geomorphological map, and identified additional, previously unidentified, depressions. However, the delineation of the shapes was not always correct and the similar shapes of periglacial depressions and blow outs caused mix-ups of those landforms in the classification. Nonetheless, these first results show the potential of CNNs for robust and time-efficient geomorphic mapping.

P-1829

The application of high-resolution structure-from-motion photogrammetry and digital field-mapping systems to interpret glaciated landsystems in the Keady region, Northern Ireland

Leanne Hughes¹, Sam Roberson², Alex Donald²

¹British Geological Survey, Keyworth, Nottingham, United Kingdom. ²Geological Survey Northern Ireland, Dundonald House, Belfast, United Kingdom

Abstract

High-resolution (0.4 m) Structure-from-Motion (SfM) Digital Surface Models (DSMs) created from aerial imagery allow for detailed, high-accuracy mapping of glaciated landsystems. This study demonstrates the advantages of using these techniques compared to previous low-resolution (50 m) digital terrain models and satellite imagery.

Geological fieldwork is resource intensive and heterogenous glaciated terrains, typical of Ireland, can be time consuming to interpret. Techniques that reduce time in the field through more accurate remote interpretation allow resources to be used more effectively. In the Keady region, Northern Ireland, the authors have used photogrammetric DSMs and digital field data capture systems to augment existing field mapping strategies. Geomorphological landforms and surface stratigraphic units captured digitally in a desk study using ArcGIS SIGMA toolkit were verified and updated during field work on the ground.

Compared to interpretations of the terrain undertaken using lower resolution datasets, the accuracy of remote mapping checked in the field using SfM DSMs was markedly higher. Significantly less time was required adjust the boundaries of sediment-landform associations, allowing a wider area to be covered. This allowed operators to focus on remaining areas of uncertainty, e.g. those under dense vegetation cover.

Digital Mapping...
We digitally map superficial deposits more accurately by using high-resolution terrain data.

Why?
Data informs developers, researchers and asset owners. Digital data provides best value.

How?
Structure from motion derived terrain used in the office to interpret landforms and geomorphology beforehand.
In the field the geologist is free to record information about sediments and rock types without having to draw in all the changes in slope.

A tablet PC based field mapping system is used to ground truth the office data. It has a GPS, camera, structural tools and GIS within a map workflow.
The map data is in the same GIS package throughout, and cartographically attributed by the geologist when the data has been finalised. This reduces duplication.

Results
Structure from motion photogrammetry in Armagh provided a high level of detail for field mapping to add to. Drumlins, Rogen and glacial sediments were newly identified.
SfM technology can be used to map areas that might be difficult to access. Keeping the data in the hands of the geologist means less potential for error in data transformation.
The next step in development is to enable crowd sourced data to be input by users in the field on an app. Smartphone ubiquity puts this tech in reach of the majority.

P-1830

Operational framework for rapid, very-high-resolution mapping of glacial geomorphology using low-cost unmanned aerial vehicles and structure-from-motion

Marek Ewertowski¹, Aleksandra Tomczyk¹, David Evans², David Roberts², Wojciech Ewertowski¹

¹Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznan, Poland. ²Department of Geography, Durham University, Durham, United Kingdom

Abstract

The ongoing glacier retreat has resulted in the continuous exposure of proglacial areas. Such areas contain essential information about the glacial process–form relationships that manifest themselves in specific landform assemblages (glacial landsystems). However, the preservation potential of freshly exposed glacial landforms can be very low, as proglacial terrains are one of the most dynamic parts of the glaciated landscapes. Rapid mapping and geomorphological characterisation of such areas are important from a glaciological and geomorphological standpoint, for a proper understanding and reconstruction of the glacier–landform dynamics. Recent advances in technology have enabled the development of low-cost alternatives for traditional aerial surveys. Small unmanned aerial vehicles (UAVs) can be used to acquire high-resolution (several cm ground sampling distance), low-altitude images. The UAV-based images can subsequently be processed using structure-from-motion (SfM), to generate detailed orthomosaic and digital elevation models.

This study aimed to demonstrate an operational framework for using low-cost UAV and structure-from-motion photogrammetry for the rapid mapping and monitoring of the glacial geomorphology, in front of retreating glaciers. The proposed operational framework incorporates various organisational and technical aspects related to mission preparation, mission execution, and data processing; and consists of seven stages: (1) Preparation and selection of the appropriate platform; (2) transport; (3) preliminary on-site activities (including optional ground-control-point collection); (4) pre-flight setup and checks; (5) conducting the mission; (6) data processing; and (7) mapping and change detection. Operational procedures were developed from several years of application of different types of consumer-grade UAVs over a wide range of case studies representing ice margins of glaciers in Svalbard, Iceland, and Peru.

We illustrated the application of the framework by a mapping case study on the glacial foreland of Hørbyebreen, Svalbard, Norway. A consumer-grade quadcopter (DJI Phantom) was used to collect the data, while images were processed using the structure-from-motion approach. The resultant orthomosaic (1.9 cm ground sampling distance—GSD) and digital elevation model (7.9 cm GSD) were used to map the in detail fine-resolution glacial-related landforms. It demonstrated the applicability of the proposed framework to map and monitor specific changes in a rapidly evolving proglacial environment, using a low-cost approach. The coverage of multiple aspects ensures that the framework is universal and can be applied in a broader range of settings. The proposed approach opens up new perspectives on detailed mapping and monitoring of modern glacial land-systems and the development of models of process-form regimes in glacial geomorphology.

This research was funded by the National Science Centre, Poland, Grant Number 2011/01/D/ST10/06494.

Reconstructing historical outburst floods of the Kotá valley, SE Iceland.

Stephanie Mills^{1,2}, Anne Mather², Timothy Barrows^{1,3}, Caroline Clason², Ralph Fyfe²

¹University of Wollongong, Wollongong, Australia. ²University of Plymouth, Plymouth, United Kingdom. ³University of Portsmouth, Portsmouth, United Kingdom

Abstract

The high magnitude and low frequency occurrence of outburst floods (jökulhlaups) makes them very difficult to measure directly. In Iceland, jökulhlaups are predominantly triggered as a result of volcanic activity, either directly through volcanic eruptions, or indirectly through geothermal activity, with many volcanoes under icecaps. Iceland is therefore in a unique location for such a study, providing the opportunity to constrain the age (based on tephrochronology, historical records and recent observed events), character and distribution of past jökulhlaup events, using a combination of techniques.

We focus on the Öræfajökull eruptions of 1362 and 1727 CE and the resulting jökulhlaups in the Kotá valley, in SE Iceland, which caused fatalities and significant damage to farmland. We use a LiDAR DEM, field data and satellite imagery to create a geomorphological map of the palaeoflood events. In addition, we use unmanned aerial vehicle remote sensing, to create a 3D model of a section of the fan using structure-from-motion. This allows us to analyse the topographic features (<10m scale) of the fan surface that are otherwise not apparent in the Lidar DEM. These data allow us to forensically reconstruct the sequence of events in terms of flow routing and timing. Finally, we undertake palaeofluvial modelling using a combination of geomorphological and sedimentological evidence to reconstruct flood hydraulic parameters (regime and competence), based on palaeoflood palaeostage and competence approaches.

The 1362 eruption was very explosive and distributed light-coloured rhyolitic tephra over a wide area that serves as a valuable time marker. The 1362 jökulhlaup deposits consist predominantly of eroded fluvial valley-fill, scree slopes and “plucked” large boulders of tillite and palagonite. The 1727 deposits are typically darker-coloured, reflecting a dominantly mafic eruption. Based on mapping of these deposits, the 1727 jökulhlaup appears to have been almost as extensive as the 1362 event. Primary routing of this flood event appears to have been towards the western part of the valley, forming a large dark-coloured fan. The 1727 flood event transported large blocks of glacial ice, which persisted for decades after the event according to historical records, littering the landscape and forming kettle holes. The UAV acquired imagery reveals a complex network of kettleholes and palaeochannels. Palaeoflood modelling indicates that the 1727 event was slightly lower in magnitude than the 1362 jökulhlaup.

Configuration and Chronology of the Postglacial Marine Incursion on the Eastern Ungava Peninsula (Quebec, Canada): Implication for Deglaciation Models

Claudie Lefebvre-Fortier¹, Martin Roy¹, Hugo Dubé-Loubert², Étienne Brouard¹

¹Université du Québec à Montréal, Montréal, Canada. ²Ministère de l'Énergie et des Ressources Naturelles, Val d'Or, Canada

Abstract

Deglaciation of the Laurentide Ice Sheet on the Ungava Peninsula was complex and led to the development of glacial lakes that are difficult to integrate into current paleogeographic frameworks due to large uncertainties on the ice margin configuration and sparse chronological constraints on the ice retreat pattern. The final deglaciation of the Ungava Peninsula was marked by the incursion of the Iberville Sea into the isostatically depressed coastal areas of Ungava Bay. Previous studies show large spatial variations in the elevation of the maximum extent of the marine limit as well as a wide range of radiocarbon ages for this limit, while uplift gradients show no consistent pattern throughout the region. These inconsistencies may reflect the isolation of different ice masses late in the deglaciation and/or inadequate elevation measurements linked to low-resolution mapping techniques. Here we characterize the maximal extent of the Iberville Sea and document the regional pattern of deglaciation through detailed mapping of raised marine beaches, terraces, deltas and other deglacial landforms. Mapping was carried out using high-resolution satellite imagery (Rapideye, 5m), aerial photographs and DEMs, and observations were subsequently validated through fieldwork. We also measured the elevations of 133 landforms associated with the maximum marine limit using high-precision DGPS. Elevation measurements were focussed on a 230 km-long N-S transect along the western Ungava Bay coast, in addition to two E-W transects extending inland along the Payne and Leaf rivers. Our results indicate that the elevation of the maximum marine limit shows a gradual increase from north to south along the Ungava Coast, going from 100 m to 155 m. The calculated E-W uplift gradients yield a uniform dip towards the east, suggesting the presence of a late deglacial ice mass located on the center of the Ungava Peninsula. Our mapping also outlines geomorphic features that refine the position and configuration of the ice margin at the time of the marine incursion. The geometry of the water plane associated with the maximum marine limit can also be used to identify the origin of raised shorelines that might belong to the Iberville Sea or glacial lakes, which may be difficult to differentiate far inland. We also present an inventory of ¹⁴C ages available for the region, which will be compared to upcoming cosmogenic (¹⁰Be) ages obtained on boulders sampled from marine shorelines and deltas. The ¹⁰Be ages will refine the timing of the opening of Ungava Bay to marine water, thereby providing minimal time constraints on meltwater discharges from glacial lakes that drained into the Iberville Sea. Overall, these mapping results should refine regional sea-level curves and improve paleogeographic reconstructions depicting the deglaciation of the Ungava Peninsula.

Methodology for the predictive mapping of flat terrains within a catchment, by semi-automatic analysis of the Digital Elevation Model

Anne Raingeard¹, Frédéric Lacquement¹, Bruno Tourlière¹, Julien Baptiste¹, Hélène Tissoux^{1,2}

¹BRGM, Orléans, France. ²UMR7194, Paris, France

Abstract

The knowledge of surface geological formations over the metropolitan French territory is very much heterogeneous: sometimes well represented for their contours and descriptions, sometimes absolutely absent when they can be observed on the field. The implementation of systematic and continuous acquisitions programs at appropriate scales all over the territory cannot be intended considering vastness of the country. Therefore, finding solutions to help the mapping of subsurface geological objects in order to increase the knowledge is likely to be a relevant strategy in which the BRGM has been committed for some years.

One of the research approach consists in defining methodologies for predictive mapping by image processing and analysis with validation through field feedbacks. As part of the cartographic identification of alluvial formations, we developed a methodology based on the Digital Elevation Model (25m precision from IGN (French geographical service)) and its declinations (curvature, slope, its difference with base level etc.). The implemented workflow provides a predictive map representation of morphological terrace levels as well as the colluvium from the valley bottom or lower hillside.

We developed this methodology of semi-automatic mapping by topography analysis on a selected test area in the Pyrenean foothills (sub-watershed of the Gave de Pau). A field campaign on the basins of Baise and Ousse rivers allowed us to compare the results of the predictive cartography and the geological reality. The first results show that the proposed analysis is relevant at the scale of a multi-kilometer catchment, not affected by faults. The methodology provides valuable support for the mapping of these superficial formations, in particular by significantly saving time when drawing the map. It was noted that the estimation of the alluvial system base level was a key point in our modeling, then several interpolation methods were compared.

The development of a graphical interface allowing all the catchment analysis to be carried out in a single application will make it possible to produce predictive maps quickly and to help with the cartographic identification of alluvial stepped formations

P-1834

Accuracy assessment of using cost-effective PPK in direct georeferencing of UAS photogrammetry

Cheng-Hao Lu¹, Ming-Lin Chuang¹, Di-Yi Lin²

¹National Penghu University of Science and Technology, Penghu, Taiwan. ²National Kaohsiung University of Applied Sciences, kaohsiung, Taiwan

Abstract

This study presents a self-made and cost-effective post-processed kinematic (PPK) system for the direct georeferencing in the unmanned aerial system (UAS) photogrammetry. Contrast to the traditional UAS photogrammetry, PPK survey has many advantages: no need of Ground Control Points (GCPs), faster processing and field preparation, safer field work and cost-effective. Especially without the need of GCPs placement, this extends the application of UAS photogrammetry, such as large-scale landslide, steep sea cliff monitoring and high mountain survey, where the survey area is not accessible.

This paper presents an experimental investigation on the four repeatability of UAS photogrammetry. Four control configurations were designed and executed in the same flight plan: no-GCPs and PPK-disabled, 12 GCPs only, PPK only, PPK+1GCP. 15 check points (CPs) and 98 independent check points (ICPs) were used to evaluate the RMSE of UAS photogrammetry by using total station. The Z RMSE of CPs is 2969cm (no-GCPs and PPK-disabled), 2.45cm (12 GCPs only), 3.32cm (PPK only), 2.51cm(PPK+1GCP).

3D-modelling of Charlemagne's summit canal – merging remote sensing and geoarchaeological data

Johannes Schmidt¹, Johannes Völlmer¹, Lukas Werther², Ulrike Werban³, Peter Dietrich^{3,4}, Stefanie Berg⁵, Peter Ettl², Sven Linzen⁶, Andreas Stele⁷, Christoph Zielhofer¹

¹Institute of Geography, Leipzig University, Leipzig, Germany. ²Chair of Prehistory and Early History, Friedrich-Schiller University, Jena, Germany. ³Helmholtz Centre for Environmental Research UFZ, Department Monitoring and Exploration Technologies, Leipzig, Germany. ⁴Centre for Applied Geosciences, Eberhard Karls University, Tübingen, Germany. ⁵Bavarian State Department of Cultural Heritage BLfD, Munich, Germany. ⁶Leibniz Institute of Photonic Technology IPHT, Jena, Germany. ⁷Institute of Geography, Osnabrueck University, Osnabrueck, Germany

Abstract

The Fossa Carolina is the first hydro-engineering construction that bridges the Central European watershed in the Early Medieval. The canal was built in 792/793 AD by order of Charlemagne with the aim to connect the drainage systems of the Rhine-Main-catchment and the Danube catchment. At that time, navigable waterways played an important role for itinerant kingships, economic exchange and communication across powerful elites and religious institutions in Europe. Hence, this hydroengineering project was of high geostrategic relevance. Current studies show, that the canal was built as a summit canal with several ponds of different levels. The canal trenches were deepened into sandy to loamy valley fills between the Rhine-Main and Danube catchments. In this poster, we show for the first time, the integration of Airborne LiDAR and (geo)archaeological datasets with the aim to create a 3D-model of Charlemagne's summit canal. We develop an approach for handling with geoarchaeological data of different resolution. The canal trench geometry is derived from three archaeological excavations and four high-resolution direct-push transects. We produced a purged Digital Terrain Model (DTM) by removing all anthropogenic structures (Schmidt et al. 2018). This pre-modern DTM reflects the Carolingian topography that deals in this study as basis for the modelling approach. By means of several core drillings we interpolate the ditch floor and the adjacent dams along the entire canal. As a result, we are able to create a 3D-model that reflects the maximum construction depth of the entire Carolingian canal. Furthermore, we calculate the excavation volume of the most important hydro-engineering construction in Early Medieval Europe. As a result, we compute an excavated volume of c. 287,000 m³. The excavated volume is not equally distributed over the whole canal length. On the contrary, approx. 87 % of the entire volume corresponds with just 45% of the canal length. The present remnants of the massive dams are much smaller and reveal only a volume of approx. 120,000 m³. This difference reflects the erosion and overprint since the 8th century AD. According to current information to the construction time by dendrochronological and historical data, we finally calculate the number of workers (c. 1725 persons) that were needed for the earthwork construction.

Spatial variation in till texture and clay mineralogy across the Saginaw Lobe terrain, Great Lakes region, USA

Randall Schaetzl, Christopher Baisch, Jarrod Knauff, Thomas Bilintoh, Daniel Wanyama, Kevin McKeehan, Michelle Church
Michigan State University, East Lansing, USA

Abstract

We present a spatial/mapping approach to the study of the glacial history of the Saginaw lobe of the Laurentide Ice Sheet. The Saginaw Lobe flowed into southern Michigan, forming modern-day Saginaw Bay and leaving behind a series of small moraines in down-ice locations. Upon its retreat – and likely also during its advance – a large proglacial lake (Glacial Lake Saginaw) formed in the northeastern margins of the this “Saginaw terrain”. The Saginaw lobe advanced to the southwest, out of this lake basin and onto thinly mantled, sandstone and shale bedrock of the Michigan Paleozoic Basin. Although the Late Pleistocene deglacial chronology of this lobe has been generally assumed for decades, few numerical ages exist that could help constrain a better defined timeline. Indeed, as luminescence ages slowly emerge for terrain of the Saginaw Lobe and nearby areas, it seems clear that the lobe retreated from the region considerably earlier than is generally assumed, adding to the potential for large areas of ponded water in proglacial settings, all of which are as yet unmapped.

In this mapping project, we sampled tills on uplands across the terrain of the Saginaw Lobe, avoiding (1) areas that were affected by the lake, and (2) outwash plains. In all, we obtained 334 samples of calcareous till, by bucket auger. Sample locations were sited generally uniformly across >20,000 km² of the Saginaw terrain. Additionally, we recovered 17 samples of lacustrine clay from two areas on the former lakebed of Glacial Lake Saginaw. Grain-size analyses on these samples, by laser diffraction, revealed that the majority of the samples are texturally bimodal, with a mode in the clay-fine silt fraction and one in the very fine to medium sand fractions. Samples with a larger “fine” mode were typically in locations that were either (1) immediately down-ice from what would have been ponded by Glacial Lake Saginaw as the ice advanced into the region, and (2) areas which would have been trapped between the Saginaw ice and the large, preexisting West Branch Moraine. Down-ice, tills become sandier, which we attribute to the increasing influence of sandstone bedrock, as well as increasing distance from the clay source (the lakebed).

Our data highlight the tremendous spatial variability that can exist across a till sheet that, until now, was considered to have been comprised almost entirely of loam-textured till. Maps and grouping algorithms in ArcGIS helped us to identify natural groupings of these till textures, and in so doing, better elucidate the workings of the Saginaw Lobe as it advanced onto, and receded from, the landscape of southern Michigan.

P-1837

New insights into the glacial history of the eastern Cobequid Highlands, Nova Scotia, Canada as revealed by lidar-based surficial mapping

Denise Brushett

Nova Scotia Geological Survey, Halifax, Canada

Abstract

Surficial geological mapping based on the interpretation of LiDAR data has led to new insights into the Wisconsinan glacial history of the eastern Cobequid Highlands, where local ice-flow centres (the Appalachian Glacier Complex) prevented the incursion of Laurentide ice and produced regions of complex ice-flow chronologies associated with five phases of ice-flow and a multitude of surficial deposit types. New glacial geomorphological features have been identified and include eskers, flutes, kame and kettle features, meltwater channels, moraines, colluvial and alluvial deposits, many of which were not observed in previous lower resolution datasets (DEMs and aerial photographs). This surficial mapping project is one component of a joint surficial and bedrock mapping program conducted by the Nova Scotia Geological Survey to evaluate the mineral exploration potential (epithermal gold); guide geochemical sampling of till and stream sediments; and determine mineral dispersal patterns, which are discussed in this presentation.

The identification of new surficial landforms and deposits in the Eastern Cobequid Highlands allows us to update the Quaternary knowledge in this region and further our understanding of the glacial history, patterns of ice flow, and their associated landforms. It is anticipated that future surficial mapping and sampling programs will also avail of LiDAR data as the Nova Scotia LiDAR Acquisition Project aims to have all of Nova Scotia mapped with LiDAR by 2020.

Põlluotsa (NW Estonia), revisited.

Kuldev Ploom¹, Anatoly Molodkov², Kersti Kihno³, Arvi Liiva³

¹Geological Survey of Estonia, Rakvere, Estonia. ²Tallinn University of Technology, Tallinn, Estonia. ³University of Tartu, Tartu, Estonia

Abstract

In 1995, during the large scale (1:50 000) geological mapping in NW Estonia, peat was found in the Põlluotsa gravel pit buried under the coastal deposits of Ancylus Lake. A short description of the site was given next year during the field meeting of the Peribaltic Group in Lithuania.

Since then the site and its surroundings were visited occasionally, and some new data (OSL, ¹⁴C, pollen, *etc.*) were gathered. Põlluotsa area, an archipelago of islets during the Ancylus time, where buried pre-Ancylus organic matter spreads sporadically over several square kilometres, seems to be a very complex area in geological sense:

- The transgressive nature of the profile deposits indicates that the peat here does not mark the lowest point of the Yoldia Sea regression but formed as a response to the ascending groundwater level caused by the transgression of the Ancylus Lake.
- Local pollen zones from short sections influenced by local conditions mimic effectively the beginning of the (climatic) Boreal period with typical high *Pinus* pollen content. Sometimes this causes the 500–700-year underestimation of the age of only pollen-dated deposits. Of the abovementioned local conditions, the most important is probably the flooding by the waters of Ancylus transgression the relatively low-growing *Betula* brush and so leading to overrepresentation of *Pinus* pollen.
- Exceptionally old, and inverse, IR-OSL-dates of ca 44–25 ka (MIS-3) from the sands of Ancylus Lake suggest a fast redeposition from the sediments older than the Last Scandinavian Ice Sheet, which are very uncommon in northern Estonia, but nevertheless cannot be excluded in the area.
- For the first time in Estonia subfossil Yoldia Sea mollusc fauna was found here. Its freshwater origin, indistinguishable from the one of Ancylus Lake hints that Yoldia fauna may have simply not recognized earlier.
- Between the deposits of Yoldia Sea and sometimes deformed and eroded late-glacial varved [\[WU1\]](#) clays, turbidite-like purely-sorted sands and sandy gravels were found, representing the Billingen drainage event which ended the existence of Baltic Ice Lake.
- Geomorphological, mineralogical and OSL-data hint to the existence around of an ice-marginal zone, younger than youngest generally accepted one in Estonia (Palivere zone).
- A search for the older source sediments in the area led to discovery of even more ancient deposits formed, according to OSL-data, in the Late or even Middle Pleistocene, so far unknown in NW Estonia. It is also not excluded that they were redeposited (reworked) from original sands without access to daylight (*i.e.* they have kept initial age information) by tsunami or storm surge, or they were transported and deposited later, unchanged, by one of the ice sheets.

Abstract

Badlands are typically characterised by dry and unproductive terrains, which lack soil and are unsuitable for agricultural practices, vegetation or forestry. The growing number of badlands is a substantial problem in the world, particularly in temperate Mediterranean settings, and constitutes a major threat for local land management, economy and urban life. Sediments in a typical badland area are usually made of fine grained sediments such as clay, silt and sand (i.e. from a variety of rock sources). The development of temperate Mediterranean badlands is usually associated with intensive slope erosion caused possibly by change in climate (e.g. lengthy extreme wet periods) or human activity (e.g. bad land use). The influence of other external agents such as active faulting or depositional environments, that serve as conditioning or triggering factors, are hardly emphasised and recognised in the literature. Lithology and the rock structure have not been the centre of focus of most badlands research either.

The Kula Badlands, in the headwaters of a typical Mediterranean small tributary to the Gediz river in western Turkey, is situated in a region known for its Quaternary volcanism in an extensional tectonic regime, exhibit a notable example of intensive erosion. Base level control and lava flow damming of this small Mediterranean system has been mentioned in previous research. However, little is known about the stratigraphy, sedimentation history and the influence of the tectonic regime on these small tributaries and the development of Kula Badlands. This research is an attempt to identify the geological complexity of a badland terrain with field geological mapping and facies analysis to establish a benchmark in badlands research. We also collected samples for single grain optically stimulated luminescence (OSL) dating to build a robust geochronological framework with age control. The reconstruction of surface dynamic in relation to sedimentation and erosion history using age control will provide further insights in our investigation of badland development rates as a Mediterranean analogue.

Mobile streamlined bedforms beneath an Antarctic ice stream

Geoffrey Boulton

University of Edinburgh, Edinburgh, United Kingdom

Abstract

Mega-scale glacial lineations made up of unlithified sediments beneath the Rutford ice stream in west Antarctica have been known about for some years [e.g. Smith et al. 2007; Smith and Murray, 2009]. New seismic investigations along closely spaced seismic lines in areas of earlier surveys have revealed details of internal structures from which the evolution of the streamlined bedforms can be deduced. Amplitude vs Offset (AVO) experiments and radar surveys also permit some of the physical characteristics of the sediments, including porosities, to be established. Major internal discontinuities separate earlier lineation sets from later sets that have overridden them, reflecting the evolution of the sediment masses in space and time as part of an evolving mosaic. Internal structures also demonstrate that the up-flow (stoss) terminations of the later set have been eroding, whilst the down stream (lee) terminations have been extending and prograding. The prograding masses also show a down-flow front, beyond which earlier lineations are preserved, suggesting that the former are part of an advancing sediment carpet. There are no acoustic emissions from the area of the prograding surface, whereas there are strong emissions from beyond the sediment front, suggesting an un-resistant bed in the former area, which is also an area of high sediment porosity, and a resistant sediment bed downstream of the front. The paper discusses the possible physical conditions that have produced these contrasts, and insights into the evolution of mobile streamlined bedforms.

Drumlin Mapping Using Deep Learning Object Detection Systems

Shane Sookhan, Nick Eyles
University of Toronto, Toronto, Canada

Abstract

Recent research has suggested that drumlins and MSGLs belong to a continuum of genetically-related bedforms which are significant geomorphological evidence of ice sheet dynamics. Understanding their origin and formation is therefore crucial to modelling past and future ice sheet behaviour. Current formation hypotheses are inadequately detailed and unable to mathematically model the genesis of all bedform morphologies. This is due in large part to the logistical difficulties associated with mapping entire bedform populations which has resulted in the use of limited datasets with small sample sizes that do not account for the full morphological variability. The recent proliferation of high-resolution digital imagery presents an opportunity to address this data gap, but efficiently mapping bedforms from such data has proven difficult. This presentation explores the viability of using machine learning-based object detection to accurately and efficiently map drumlins and MSGLs. Deep learning object detection systems including Fast R-CNN (region convolution neural network), YOLO (You Only Look Once) and SIMRDWN (Satellite Imagery Multiscale Rapid Detection with Windowed Networks) are adapted and trained to identify and map subglacial bedforms from high-resolution digital elevation models. The results of these methods are compared and their potential for use in drumlin modelling research is evaluated.

The new landslides and rock glaciers inventory map of Canton Ticino (Southern Switzerland)

Christian Ambrosi, Dorota Czerski, Cristian Scapozza

Institute of Earth Sciences, University of Applied Sciences and Arts of Southern Switzerland, Canobbio, Switzerland

Abstract

The landslide and rock glacier inventory map of Canton Ticino was recently upgraded joining many studies performed since 2005 following a multi-method approach combining 2D and 3D digital photo-interpretation: (1) 2D photo-interpretation using SWISSIMAGE orthophotos and swissALTI3D hillshade, @swisstopo; (2) landslide mapping by 3D digital stereoscopic photogrammetry on analogical and numerical aerial photographs (1950-2015); (3) landslide mapping by digital monophotogrammetry thanks to the WSL-Monoplotting-Tool on ancient oblique non-metric photographs; (4) geological structures and shallow landslide mapping based on field verification of photointerpreted maps; (5) analysis of InSAR (Satellite Synthetic Aperture Radar Interferometry) and GBR (ground base radar) data for the state of activity of landslides and rock glaciers; (3) geodetic monitoring for landslide and rock glacier activity: GPS, theodolite, laserscan and UAV surveys.

This mapping allowed the inventory of 6599 hillslope landforms, from which 2035 were classed as landslides (covering a surface of 184.4 km²), 4376 as shallow landslides (covering a surface of 133.7 km²) and 188 as Deep Seated Gravitational Slope Deformations (DSGSD). Landslides are composed by 1494 slides, 86 flows, 390 falls (comprised between 100 and 1'000'000 m³) and 65 rock avalanche deposits (> 1'000'000 m³). 334 landslides were considered as active (238 slides, 17 flows and 79 falls). Shallow landslides includes: 1532 erosion areas; 2000 talus slopes, scree slopes, coarse-scrree slopes and rockfall deposits (< 100 m³); 27 debris flow deposits (from which 16 are considered as active); 817 mixed cones composed both by rockfall and debris flow deposits (from which 97 are considered as active).

Based on this mapping, the regional rock glacier inventory was also updated. Actually, 281 rock glaciers and related periglacial landforms were recognised in the Ticino Alps, comprising 48 ice-cemented active rock glaciers, 17 ice-cored active rock glaciers, 51 ice-cemented inactive rock glaciers, 3 ice-cored inactive rock glaciers, 157 relict rock glaciers, 3 push-moraines and 2 large gelifluction lobes. The 124 (44%) active/inactive rock glaciers, push-moraines and large gelifluction lobes are indicators of current permafrost conditions, whereas the 157 (56%) relict rock glaciers are indicators of former permafrost conditions during the Lateglacial and the Early Holocene.

Abstract

We have discovered two eskers associated with ~110–150 Myr old glaciers, in the Phlegra Montes [1] and NW Tempe Terra [2] regions of Mars' northern mid-latitudes. Eskers are sinuous sedimentary ridges deposited by meltwater flowing in glacial drainage conduits. Mars' present climate is extremely cold and arid and, until recently, it was widely thought that mid-latitude debris-covered glaciers on Mars had been pervasively cold-based since their formation 10s–100s Myr ago. However, eskers associated with existing glaciers indicate that localised wet-based glaciation has occurred during Mars' most recent geological period.

The mid-latitude glacier-linked eskers are both located within glaciated tectonic rift valleys or grabens. This suggests that, under cold recent climate conditions, locally-elevated geothermal heat flux (above the modelled global average of 23–27 mWm⁻²) may have been a prerequisite for glacial melting. We used a 1D model of heat flow through glacial ice to explore the environmental requirements for basal melting, incorporating the effects of strain heating for the first time [2]. We calculated the temperature at the glacier bed by comparing rates of geothermal and viscous strain heating of the basal ice with the rate of heat loss to the surface under different ice thicknesses.

We found that, under scenarios where geothermal heat is the only source of heat to the bed, basal melting requires conditions that seem unlikely for Mars' recent geologic history (surface temperatures >215 K, ice thicknesses >1100 m, and geothermal heat flux >80 mWm⁻²). However, when we incorporated strain heating, we found that it provided up to 14.5 K of additional warming to the basal ice and reduced significantly the geothermal heat flux, surface temperature, and ice thickness required for basal melting. This arises from a highly non-linear response of strain heating to ice temperature and driving stress. Ice convergence and large deviations in driving stresses (associated with localised variations in ice surface slope and/or ice thickness) may have encouraged strain heating of basal ice within the steep-sided tectonic rifts/graben that host the glacier-linked eskers. Thus, both geothermal and strain heating likely played vital roles in encouraging geologically-recent esker-forming glacial melt events in Mars' mid-latitudes.

We have also used high-resolution (0.25–2 m/pixel) remotely-sensed data to: analyse the 3D morphometries of the Martian eskers; compare them to terrestrial analogues; and explore the spatio-temporal nature, and sediment-discharge dynamics of esker-forming glacial melt events on Mars [3].

This work was funded by STFC grant ST/N50421X/1.

Geomorphological and sedimentary signatures of transient subglacial hydraulics during the November 1996 jökulhlaup, Skeiðarárjökull, Iceland

Andrew Russell¹, Mandy Munro-Stasiuk², Andrew Gregory³, David Blauvelt⁴

¹Newcastle University, Newcastle-upon-Tyne, United Kingdom. ²Kent State University, Kent, USA. ³ERM, Manchester, United Kingdom. ⁴National Intelligence University, Washington D.C., USA

Abstract

The landform and sedimentary record of former glacial meltwater systems provides valuable information about the dynamics of former ice-sheets. Although it is well known that ice-sheet plumbing systems can respond rapidly to transient processes such as the drainage of stored meltwater and glacier surging, the identification of such process within the Quaternary record is difficult due to the paucity of accessible modern process analogues. This study presents evidence of the sedimentary and landform signature of extreme hydraulic transience during a well-studied glacier outburst flood (jökulhlaup).

A volcanic eruption beneath Vatnajökull ice cap generated 3.8 km³ of meltwater which travelled into Grímsvötn subglacial lake until it reached a critical level for drainage. The resulting jökulhlaup reached a peak discharge of 45-53 x 10³ m³s⁻¹ within 14 hours. After its release from Grímsvötn, the jökulhlaup propagated as a high pressure subglacial flood wave taking 10.5 hours to reach the glacier snout. Negative effective pressure during passage of the subglacial flood wave induced hydraulic jacking of the glacier by 2–5 m. As the jökulhlaup progressed, discharge from the glacier became progressively focussed on major conduit outlets. To exit the glacier, floodwaters had to ascend ~300 m to the sandur surface bursting from multiple englacial vents and fractures, spreading progressively, along the entire 23 km wide ice margin over a 6-hour period.

Recession of the margin of Skeiðarárjökull, by ~ 2 km since 1996, reveals corridors of subglacial meltwater activity which are inset with the drumlinised landscape occupying areas of low elevation and on the ice-distal sides of drumlins. Parallel depressions, subglacial cavity fills, hydrofracture-fills and eskers within these corridors can be linked directly to known November 1996 jökulhlaup outlets. The internal sedimentary architecture of the hydrofractures and cavities is entirely conformable with the surrounding glacier ice and indicates deposition from jökulhlaup flow ascending from beneath the drumlinised surfaces (glacier bed). Hydrofracture and cavity-fills are interbedded with englacial eskers demonstrating synchronous deposition. Rectilinear ridges composed of glacial sediment coalesce into single-crested esker ridges feeding directly to November 1996 jökulhlaup conduit portals. Rectilinear gravel ridges comprise clastic dykes which reflect the upward injection of fluidised sand and gravel from an over pressured aquifer towards the former ice-bed interface. Substrate disruption/evacuation and ridge formation occurred simultaneously during the passage of the high pressure subglacial wave during the early stages of the 1996 jökulhlaup.

This study demonstrates the ability of highly pressurised jökulhlaup flow to produce distinctive assemblages of subglacial landforms and deposits. Such assemblages are associated with large englacial eskers, giant supraglacial ice-walled channels and distinctive pitted ice-contact proglacial jökulhlaup outwash fans.

Geomorphic, sedimentary and hydraulic reconstruction of a glacial lake outburst flood in northern Alberta, Canada

Sophie Norris¹, Martin Margold², Daniel Utting³, Duane Froese¹

¹University of Alberta, Edmonton, Canada. ²Charles University, Prague, Czech Republic. ³Alberta Geological Survey, Edmonton, Canada

Abstract

Glacial lake outburst floods occurred frequently during the last deglaciation of the Laurentide Ice Sheet. Within the Interior Plains, these floods carved large spillway systems, however due to the lack of abundant sediment, deposits within spillways are rarely preserved. Here, we present geomorphic and sedimentary evidence and hydraulic modelling of the eastern Beaver River Spillway, formed by the catastrophic drainage of the ice-dammed glacial Lake Algar, in northcentral Alberta. During this flood, coarse-grained sediment eroded from local till formed large pendant bars. Within the first ~50km of the spillway (Reach 1), pendant bars contain downstream orientated foresets overlain by horizontally bedded coarser gravels. The remaining pendant bars (Reach 2), present downflow of a moraine barrier, differ, comprising massive, matrix-supported, inversely-graded gravels capped by a boulder layer. We use a HEC-GeoRAS/HEC-RAS system in conjunction with palaeostage indicators, to estimate the steady-state water surface elevation. Modelling results show that peak discharge within Reach 1 of the eastern Beaver River Spillway was approximately 14,000-21,000 m³ sec⁻¹. For Reach 2, 30 km downstream, the peak discharge was estimated at 23,000-40,000 m³ sec⁻¹. The downstream discharge increase, consistent with the sedimentary change in pendant bar deposits, is attributed to sediment bulking of the flood flow. This provides the opportunity to observe a range of flow conditions, and associated sedimentology, from a single flood event.

Cool deltas. Sedimentary environments of Salpausselka I and II moraine ridges near Lahti, Finland

Bartosz Kurjanski¹, Brice Rea¹, Matteo Spagnolo¹, David Cornwell¹, John Howell¹, Jukka-Pekka Palmu²
¹University of Aberdeen, Aberdeen, United Kingdom. ²Geological Survey of Finland(GTK), Espoo, Finland

Abstract

Two large “moraine” ridges (Salpausselka I and Salpausselka II), extending to over 600 km in length, delineate two major stillstand/readvance positions of the Fennoscandian ice sheet during the last deglaciation, inferred to be chronologically related to the cool climate event known as the Younger Dryas (age) [\[SM1\]](#). During this time the Baltic ice lobe and the Finnish Lake District [\[SM2\]](#) ice lobe, constituting a part of the southern margin of the Fennoscandian ice sheet, were grounded in a large proglacial lake, the Baltic ice lake, a predecessor to the modern-day Baltic Sea. Most of the sediments were delivered to the ice margin by meltwater and deposited in the form of ice-contact deltas, over a very short period (230 and 250 years respectively for Salpausselka I and II). As a result, the “moraine” ridge is mostly composed of glaciofluvial sands, gravels and boulders rather than diamicton which is more typical of moraine sedimentology.

In this study, high resolution LIDAR data (2m horizontal, 0.3m vertical), provided courtesy of the National Land Survey of Finland and processed by the Geological Survey of Finland, ground penetrating radar profiles and outcrops were analyzed and interpreted. These provide a [\[RDBR3\]](#) record of rapid sedimentation from high-magnitude meltwater discharge, through subglacial channels, resulting in rapid buildup of ice contact fans to the water surface and subsequent progradation of deltaic forests. Renewed retreat of the ice margin lead to abandonment of the Salpausselka I and deposition of the Salpausselka II ridge, 25 km to the north. In the Lahti region, where the two ice lobes were confluent, the largest deltaic complex developed. Sediments of Salpausselkas in Finland are a world class example of a [\[RDBR4\]](#) sedimentary environment which records, with great detail, the processes of the formation of ice-contact, Gilbert-type, deltas marking stillstand positions of the southern margin of the Fennoscandian Ice Sheet during the Younger Dryas.

P-1847

The geomorphology and formation of Late Pleistocene outwash fans in northern Poland

Marcin Sobiech, Wojciech Wysota
Nicolaus Copernicus University, Toruń, Poland

Abstract

Outwash fans are common landforms in contemporary and Pleistocene glacial landscapes. Research on the subject has usually concerned the general morphology of sandurs, and the lithofacial characteristics and depositional processes of their formation. So far, there has been no detailed geomorphic analysis of sandurs, and of outwash fans in particular. The research examined the morphometric properties of outwash fans in northern Poland and the processes of their genesis.

In 16 test areas, surface and morphometric characteristics were analyzed using high-resolution (1×1 m) elevation data from Airborne Laser Scanning (ALS). The analysis also includes geological and geomorphological data, mainly from the detailed 1:50,000 geological map of Poland. First, geomorphological maps and surface geological structure of the test areas were collected. Then, a detailed mapping of surface topographical macroform was performed, and morphometric parameters of 18 identified outwash fans were determined in detail.

Based on the research, two main types of outwash fans were distinguished. (1) *The typical outwash fans* formed at the outlets of N- and R-type subglacial channels and also sometimes at the extension of upward-opening crevasses along degraded channels within the ice sheet front. As a whole spatial form, these fans represent a record of the subglacial meltwater outflow in the ice sheet forefield. These processes were accompanied by the supply of supraglacial debris, which nonetheless did not significantly affect their morphological development. (2) *The transitional outwash fans* were formed by subglacial meltwater outflows from N-channels, and debris flows from the ice sheet front and accumulating on the extension of short ice-marginal fans.

The outwash fans were created as a result of the temporally and spatially variable activity of meltwaters of diverse flow energies. In most cases, these landforms formed at the outlets of N-channels, and more rarely of R-channels, as a result of repeated outflows of subglacial meltwaters. The macro-relief of some outwash fans suggests that their formation may have involved catastrophic flows.

P-1848

Exploration of a morphogenetic signature for eskers

Meaghan Dinney, Tracy Brennand
Simon Fraser University, Department of Geography, Burnaby, Canada

Abstract

Eskers are typically defined as sinuous ridges of sand and gravel deposited by glacial meltwater processes. This definition does not express the variability in esker form observed in Quaternary and contemporary landscapes. Eskers may be straight to sinuous, consist of single or multiple anabranching ridges, and contain a range of grain sizes representative of the complex interplay between glacier ice, water, and debris. These differences in form and structure are associated with variations in genesis. Esker pattern, morphometry, sedimentary architecture, and composition record the hydrologic and sediment supply conditions responsible for their formation. The use of eskers as indicators of paleo-ice sheet hydrology is often underlain by the assumption that all eskers are of subglacial origin. Studies of eskers in paleo and modern environments suggest that this assumption is not valid. This project investigates the relationship between esker morphometry and genesis. The results will help to better understand glacial hydrology and to inform ice sheet models containing hydrology.

Little research has been done to quantitatively describe esker morphometry. The increasing availability of high-resolution digital elevation data makes assessing the relationship between esker form and genesis possible. Here we present a database of esker morphometry and genetic interpretations sourced from original field research and mining of relevant esker literature. Morphometric indices such as length, sinuosity, continuity, and cross-sectional shape are computed for each record in the database. These indices are calculated at a range of digital elevation model resolutions in order to assess their scale-dependency. Genetic interpretations and supporting evidence are also summarized. This project primarily focuses on relative position in the glacier (subglacial, supraglacial, englacial, etc.) as a genetic marker, but other genetic interpretations have been recorded. This database confirms the variability in esker morphometry and genesis and provides a basis from which to explore a morphogenetic classification of eskers.

P-1849

An empirical approach to assessing the influence of hydrology on palaeo-ice sheet flow and retreat over centuries to millennia

Stephen Livingstone, Ádam Ignéczi, Andrew Sole, Chris Clark, Felix Ng, Jeremy Ely
Sheffield University, Sheffield, United Kingdom

Abstract

Recent observations have shown that meltwater storage (in lakes on or beneath the ice) and routing on, through and beneath ice sheets can critically affect ice flow (speed up vs slowdown) and tidewater glacier recession, on up to decadal timescales. Despite significant recent advances, theoretical limitations and the computational expense of incorporating physically-based ice sheet hydrology into models currently limits their scope to studying individual catchments and short time periods. It is therefore uncertain whether hydrological controls only influence short-term fluctuations in flow speeds and retreat, which could be thought of as noise around a mean value, or whether they are fundamental drivers of centennial to millennial change and ice sheet mass loss.

We present an empirical approach for determining the influence of hydrology on ice flow and margin position change of palaeo-ice sheets over centuries to millennia, based on recent work that demonstrates the routing, storage and drainage of surface meltwater is controlled by transfer of basal topographic variability to the ice surface (Ignéczi et al. 2018; Ng et al., 2018). Using modelled ice sheet geometries, modelled surface mass balance, high-resolution bed topographies and empirical relationships from contemporary ice sheets, we demonstrate that it is possible to reconstruct a representation of the surface drainage system and likely drainage volumes to the bed. Combined with the application of hydrological routing analyses to produce first order approximations of subglacial drainage catchments and basal water volumes, we aim to assess the extent to which variations in the coverage of the surface drainage system, driven by bed roughness and changes in ice geometry and surface mass balance exert a control on empirically-derived retreat rates. The reconstructed surface drainage patterns will also be compared with the distribution and morphology of mapped subglacial meltwater landforms, such as channels and eskers, to determine the role of supraglacial hydrology on their formation.

Riverscape response to glacial lake outburst flood mapped using UAV surveys: a case study from Zackenberg Valley, NE Greenland.

Marek Ewertowski, Aleksandra Tomczyk

Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznan, Poland

Abstract

Currently, the primary challenge for research related to Earth-surface dynamics in the Arctic is to recognize and quantify geomorphic response to global warming, including the response to (1) high-frequency climate variability (e.g. freeze-thaw cycle, rainy and dry seasons); (2) low-frequency, but high-magnitude extreme events (glacial-lake outburst flow, catastrophic debris flows); and (3) long-term landscape and climate evolution. Previous studies also indicated that there is a need to collect detailed examples of fluvial change in flood-affected areas as our understanding of the geomorphic response to large floods is still incomplete. In this study, we used high-resolution pre-flood, during-flood and post-flood imagery collected with an unmanned aerial vehicle (UAV), which provided us with an excellent opportunity to observe and measure such a response.

The study was carried out in Zackenberg Valley (at the lower reach of the river) located in central Northeast Greenland (74°30'N; 20°30'W). The Zackenberg Research Station, established in 1995, provides access to field-based observations in this High Arctic region. Zackenberg River drains local ice cap situated approximately 30 km from the seashore, and glacial outburst floods have regularly been reported since 1996, usually in July or August. We aimed to quantify the geomorphic effects of the flood which happened on the 6th of August 2017. We mapped 2 km long section of the river, located near the river mouth and Zackenberg Research Station to quantify short-term riverscape response to the flood. Three survey sessions utilising small quadcopter were performed on: 5th August 2017 (a day before the flood started), 6th August 2017 (during the high-water conditions) and 8th August 2017 (after the river returned to the normal water level). From each survey session, detailed orthomosaic (2 cm cell size) and digital elevation model (DEM, 7 cm cell size) have been produced. Volumetric transformations were calculated using geomorphic change detection approach by subtraction of DEMs from subsequent periods. Planar transformations were investigated using time-series of orthomosaics.

Riverbanks retreated by a mixture of two main processes: strong currents removed material, and thermo-erosion of permafrost in the banks resulted in the development of overhanging sections or collapsing of large blocks of sediments and ground ice. The maximal later erosion recorded as an immediate effect of this single flood event was up to 9 meters. However, the occurrence of overhung sections and tension cracks indicate that further bank failure is likely to happen. Morphology of river channel also changed, and numerous gravel and sand bars migrated as a result of the flood. Collected information present a useful analogue of the geomorphic response of small river channels affected by large floods.

The research has received funding from INTERACT under the European Union H2020 Grant Agreement No.730938, project number: 119 [ArcticFan]

P-1851

Late Wisconsin meltwater routing In a large embayment along the southern margin of the Laurentide Ice Sheet in Michigan, USA

Alan Kehew^{1,2}, John Esch³, B. Brandon Curry⁴, Sebastien Huot⁴, John Yellich²

¹Western Michigan University, Kalamazoo, USA. ²Michigan Geological Survey, Kalamazoo, USA. ³Michigan Dept. of Environmental Quality, Lansing, USA. ⁴Illinois State Geological Survey, Champaign, USA

Abstract

Soon after the LGM, a large embayment developed along the southern margin of the Laurentide Ice Sheet bounded to the west, north and east by the Lake Michigan (LML), Saginaw (SL), and Huron-Erie (HEL) lobes, respectively. The movement of these lobes was asynchronous, and therefore meltwater was released from them over a long interval of time. There is little radiocarbon control on ice margin fluctuations, and although we have a growing luminescence database from samples of glacial outwash, the uncertainties of this method may limit resolution of closely spaced meltwater events. Working out the source of meltwater flows from this area is important because the Kankakee Torrent, a major glacial lake outburst in Illinois that flowed down the Mississippi Valley to the Gulf of Mexico, was probably triggered by meltwater flow from the study area.

Based mainly on cross-cutting relationships, the earliest meltwater flow from the embayment originated from a network of tunnel valleys ending at the Kalamazoo moraine of the SL and probably also from the HEL. This meltwater flowed westward until diverted to the south by the presence of the LML, through an interlobate lowland. The LML lobe itself then began to contribute meltwater to the embayment. When the LML retreated to the Valparaiso position, glacial Lake Dowagiac formed in a long linear lowland between the edge of the LML and the Kalamazoo moraine to the east. The rapid drainage of this lake is the most likely source of meltwater that flowed into glacial Lakes Wauponsee, Watseka, and Pontiac south of the LML, causing the lakes to overflow and cutting spillways leading to the Illinois and Mississippi Valleys at about 19 ka. BP. Evidence for a large-scale release of meltwater from the lake includes streamlined erosional hills in the basin.

After the LML retreated westward of the Kalamazoo and Valparaiso moraines, an outburst from an as yet unknown source cut a large spillway through both moraines, which diverted meltwater west of the embayment. The most recent meltwater flow through the embayment came from the HEL and flowed southward along the edge of the Kalamazoo/Valparaiso morainic system.

Patterns of ice-marginally related glacifluvial sedimentation in Eastern Lithuania

Eglė Šinkūnė^{1,2}, Mindaugas Kazbaris², Tomas Aidukas², Petras Šinkūnas^{1,2}

¹Institute of Geosciences, Vilnius University, Vilnius, Lithuania. ²Institute of Geology and Geography, Nature Research Centre, Vilnius, Lithuania

Abstract

The situations of the ice meltwater running from supraglacial outlets and glacial conduits seem to be common during the Late Pleistocene glaciations in Eastern Lithuania. Depending on the conditions the glacifluvial sedimentation took place in front of the glacial margin in form of glacifluvial ice-marginal ridges or further on terraces of proglacial valleys. During the detailed sedimentological study, the main attention was paid to the ice-marginal ridges (end moraines) composed of the glacifluvial sediments to understand the role of subaerial terminoglacial fans in their formation. Sediments forming some of such ridges are completely glacetectonically dislocated. In the other cases, only the sediments of ice-contact zones in glacifluvial ridges are slightly deformed. The glacifluvial sediment sequences at the other sights show the features created only by sedimentation from ice meltwater flows. The architecture of such landforms usually displays extensive bodies of horizontal to low-angle stratified fine- and coarse-grained sediments with some outsized clasts inside the beds. Subhorizontally laminated, sometimes cross-bedded pebbles and granules usually matrix supported, coarse- and various-grained sand beds make some rhythmites. These mostly coarse-grained rhythmite sheet-shaped beds have a slight inclination away from the former glacial ice margin. In some sites, the inclination of beds is quite high in all the deposit sequence. The sand cross-laminae if present has the same preferred dip direction as the inclination of sediment beds. Such deposit architecture likely represents sheet-flow sedimentation in front of the glacial ice margin forming the sediment ridges in the initial form of glacifluvial fans or their coalescences.

Abstract

Subglacial water drainage plays a significant role in glacier flow dynamics. Various forms of subglacial drainage have been observed beneath modern ice sheets, and the same forms of drainage likely occurred beneath paleo-ice sheets, such as the Laurentide Ice Sheet (LIS). Records of paleo drainage are well preserved in Wisconsin's geomorphic record and can serve as a widespread and easily accessible means to investigate aspects of subglacial drainage that are difficult to directly study on modern-day glaciers. Tunnel channels were common subglacial drainage features of the LIS in Wisconsin during Marine Isotope Stage Two (MIS 2). Their locations are marked by a linear series of collapse depressions that extend up to ~15 km perpendicular to the margin. Geologic evidence indicates tunnel channels resulted from sudden subglacial lake drainage eroding into subglacial material, and that only a few drainage events occurred for any particular channel.

This poster presents the results of recent geologic mapping, geophysical surveys, drilling and subglacial hydraulic modeling of tunnel channels along a portion of the Green Bay Lobe (GBL) in central Wisconsin. One km seismic profiles were collected across tunnel channels with 2.5 m common midpoint spacing at nominally 12 folds. Hammer blow and assisted weight drop sources were used and impacts were stacked ca. 5-fold to improve the signal to noise ratio. Core samples were collected with rotasonic and direct push drilling methods to depths of 125 m, including the center of a tunnel channel. We find that the channel incised ca. 65 m into the surrounding unlithified material, which is 6 times greater than the modern surface expression, and has a width of 450 m, which is nearly equal to the width of the surface expression.

Using modeled estimates of the subglacial hydropotential gradient along the western margin of the GBL we identified potential locations for subglacial water pooling. Linear surface depressions appear to correlate well with areas where subglacial water likely pooled. Our modelling of the subglacial hydraulic potential near the margin of the GBL suggests permafrost was not necessary if an adverse bed slope was approximately 11 times greater than the surface slope. This condition occurs at several locations along the western GBL, and in all instances coincident with the presence of tunnel channels. However, there is strong evidence that permafrost was present as ice advanced to the MIS 2 margin, and permafrost must have been present for buried ice to survive through multiple ice advances in the area.

The glacial geomorphology of the last glacial termination of the Godley Glacier, Tekapo Valley, New Zealand

Jenna Sutherland¹, Jonathan Carrivick¹, David Evans², James Shulmeister³

¹University of Leeds, Leeds, United Kingdom. ²Durham University, Durham, United Kingdom. ³The University of Queensland, Queensland, Australia

Abstract

A 2 m digital elevation model (DEM) generated from airborne LiDAR data, supplemented with aerial imagery and field evidence, are used to map the glacial geomorphology of the Tekapo Valley, Canterbury, New Zealand. The map presents the distribution of glacial landforms and sediments associated with the last recession of the Late Otiran Godley Glacier. It represents the most-detailed and finest-resolution geomorphological map of any glacial valley in New Zealand, which contain important and hitherto understudied palaeo-glaciological archives of landforms and sediments. The DEM reveals previously unrecognised, low-amplitude, ice-marginal landform assemblages including eskers, drumlins, and crevasse-squeezed ridges, overprinted by inset sequences of latero-frontal recessional push moraines. These landforms indicate a final ice stagnation phase. Their presence has significant implications for the nature of subglacial drainage and for the final stages of glaciation. The landforms record spatiotemporal land-system change that is fundamentally diagnostic of an active temperate piedmont lobe of a debris-charged glacier. The mapping is combined with 80 km² high-resolution (1 m grid) multi-beam swath bathymetry of Lake Tekapo which reveals widespread and spectacular sub-aqueous slumps. Sub-aqueous slumps are a dominant feature of the lower slope lake walls, covering 20 % of the marginal lake basin floor.

We highlight the nature of deglaciation, which is characterised by exceptional sedimentation and the widespread presence of water associated with proglacial settings. These conditions prevailed to produce a glacial land-system characterised by extensive outwash fans and relatively small terminal moraines. The new geomorphological dataset presented here facilitates land-system analysis at the ice-lobe scale. We produce detailed reconstructions of (i) ice-margin recession (ii) evolving ice-dynamics and (iii) evolving palaeo-lake systems. The glacial landsystem of the Tekapo Valley constitutes important palaeo-glaciological reconstructions for modern dynamics of the Godley Glacier and its proglacial lake. The mapping serves as a foundation into more detailed research into the timings of change and will underpin future chronological investigations. A reliable geochronology is crucial for elucidating the temporal glacial evolution of the Tekapo Glacier throughout the Last Glacial Maximum.

A response of the Middle Pleistocene fluvial systems on climate changes - a case study from Gdansk Pomerania region, northern Poland

⁴Institute of Geology, Tallinn University of Technology, Tallin, Estonia

Abstract

Fluvial systems are characterized by cyclic variability of sedimentary processes and styles. This variability is controlled by both autogenic factors, resulting from the nature of this environment, as well as allogenic factors. Tectonic activity, climate and base-level changes are the main allogenic factors. During the Pleistocene the main role have played climatic changes in glacial-interglacial cycles and sea-level changes connected with them.

Transformation of fluvial system from braided to meandering river type is presumably interpreted as a result of changes from cold to warm climate conditions (Zieliński and Goździk, 2001). However, studies of the deposits of modern and ancient rivers operating in cold climate areas show that at the same time various types of fluvial systems were developing.

The area of Poland underwent repeated transgressions of the Scandinavian Ice Sheet (SIS). Northern part of Poland, which was within the reach of all SIS transgressions, experienced several rebuilt of fluvial systems. Fluvial sediments in several key sites in the region of Gdańsk Pomerania were subject to research. As part of the research, sedimentological analysis was carried out, dating of sediment age with luminescence methods and palynological analysis. The aim of the studies is to establish the impact of climate on sedimentary processes, stratigraphical scheme for fluvial series and to reconstruct palaeogeographical evolution of study area.

Fluvial systems have evolved according to a specific scheme in which four phases can be distinguished. After regressions of SIS, firstly developed outflow of melted water along ice-sheet margin, mainly towards W-NW. In this phase ice-marginal valleys and outwash plains have formed with high ratio of sediment aggradation. The second phase began with a deep incision during amelioration of climate and deposition of interglacial/interstadial series of braided rivers, which are relatively thin and rare. The third phase during deterioration of climatic conditions to cool and humid resulted in a change of sedimentation style to meandering with well-preserved point-bars (Sokołowski et al., 2017). The further cooling and drying of the climate caused widespread aggradation of permafrost and increasing of aeolian processes.

Three periods of SIS advances were detected, during MIS 10, MIS 8 and MIS 6a, respectively. Between these advances fluvial systems developed (MIS 9, 7 and 6), with repeated scheme of evolution from warm, braided systems to cool and cold climate meandering systems with outflow towards S, NW and SSW.

⁴Cardiff University, Cardiff, United Kingdom

Abstract

Despite the generally erosive nature of temperate ice, the geomorphic expression of glaciation in the British Isles and Ireland represents a palimpsest of successive Quaternary ice ages. To reconstruct more fully the history of glacial advance and retreat – and the palaeoenvironmental and climatic conditions these fluctuations represent – it is necessary therefore to establish accurate, precise, and reproducible chronologies for the glacial-geologic record. As a relative newcomer to the geochronology toolkit, cosmogenic nuclide (CN) surface-exposure dating is being applied increasingly to glaciated landscapes at all latitudes, and holds particularly exciting potential for divulging the timing of glacial and paraglacial events in Britain and Ireland. We present a new record of post-LGM cryospheric change in NW Scotland based on cosmogenic beryllium-10 dating of moraines and perched erratics, extending from the point at which the British-Irish ice sheet retreated onto the modern coastline to the disappearance of the last corrie glaciers. In addition to documenting discrete phases of cryospheric retreat and readvance, which we attribute to atmospheric warming and cooling events, respectively, this emerging chronology highlights the necessity of employing a robustly calibrated CN production rate, without which cosmogenic chronologies are effectively floating. We applied a new ^{10}Be production rate calibrated against independently dated moraines on Rannoch Moor, central Scottish Highlands, that is appropriate for use throughout the former domain of the last British–Irish ice sheet.

Frontal and Equilibrium Line Altitude Fluctuations since the Little Ice Age in the Miyar Basin, Lahaul Himalaya

Rakesh Saini¹, Milap Chand Sharma², Sanjay Deswal³

¹Dr Harisingh Gour Cnetral University, Sagar, India. ²Jawaharlal Nehru University, Sagar, India. ³Government College , Dujana, India

Abstract

We compare the present day terminus position and Equilibrium Line Altitude (ELA) with that of the last glacial expansion (Little Ice Age) that occurred in the Miyar basin Lahaul, India. The positions of the contemporary glaciers were mapped using high-resolution satellite images provided in 3D Google Earth and ESRI online images further supported by fieldworks using handheld GPS. The positions of the last glacial expansion were marked based on the field based mapping of the moraines between 2008 and 2016 supported by the Google Earth and ESRI Earth maps. The last glacial expansion moraines are well deposited in the form of the lateral moraines in all the major glacier valleys. The moraines are morpho-stratigraphically distinct from the earlier Holocene moraines with fresh sediments and landforms assemblage within 2 kilometres from the present glacier terminus supported by available historical maps of 1840-70s. The former terminus of a few glaciers, including Tharang, were incorporated and shown in the historical map of captain Harcourt (1871) and in the Great Trigonometrical Survey map (1840-70). Based on the available archaeological and palaeo-climatic history of the region of the last millennium, we suggest that by the late 18th and early 19th century the glaciers recorded expansion in the basin.

During this advance (late 18th to early 19th Century) Tharang glacier expanded down-valley by ~1.8 km, terminating at 3936m asl from its present position of 4486m asl, with an ELA depression of ~275 m relative to the contemporary ELA at 5130 m. Well preserved pair of lateral moraines in the upper Tharang valley marks the limit of this advance. The moraines are similarly marked on the GTS map. Comparatively, during the same advance, Pimu glacier experienced more expansion (~2.35 km), with terminus extending down to ~4276 m a.s.l. compared to the present position at ~4579 m asl (fig.4.7). Similar size of advance is recorded in Karpāt (~2.33 km) and Khanjar (2.31 km) glaciers. Relatively moderate advances (1-2 km) are observed at Darjeyang, Menthosa, Dali, Miyar, Tharang, Gumba and Hulāt glacier, whereas lesser (<1km) expansion is recorded in Takdung, Chhudong, Uldhampū, Palbo and Gangpo glaciers.

The contemporary ELAs in the basin range from 5062 to 5324 meter a.s.l. with a mean ELA of 5145m a.s.l. for the basin. However, during the Little Ice Age period, the ELAs varied between 4833 to 5193m. All the valley glaciers experienced noticeable depression in equilibrium line altitude. There are glaciers (*Karpāt, Darjeyang, Tharang, Menthosa and Dali*) which notice >250m change in ELA, whereas there are glaciers that experienced 250-150m ELA change (*Hulāt, Pimu and Palbo*). However, Khanjar, Gumba, Takdung, Chhudong, Miyar, Gangpo and Uldhampū noticed the lowest ELA change with 95, 70, 51, 46, 41, 35 and 18m ELA depression, respectively.

Abstract

The Makgadikgadi–Okavango–Zambezi Basin (MOZB) lies within a fault-bounded trough that many believe propagated westward from the East African Rift System into NW Botswana. This depression forms a depo-center within the intracratonic Kalahari Basin of southern Africa. Through dedicated studies, the surficial sediments that were deposited in the ephemeral lakes of the Makgadikgadi Pans, the Okavango River alluvial fan (i.e., Okavango Delta), and the surrounding aeolian dunes, are relatively well characterized and understood. Moreover, structural and seismic studies have defined the tectonic settings of the MOZB. Conversely, little is known about the sub-surface litho- and chrono- stratigraphies, and their relations with depositional environments and regional tectonics. The provenance of sediments in combination with cosmogenic nuclides dating from three boreholes located west of the present Okavango Delta were studied to reconstruct the spatial and temporal evolution of the sedimentation. Independent approaches for interpreting the in situ-produced ¹⁰Be and ²⁶Al concentrations (i.e., simple burial dating model, isochrone dating model, aeolian accumulation model) reveal three discrete depositional phases during the Plio-Pleistocene (>3, 2.2-1.8, <1.5 Ma), intermitted by hiatuses. The youngest phase seems to be the most widespread and extends to the southern Kalahari Basin. Stratigraphic variations in sedimentological and geochemical properties indicate changes in depositional environments through time and space, from low-energy deposition in still water to deposition in high-energy fluvial systems, all finally covered with aeolian sand. Duricrusts formation within all these units suggests later cementation by migrating solutions. Shifts in isotopic ratios of Sr, Nd, and Pb reveal changes in the sediment sources. These changes suggest adjustments of the drainage systems linked to tectonic events of the suggested southwestern-most extension of the East African Rift System.

Abstract

Recent studies demonstrate the potential of using cosmogenic noble gas systems as Earth surface paleothermometers. In particular, diffusive properties of cosmogenic ^3He accumulated in quartz at subzero temperatures should enable *in situ* paleotemperature reconstructions in mountainous areas where other direct and continuous temperature proxies (e.g. lake sediments, speleothems) are generally scarce. Glacially-scoured surfaces revealed following glacier retreat since the Last Glacial Maximum (LGM, ~26-20 ka) constitute promising sample targets for obtaining a temporal sequence of *in situ* paleotemperature reconstructions. If attainable, such information would be crucial to improve our understanding of glacier dynamics and past changes in atmospheric circulation patterns during deglaciation. However, converting bedrock ^3He concentrations directly into paleotemperature estimates requires (1) a robust reconstruction of the bedrock exposure history, (2) an accurate quantification of the ^3He diffusion kinetics and domain size, and (3) an understanding of rock-air temperature interactions over multi-frequency temperature oscillations.

In this study, we present ^3He data measured from bedrock surfaces sampled along well-constrained deglaciation profiles (based on cosmogenic nuclide surface exposure dating) in three different sites in the central Alps: Gotthard Pass (^{10}Be and ^{14}C), Gelmersee (^{10}Be), and Mer de Glace (^{10}Be). We investigate lithological effects on ^3He diffusion kinetics at both the macro (rock type) and micro scales (grain size and shape), as well as the potential influence of snow or soil covering since glacier retreat on bedrock temperatures. Effects of topographic factors such as elevation and aspect are also examined, as well as temperature fluctuations at the daily, seasonal and millennial time scales. The ^3He -derived paleotemperatures we present will be compared to paleotemperatures inferred from other paleoclimate proxies available for the European Alps, allowing us to explore the spatial variability of past climate conditions and/or paleo-lapse rates across the Alps since the LGM.

Cosmogenic isotopes transect on the northeastern Laurentide ice sheet cold-based plateaus

Tommy Tremblay¹, John Gosse²

¹Canada-Nunavut Geoscience Office, Iqaluit, Canada. ²Dalhousie University, Halifax, Canada

Abstract

Cosmogenic $^{26}\text{Al}/^{10}\text{Be}$ analyzed in quartz from bedrock (tor), regolith and till across transects on cold-based plateaus once glaciated by the Laurentide Ice Sheet (LIS), provide insights into the spatial relationship between basal thermal regime and glacial erosion among different mapped morphometrically-based subglacial erosion zones. Isotope transects extend from the “internal zone” of the northeastern LIS LGM ice dome region (Boothia and Melville peninsulas) to the “external zone”, toward the LGM ice margin (represented by Hall Peninsula on southern Baffin Island). ^{10}Be concentrations (normalized to SLHL) indicate relatively homogeneous inheritance within the plateau zones. Total erosion rates and burial duration (by ice or sediment) during the Quaternary can be estimated from numerical models. Assuming homogenous erosion rates among the cold-based plateaus, the hypothetical link between the variations of the $^{26}\text{Al}/^{10}\text{Be}$ ratios and the relative ice cover durations can be tested against other causes for the variations of the ratios such as burial by sediment cover or analytical uncertainty, because the studied plateaus have different ice cover durations during over the Pleistocene, as suggested by modelled ice cover (for example ICE 6) and deglaciation ages ranging between 11 and 6 ka Cal (considered a proxy for ice burial duration). This new work will complement the glaciodynamical studies on contrasting ice flow regimes in this region, from cold-based regions to ice streams.

P-1862

Cosmogenic isotope dating of glacial forms in Miętusia and Mała Łąka valleys, Tatra Mountains (Western Carpathians)

Anna Tołoczko-Pasek¹, Régis Braucher², Leszek Marks¹, ASTER Team²

¹Warsaw University, Faculty of Geology, Warsaw, Poland. ²Aix-Marseille Université, CNRS-IRD-College de France, Aix-en-Provence, France

Abstract

Miętusia and Mała Łąka valleys were glaciated at the turn of Holocene and Pleistocene, with the maximum extent during Last Glacial Maximum. That was one of the assumption of this project that we wanted to proof by dating glacial forms. Both valleys are located in Western Tatra Mountains (Western Carpathians). We used cosmogenic isotope of ³⁶Cl because of geological structure of the studied area. It is mainly composed of Triassic dolomites and limestones.

Tatra Mountains are at the border of oceanic and continental climate, which gives this region high temperature amplitude and maximum precipitation during summer months. High amount of precipitation cause high level of chemical denudation and high level of changes in glacial forms (especially in lower parts of the mountains).

In the study we show 29 in situ-produced ³⁶Cl-based cosmic ray exposure dating from maximum and recessional moraine boulders and bedrock. Dates from moraine boulders ranges from $16,8 \pm 0,8$ ka to $8,8 \pm 0,4$ ka, with high standard deviation for one moraine. From those results it is very hard to determine reliable moment of glacier stabilization and age of the forms. Unfortunately it makes those glaciers very hard to use as a paleoclimatic information source, because we can not place these climatic conditions in specific range of time.

Results of the investigation based also on the results from previous research shows that rate of denudation of glacial forms made of mix fraction in both valleys is high.

The project is funded by the National Science Center in Poland: decision no. 2016/23/N/ST10/03044.

P-1863

Glacial stratigraphy and till micromorphology at Pine Point, southern Northwest Territories, Canada

Jamie Saper¹, John Menzies¹, Roger Paulen²

¹Brock University, St. Catharines, Canada. ²Geological Survey of Canada, Ottawa, Canada

Abstract

The Pine Point Mississippi Valley-type (MVT) Pb-Zn mining district extends 50 km along an east-west trend south of Great Slave Lake, Northwest Territories, in northern Canada. The district contains 50 open pits that expose glacial sediments, in some cases more than 20 m thick, providing a unique opportunity for glacial stratigraphic analyses. A detailed stratigraphic study is being undertaken on a thick (>20 m) basal till sequence at open pit M-52 in the north-central part of the district. The goal of the research is to augment the existing knowledge of the regional Quaternary stratigraphy and to investigate the mechanics of till deposition/emplacement throughout the continuous till sequence to better understand the glacial dynamics for the western margin of the Laurentide Ice Sheet. Additionally, the glacial stratigraphy at pit M-52 will be correlated with the previous research conducted within the mining district, regionally with Quaternary sections exposed along the Mackenzie River to the west, and extensionally with seismic shothole and diamond drill hole stratigraphic databases. Till samples were collected for macro- and micro-sedimentological studies.

Macrosedimentology studies incorporate glacial stratigraphy, sedimentology, clast fabrics, geomorphology, and laboratory analyses for matrix geochemistry and indicator minerals. The walls of pit M-52 expose two visibly distinct tills, a grey till exposed at the base of the section and an upper brown till. When a complete vertical section was cleared and examined, the contact between the two tills was indiscernible and suspected to be gradational over several metres. The upper brown till could reflect surface oxidation of the lower grey till. However, based on previous research conducted in the region, it is unlikely that there is only a single till exposed in the pit walls. The suspected gradational contact is likely a product of extensive glacial inheritance and mixing as glacial dynamics shifted during till accretion. Clast fabrics were measured in the section and revealed that the grey till close to the bedrock surface reflects SW ice flow, the middle of the section in the gradational zone reflects NW flow, and the brown till near the top displays evidence of NW ice flow.

Detailed glacial microsedimentological data analyses for 38 samples, collected from the two till units, will be used to determine the stress conditions and rheological environments during till emplacement/ deposition. The use of micromorphology in this study is as a primary tool for the analysis of these subglacial sediments, providing far greater detail on the depositional and deformation histories recorded by these sediments than previously obtained from macroscale studies.

P-1864

Differentiating iceberg scoured sediments from subglacial tills and mass-wasting deposits at the microscale

Lorna D. Linch

University of Brighton, Brighton, United Kingdom

Abstract

Visual comparison of 'sets' (or 'suites') of microstructures permit differentiation or co-association of sediments from the same or different sedimentary environments. This non-statistical, subjective method is successful when clear and marked differences between microstructure 'sets/suites' are clearly discernible - especially when coupled with other data such as the geomorphic context, clast provenance or the presence of features diagnostic of specific environments. This research compares sets of microstructures identified in iceberg scoured sediments (clay, pebbly sandy mud, sand and diamicton), subglacial tills and mass-wasting deposits. The set of microstructures associated with iceberg scour are distinctly different from the sets of microstructures found in subglacial tills and mass-wasting deposits. In iceberg scoured sediments rotation/ductile deformation is dominated by folds and realigned bedding; planar/brittle deformation is dominated by faults and discrete shears; sediment mixing is dominated by intraclasts type III and multiple domains; porewater is dominated by water escape and flow; and plasmic fabric is dominated by unistrial plasmic fabric. In general, iceberg scour sediment deformation is dominated by planar/brittle deformation, sediment mixing and porewater processes - regardless of grain size (clay, pebbly sandy mud, sand and diamicton). This contrasts with subglacial tills and mass-wasting deposits that are instead dominated by (a wider variety of) rotational/ductile and planar/brittle structures, including a range of plasmic fabrics. Finally, dropstones are notably abundant in iceberg scoured sediments, but remain rare in subglacial tills and mass-wasting deposits. Using sets of microstructures to differentiate or co-associate sediments in this way is crucial for palaeoenvironmental reconstruction. In particular, the set of microstructures that have been identified in iceberg scoured diamicton may even lead to the re-interpretation of sediments that previously have been assigned a subglacial origin, providing new insights into ice-sheet and glacier reconstructions.

P-1865

Microfabric of soils of the Russian Plain formed in basal tills of Saalian glaciation.

Pavel Kust^{1,2}, Alexander Makeev¹, Marina Lebedeva², Konstantin Romanenko², Konstantin Abrosimov²

¹Lomonosov Moscow State University, Moscow, Russian Federation. ²V.V. Dokuchaev Soil Science Institute, Moscow, Russian Federation

Abstract

Base tills of Moscow (Late Saalian / Warthe / MIS 6) glaciation form an important component of landscapes in northern Europe, including the center of the Russian Plain. They are often covered only with a thin veneer of sands, sandy and silty loams - the cover layer, so that basal till and cover layer forms bipartite sediment.

Such bipartite sediments are among the oldest soil parent materials subjected to pedogenesis starting from the time of their deposition (MIS 6) till now. This was confirmed by our numerous OSL datings of the cover layer and spatial field studies. Thus, an assemblage of bipartite sediments features was formed within several climatic cycles. We have subdivided them to a) pre-depositional, b) syn-depositional and c) post-depositional (cryogenic and pedogenic).

Morphologically, the impact of a pedogenesis during the last interglacial (MIS5e) has resulted in the formation of pedogenic structural architecture (cracks, subangular blocky peds) with a superimposed well-developed set of cutans. These lead to the formation of a sequence of Bt horizons. Holocene pedogenesis being mostly of eluvial-illuvial character, probably strengthens initial lithological discontinuity of bipartite parent material: soil horizonation is clearly seen within the cover layer unit (a sequence of A and E or Bw horizons), while the boundary between the basal till, and the cover layer, especially in the frost fissures remains abrupt.

Transformation degree of pre-depositional and syn-depositional features under the influence of pedogenesis have been studied in various regions of the Russian Plain (Moscow, Yaroslav, Tver and Archangelsk) using a set of morphological (X-ray high resolution microtomography on Skyscan 1172 (Bruker, Belgium) for visualization and morphometric analysis of the internal microstructure in non-disturbed natural samples of peds; micromorphology on polarizing microscope and photo scanner; submicromorphology on SEM) and analytical methods.

Many depositional features show high stability under pedogenetic impact. They look similar for the lower soil horizons (BC and C) formed in the basal till at a depth approx. 2m and for those subjected to intensive pedogenesis (Bt1 and Bt2 horizons at a depth approx. 60 cm). These key features include: high weathering through the whole strata; bright reddish-brown color (up to 5YR 6/6 by Munsell soil color chart) inherited from sediments mobilized by the glacier; overconsolidated matrix supported fabric with low porosity as a result of big pressure under the glacier; till architecture including sand lenses, shearing features, folding, thrusting and rotational structures, tension fractures and other evidences of emplacement of matrix within the mobile sediment.

The research was supported by the Russian Foundation for Basic Research, Project №17-04-01221

The role of pressurised water in large-scale glaciotectonic thrusting: Evidence from thrust-block moraines in Melasveit, W-Iceland

Thorbjörg Sigfúsdóttir^{1,2}, Emrys Phillips^{3,4}, Ívar Örn Benediktsson²

¹Lund University, Lund, Sweden. ²University of Iceland, Reykjavík, Iceland. ³British Geological Survey, Edinburgh, United Kingdom. ⁴Queen Mary University of London, London, United Kingdom

Abstract

Pressurised meltwater has major effect on deformation and sedimentary processes in proglacial and ice-marginal settings. In particular it is thought to enhance the ability of glacier to detach and transport large blocks of sediment /bedrock by minimising friction occurring along structural surfaces. However, a detailed understanding of the processes occurring during the detachment, transport and emplacement of such blocks has yet to be established. Furthermore it has been argued that unconsolidated sediments must be frozen in order to keep such sediment blocks intact during transportation.

A detailed microscale study was carried out on the structures developed within décollements in two submarine moraines of Late-Weichselian age in Melasveit, western Iceland. The aim of this study is to investigate how detachments form in glaciotectonised sequences and how large blocks/rafts of unconsolidated and unfrozen sediment can be dislocated and transported by glaciers. The moraines are primarily composed of thrust-stacked blocks of glaciomarine sediments and are part of a series of ice-marginal features formed during the active retreat of a marine-terminating glacier. Due to isostatic rebound since the deglaciation, these moraines are now revealed above sea-level and their internal architecture is well-exposed in extensive coastal cliffs. A detailed glaciotectonic model is proposed which argues that the introduction of pressurised water into weak beds (silt/sand) played a key role in the detachment and movement of the thrust-blocks. This resulted in fluidisation of these weaker sediments resulting in decoupling between the allochthonous thrust-blocks and the underlying sediments/bedrock. The deformation associated with the transport of the thrust blocks was focused within relatively thin, water-lubricated zones allowing the blocks to move without undergoing extensive internal disruption. Temporal and spatial changes in the style of deformation have been recognised during the transport and subsequent accretion of the thrust-blocks reflecting fluctuating water pressures within the detachments. Repeated events of hydrofracturing and water-escape caused the thrust-stack to drain, resulting in the progressive locking up of the detachments and eventual accretion of the thrust blocks. The model may be applicable to other similar thrust-block complexes as well as for processes occurring during glaciotectonic sediment rafting.

P-1867

Using micromorphology to access the impacts of periglacial and mass flow processes on tills exposed at retreating glacier margins

Ewelina Lipka¹, Emrys Phillips², Katarzyna Skolasińska³, Grzegorz Rachlewicz¹, Witold Szczuciński³

¹Institute of Geocology and Geoinformation, Adam Mickiewicz University in Poznań, Poznań, Poland. ²British Geological Survey, Edinburgh, United Kingdom. ³Institute of Geology, Adam Mickiewicz University in Poznań, Poznań, Poland

Abstract

Micromorphology is increasingly being used to investigate the textural properties and microstructures developed in Pleistocene and older glacial deposits in order to provide a greater understanding of the processes involved during their formation. However, in contrast, comparable studies of contemporary glacial deposits are relatively limited. Consequently, the impacts of periglacial and mass flow processes on tills exposed at the margins of retreating glaciers are poorly understood. This lack is being addressed by an ongoing detailed micromorphological study of recently exposed tills in the marginal zone of the Hansbreen glacier in southwestern Spitsbergen. In thin section these contemporary glacial sediments comprise a coarse-grained, weakly compacted, open-packed, clast-rich diamicton with a silt-rich matrix. The lack of clay minerals within the matrix is reflected in the lack of a well-developed plasmic fabric; apart from a locally developed skelsepic fabric enclosing some of the larger clasts (skeleton). Turbate structures are common and defined by arcuate to circular arrangements of coarse silt- to fine sand-grade clasts locally enclosing coarser sand to pebble sized clasts. "Necked" structures are also present formed by the squeezing of the relatively softer matrix in between the larger, more rigid clastic grains. Penecontemporaneous diagenesis of the till matrix has resulted in the localised formation of a carbonate and Fe-oxide cements. Detailed analysis of the clast microfabrics developed in the till has revealed that the earliest fabric (S1) is a subhorizontal foliation this is cross-cut by two later fabrics (S2, S3) which form a conjugate pattern. The spacing of the fabric domains of these S2 and S3 fabrics is governed by the presence of large granule to pebble sized clasts leading to partitioning of deformation within the matrix of the diamicton. These fabric are also observed to wrap around the larger clasts indicating that they acted as rigid, possibly relatively immobile bodies with the deforming matrix. One sample (8A) represents mass flow sediment that was sampled over a dozen years after deposition, in contrary to other deposits sampled here. The clast microfabric analysis has revealed more prominent vertical fabric in this sample, particularly regarding larger clasts. Observed differences in the texture and style of deformation recorded by this sample are due to the combination of mass flow and subsequent frost heave. Nevertheless, the style of deformation identified within the Hansbreen tills is comparable to that observed with Pleistocene subglacial deposits. Consequently initial results suggest that structures formed in response to subglacial shearing may be preserved within exposed tills unless they undergo significant remobilisation and mass flow.

Middle Holocene palaeoenvironments and paleoclimates in the Middle Atlas: the multidisciplinary study of a Moroccan tufa (Aït Said ou Idder)

Julie Dabkowski¹, Quentin Wackenheim¹, Larbi Boudad², Nicole Limondin-Lozouet¹, Denis Fiorillo³, Jean-François Berger⁴

¹CNRS-Laboratoire de Géographie Physique, Meudon, France. ²Université Moulay Imail, Département de Géologie, Meknès, Morocco. ³MNHN-Archéozoologie et Archéobotanique, Paris, France. ⁴Université de Lyon 2, Environnement, Ville et Société-IRG, Lyon, France

Abstract

Calcareous tufas are continental open-air carbonates that routinely host evidence of past environmental conditions via well-preserved faunal and floral assemblages. Additionally, as they mostly comprise of calcite precipitated at ambient temperature, tufas are also suitable targets for palaeoclimatic reconstructions, especially from oxygen and carbon isotopes, which allow combining palaeoenvironmental to truly synergic but independent climatic reconstructions.

Tufas are common in areas with carbonaceous bedrock such as the Moroccan Middle Atlas. However, under these latitudes, they are usually indurated. These “travertineous” facies are not suitable for palaeoenvironmental researches as molluscan shells, the usually best-preserved bioproxy in tufas, cannot be extracted by sieving. At Ait Said ou Idder, a deposit dominated by crumbly friable facies rich in terrestrial molluscs was recently discovered. A ca. 8m-high profile was investigated in September 2017 and sampled continuously for malacology and, parallel, for geochemistry allowing the first multiproxy study of Middle Atlas tufa deposit.

Stratigraphy and micromorphology identify two deposition phases. The earliest deposits comprise oncolithic facies, indurate phytoherms and stratified sandy tufa, characterising fluvio-palustrine tufas. After a marked erosive episode, the second phase comprises detrital tufa (encrusted phytoclasts, oncoliths, etc.), locally including decimetric bushes of vegetation encrusted *in situ* and alternating with greyish layers. This pattern of facies is typical of tufa depositing on a low slope. The bottom of this second phase is especially rich in charcoals, ashes and burned elements (including a flint), suggesting a fire event. This darkish layer was dated around 6500 cal. BP (3 radiocarbon dates on charcoals). The following grey levels provide ages between ca. 6200 and 4900 cal. BP (on shells), which assigns the sequence to the Middle Holocene.

Isotopic data range between -9.74 and -7.56 ±0.08 for $\delta^{13}\text{C}$ and between -7.8 and -7.3 ±0.1 for $\delta^{18}\text{O}$ which correspond to Mediterranean temperate to semi-arid conditions. Only little variations are observed in the $\delta^{18}\text{O}$, indicating constant to slightly increasing temperatures from ca. 6.0 ka cal. BP. The $\delta^{13}\text{C}$ shows strong changes in the uppermost unit of the fluvio-palustrine phase where relatively drier conditions are recorded. The most humid period is then observed between ca. 6.5 and 6ka cal. BP. From ca. 6ka cal. BP, the $\delta^{13}\text{C}$ slightly decreases, parallel to the $\delta^{18}\text{O}$, which may indicate conditions becoming more semi-arid.

Comparison with mollusc data will allow further developing these interpretations of geochemical data and discussing, for the relationship between climate and environment at a time (the Middle Holocene) which is usually not recorded in other regional continental records (mostly lacustrine and fluvial deposits). As part of the PaléoMex-INEE “Transect Maghreb” program involving various investigations in Morocco and Tunisia, this work will finally contribute to understanding the adaption of societies to climatic changes.

Abstract

Although loess deposits are widely recognised as providing some of the best terrestrial records of past climates, quantitative palaeoclimatic data are rare. Here we propose to reconstruct past temperature and precipitation in European loess sequences using an innovative new approach developed in the Nussloch sequence. Indeed, this reference sequence provides one of the most complete palaeoclimate records for the last glacial in western Europe. Its upper part of the section spans 35-22 ka and is characterised by alternating primary loess and tundra gley horizons whereas its middle part spans 50-35 ka and is characterized by arctic and boreal brown soils.

High concentrations of fossil calcite (sparite) granules produced by earthworms (ECG) occur in most of the stratigraphic units at Nussloch but especially within tundra gley layers and boreal to arctic brown soil horizons allocated to short interstadial periods (millennial). Present-day observations demonstrate that earthworms release their granules at the soil surface, indicating that fossil ECGs are coeval with the soil development. In case of upbuilding soils developed in (paleo)environments where aeolian processes (loess sedimentation) is still active, ECGs are preserved within the upper part (5-15 cm) of these soil horizons. It is especially well illustrated in the loess-palaeosol sequence of Nussloch (Germany) where they are particularly abundant in interstadial brown soils and tundra gley horizons, the latter reflecting short-term pulses of permafrost aggradation then degradation during rapid warming events (interstadials). Stable isotope analyses performed on ECGs provide quantitative estimates of past summer temperature and annual soil moisture, which can be calibrated to generate mean annual precipitation values. The synthesis of ECG concentration variations and palaeoclimate data provides a new proxy for Last Glacial terrestrial environments, which will facilitate more meaningful correlations with ice core and marine datasets on millennial timescales.

³ELTE Eötvös Loránd University, Budapest, Hungary

Abstract

Earthworm biospheroids (EBS) are frequent constituents of loess-paleosol sequences, where they show wide temporal and spatial abundance. EBS are composed of biogenic CaCO₃ excreted by the calciferous glands of earthworms. These features are considered to be in isotopic equilibrium with soil CO₂ being dissolved in (soil) solutions; whereas their oxygen isotope composition is related to the meteoric waters and thus to the alterations of temperature.

EBS were collected from loess-paleosol sequences of different thickness along a North – South transect in the Carpathian Basin: as from Verőce (~18 m), Süttő (~17 m), Paks (~10 m), Hévízgyörk (~8 m) and Villánykövesd (~8 m). Bulk samples were taken in 10 cm vertical resolution in a weight of 100 g. After the wet sieving process of bulk samples on a 500 µm sieve, 1-10 pieces of EBS were collected. 450 µg material/EBS was proceeded for measurements with IRMS in order to reveal stable carbon and oxygen isotope compositions.

The mentioned five sequences were divided into different sedimentary units containing EBS, and thus provided high amount of stable isotope data (471 pair of data). Data were processed by applying a novel method called combined cluster and discriminant analysis (CCDA), which defines a statistically optimal group number and determines the largest homogeneous groups. The method can be applied for cases, when data from more than one source are available for the same parameter range, in a way that more observations are available from each source.

The parameter range contained two different parameters, as the stable carbon ($\delta^{13}\text{C}$) and oxygen ($\delta^{18}\text{O}$) isotope compositions. The sources of the observations were the following sedimentary units during the CCDA: 1) typical and/or sandy loess; 2) “other” loess (e.g. stratified, redeposited, strongly reworked); 3) paleosols with their upper and lower transition horizons and the CaCO₃ accumulation zone; 4) CaCO₃ accumulation zone.

The main aim of the study was to group the data from the different sedimentary units optimally, thus to determine homogeneous groups – and when it was not possible, to detect the reasons of inhomogeneity. Homogeneous groups were composed of EBS from various sedimentary units, but indicated similar formation circumstances. Difference was made on regional basis, where the mentioned units of Paks, Süttő and Hévízgyörk profiles belonged to the same group, but those from Verőce and Villánykövesd were completely separated. The Verőce section has a special position in a mountain foreland area, developed on an alluvial fan system, whereas the Villánykövesd sequence represents sub-mediterranean effects. Inhomogeneity was connected to the “other” loess group from the Verőce section and the paleosol group from the Paks profile, which seems to represent the complex interaction of different formation factors.

Study was supported by the NRDIO postdoctoral research project PD128908 and the NRDIO K119366 research project.

Uranium/Thorium dating of catastrophic rock slope failures

Marc Ostermann¹, Diethard Sanders², Jürgen Reitner¹

¹Geological Survey of Austria, Vienna, Austria. ²University of Innsbruck, Innsbruck, Austria

Abstract

Deposits of catastrophic rockslides and rock avalanches composed of lithologies rich in carbonate minerals may undergo precipitation of calcite cements, crusts and small stalactites that can be used to proxy-date the slope failure event and/or subsequent geomorphic changes of the mass movement accumulations. Lithification of rock slope failure deposits to breccias may be localized to meteoric 'runoff-shadows' below larger boulders, or may comprise a layer of breccia or may affect a rockslide/ rock avalanche mass down its base. In addition, precipitation of cements and small stalactites may take place in megapores on boulder undersides. Initial cement formation probably is driven by meteoric dissolution–re-precipitation of (mini-) micritic abrasive rock powder generated by dynamic disintegration during the failure event. ²³⁴U/²³⁰Th ages of the cements support a concept that cementation starts immediately or early after a rock slope failure event.

We describe minimum age dating of a row of catastrophic rock slope failures by the U–Th isochron method, applied to meteoric calcite and aragonite cements that precipitated shortly after the failure event. For several rockslides and rock avalanches a comparison of these U–Th ages with radiocarbon ages and surface exposure ages indicates that the cementation age represents a precise and accurate proxy of the catastrophic event age. We present a concept of cement precipitation in small-scale meteoric diagenetic systems that integrates the local setting of accumulated boulders and their size and exposition.

Additionally, a very recent study showed that comminution age-dating of a large scale rockslide within prasinite lithology gained reliable results.

Abstract

In the Iberian Peninsula, vegetation reconstructions focused on pollen analysis applied to terrestrial carbonate deposits have scarcely been reported although some of them provided very successful results spanning palaeobotanically poorly-known time intervals. Concerning the current interglacial, palynological studies in Mid Holocene fluvial travertine successions from the Iberian Range (NE Iberia) have also been reported, completing the fragmentary vegetation picture of Iberian continental environments.

The main goal of this research is to characterize the Holocene vegetation landscape in a NW-SE transect from the Iberian Range applying palynological analyses to several tufa build-ups located in the Queiles, Val and Las Parras del Martín river valleys. Pollen data reveal a conifer-dominated landscape during the Early Holocene (ca. 9500-8000 cal BP) in where montane pinewoods (*Pinus nigra/sylvestris* type) and junipers were the main landscape components, well adapted to continental climate features. The riparian woodland widespread during the Mid Holocene (8000-4000 cal BP) being *Corylus*, *Salix*, *Populus*, *Acer*, *Quercus faginea/pyrenaica* type, *Ulmus*, *Juglans* and *Castanea* the most abundant broadleaved elements in the pollen profiles. At regional scale, both *Quercus faginea/pyrenaica* type and *Q. ilex/coccifera* type expanded, accompanied by many warm-loving shrubs like *Olea* and *Pistacia*. This palaeobotanical assemblage highlights the establishment of warm and humid climate features in continental Iberia across the Mid Holocene in correspondence with regional paleohydrological sequences. The onset of the Late Holocene (ca. 4500 cal BP) was defined by the noticeable increase in grazing indicators (Sordariales, Poaceae) nitrophilous taxa (*Compositae*, *Plantago*) and open-degraded areas (*Genista*), pointing to the onset of agrarian economic activities, culturally corresponding to the Bronze Age.

Towards a mechanistic understanding of carbonates on Chinese Loess Plateau by using stable isotopes

Shunchuan Ji¹, Daniel Breecker²

¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²University of Texas at Austin, AUSTIN, USA

Abstract

The stable isotope compositions of calcium carbonates are the most important archives of paleoclimate change because it thought to have form in isotopic equilibrium with soil CO₂ and soil water. But isotope composition of soil CO₂ and soil water reflect the environmental conditions and usually characteristic of seasonally changes. It is not well known what portion of the signal is recorded by the isotopic composition of pedogenic carbonate when it forms.

On the Chinese Loess Plateau (CLP), located in arid-semiarid area, calcium carbonates are widely used in paleoclimate research, but limited works focus on the formation mechanism. Here we present our monitoring work on the CLP modern soils to constrain the seasonal changes of the stable isotope composition of soil water and soil CO₂, the concentration of soil CO₂, and soil temperature at different depth. Those continue monthly dates are important for understanding the formation mechanism of carbonate on the CLP.

The Eemian tufa of Caours (France): a multidisciplinary approach of a remarkable MIS-5e sequence and associated Palaeolithic site

Pierre ANTOINE¹, Nicole LIMONDIN LOZOUET¹, Bassam GHALEB², Jean-Luc LOCHT³, Patrick AUGUSTE⁴

¹Laboratoire de Géographie physique, Environnements quaternaires et actuels. UMR 8591 CNRS-Univ. Paris I-UPEC, Meudon, France. ²Geotop-UQAM CP 8888, succ. Centre-Ville Montréal, MONTREAL, Canada. ³INRAP Antenne Hauts de France, AMIENS, France. ⁴Unité EVO ECO PALEO - Evolution, Ecologie et Paléontologie - UMR CNRS 8198, VILLENEUVE d'ASCQ, France

Abstract

New investigation leads on the Quaternary interglacial deposits of the River Somme terraces have allowed the discovery of an exceptional Eemian tufa sequence at Caours comprising several *in situ* Palaeolithic levels (Antoine et al., 2006). The Caours tufa formation (»3.5 m thick), located on the lowest fluvial terrace of the Scardon River (tributary of the Somme), is composed by irregular layers of incrustated vegetal remains and concretions (stromatoliths) passing through typical fluvial tufa faces with oncolithic sands and large scale cross beddings towards the present day valley. The lower part of this sequence (»0.5 m) includes organic tufa horizons (micro marshy soils) that have provided thousands of large mammal remains (generally modified by human activities) and Palaeolithic flint artefacts. The tufa sequence and the upper 10 cm of the underlying fluvial silts and marshy soil contain an abundant malacological fauna that evidence the initial phases of the Eemian interglacial followed by the climatic optimum. This conclusion is supported both by isotopic geochemical data ($\delta^{18}\text{O}$ of CaCO_3) as well as geochronological data. Indeed, U-series (TIMS) dates from stromatolith calcite crystals and TL dates from heated flints confirm the allocation of the archaeological layers to the Eemian optimum (MIS 5e: 123 ± 3 ka /11 dates). Palaeoenvironmental, dating and archaeological approaches at Caours allow a very detailed reconstruction of the evolution of palaeoenvironments from the end of the Saalian to the last interglacial climatic optimum. Caours appears now as one of the most complete and well preserved Palaeolithic site in Europe for the Eemian optimum and allows to demonstrate that Neanderthal was fully adapted to forested habitat and a temperate climate. In addition a 300m long transect from the terrace to the present day valley has been produced showing for the first time a continuous record of the last two glacial interglacial cycles in the Somme terraces system. This provides robust data for the discussion focusing on the location of incision processes regarding to Interglacial-Glacial climatic cycles.

Carbonates as indicator of buried paleosoils in aeolian deposits of Lithuania

Eugenija Rudnickaitė

Department of Geology and Mineralogy, Vilnius University, Vilnius, Lithuania

Abstract

New preliminary data was obtained carrying out project entitled „Ichnological and sedimentological evidence of late glacial and Holocene environmental changes in the eastern part of the European Sand Belt”. It is known that aeolian deposits cover about 2.6 % of the territory of Lithuania. The continental dunes prevail over the coastal ones. The coastal dunes are widespread in the Curonian Spit while the area of continental ones is largest in the east southern Lithuania. Examining the internal structure of continental and coastal dunes we could judge about a renewal of aeolian processes. The paleosoils buried in sand reflect periods of dunes stabilization while overlying sand beds indicate a renewal of aeolian processes. All these processes are reflected in the complex internal structure of dunes. The carbonate content (calcite and dolomite minerals) was determined for aeolian sediments. The results obtained show that carbonate content in buried paleosoils is higher than in aeolian ones. The carbonate content could be used as a criterion for very thin or poorly preserved buried paleosoils. Moreover the criterion could be used not only for outcrops samples but also for the ones taken from drill-cores. Once paleosoils will be identified, the traces of fossil and bioturbations textures will be studied. The studies will be followed by sedimentological and stratigraphical analysis which will be based on optically stimulated luminescence (OSL), radioactive carbon dating technique, geophysical and statistical methods. As a result it will enable us to establish spatial dynamics of aeolian sediments and integrate it with the results of ichnological analysis.

This research was funded by a grant (No. S-LL-18-2) from the Research Council of Lithuania.

Quaternary calcium transfer in semi-arid African landscapes: pedogenic nodules and the geochemical cascade.

Fabienne Dietrich¹, Nathalie Diaz², Pierre Deschamps³, David Sebag^{4,1}, Eric P. Verrecchia¹

¹University of Lausanne, Lausanne, Switzerland. ²University of London, London, United Kingdom. ³CEREGE-IRD, Aix-en-Provence, France. ⁴University of Rouen, Rouen, France

Abstract

Calcium (Ca) is a key element of the Earth's system and closely related to the carbon cycle. However, pedogenic Ca-carbonate constitutes a Ca-trapping pathway on continents that has not received the attention it deserves. Significant accumulations of pedogenic carbonate nodules associated with paleo-Vertisols, inherited from the Late Quaternary, are widespread in the Far North Region of Cameroon, although formed in a carbonate-free watershed. A previous study using Sr isotopes showed that Ca sources of carbonate nodules are local granite and Saharan dust. This suggests that Ca is kept in the soil system after weathering. However, the Ca sedimentary and biogeochemical pathways by which Ca is transferred from sources to the trapping compartment, i.e. the carbonate nodules, remained unclear. This present study used major, trace, and rare earth element distributions of carbonate nodules, as well as of the various other Ca compartments of the landscape, in order to document these pathways. Three main processes transferred Ca from its source, in granite and dust, to a trapping compartment, i.e. pedogenic carbonate nodules (Fig. 1). The first process involved the weathering of a granitic bedrock. The residual products were then mixed with Saharan dust to form the host sediment of the nodules. The second process is related to clay minerals, products of weathering, which accumulated Ca and other alkaline cations during Vertisol development. Weathering products, i.e. clays and oxides, as well as vegetation and soil organic matter, have to be considered as transient compartments of Ca. At the end of the African Humid Period, drier climate conditions prevailed, enhancing the precipitation and preservation of pedogenic carbonate nodules. Ca was then incorporated and sequestered into the nodules, until the present-day. Consequently, during the last twenty thousand years, an important part of the Ca was transferred from upstream granite to downstream nodules of pedogenic carbonate developed in Vertisols. Mass balance calculations in soil profiles demonstrated that the Ca accumulation in carbonate nodules exceeded the Ca released by the chemical weathering of the parent material, highlighting the role of Vertisols as Ca-trappers. Therefore, an important part of Ca is still sequestered in the soil system and has not been yet transferred into rivers. Consequently, at the landscape scale, the paleo-Vertisols have acted as Ca-trapping systems (pedogenic carbonate nodules), emphasizing the significant role of Vertisols in terrestrial Ca balances, as they cover large areas on continents. Moreover, such a spatial relationship between sources and transient trapping compartments leads to a new concept of "geochemical cascade" similar, in terms of geochemistry, to the concept of "sediment cascade" developed by continental sedimentologists.

Fig. 1: Ca location through time : Ca is transferred from granite and dust sources to carbonate nodules, highlighting the role of Vertisols as Ca- and C-trappers.

P-1877

Absolute or relative: Paleovegetational reconstructions using carbon isotopic composition of soil carbonates, soil organic matter, nodule organic matter and biomarkers

Vijayananda Sarangi¹, Prasanta Sanyal¹, Shailesh Agrawal²

¹Indian Institute of Science Education and Research Kolkata, Kolkata, India. ²Birbal Sahni Institute of Palaeobotany, Lucknow, India

Abstract

Present study aims to comprehend the factors responsible for the disparity in the abundance of C₃/C₄ plants estimated from the carbon isotopic composition of soil carbonates ($\delta^{13}\text{C}_{\text{SC}}$), soil organic matter ($\delta^{13}\text{C}_{\text{SOM}}$), organic matter occluded in soil carbonate nodule ($\delta^{13}\text{C}_{\text{NOM}}$) and biomarkers in paleosol organic matter (saturated fatty acids; $\delta^{13}\text{C}_{\text{FAME}}$). In this context, available $\delta^{13}\text{C}_{\text{SC}}$, $\delta^{13}\text{C}_{\text{SOM}}$, $\delta^{13}\text{C}_{\text{FAME}}$ and newly measured $\delta^{13}\text{C}_{\text{NOM}}$ values from four sediment cores namely Kalpi, Indian Institute of Technology Kanpur (IITK), Firozpur and Bhognipur from the Ganga plain, India have been used. The abundance of C₄ plants calculated from the $\delta^{13}\text{C}_{\text{SC}}$ and $\delta^{13}\text{C}_{\text{FAME}}$ values is consistently higher compared to the estimation from $\delta^{13}\text{C}_{\text{SOM}}$ and $\delta^{13}\text{C}_{\text{NOM}}$ values. For instance in the Kalpi core, the $\delta^{13}\text{C}_{\text{SC}}$ values indicated *ca.* 2 to 75% and *ca.* .27 to 84% higher C₄ plants than the estimation from $\delta^{13}\text{C}_{\text{SOM}}$ and $\delta^{13}\text{C}_{\text{NOM}}$ values. Similarly, the abundance of C₄ plants calculated from the $\delta^{13}\text{C}_{\text{FAME}}$ values were *ca.* 15 to 59% higher compared to the $\delta^{13}\text{C}_{\text{SOM}}$ and *ca.* 40 to 77% higher than that estimated from the $\delta^{13}\text{C}_{\text{NOM}}$ values. The difference in the estimation reflects the process through which the proxies form. The organic matter is incorporated into soil throughout the year and reflects average annual biomass, whereas SC precipitates during drier season that favours the growth of C₄ plants (enriched in ¹³C). In addition, preferential degradation of ¹³C enriched labile compounds and C₄ derived organic matter lowers the $\delta^{13}\text{C}_{\text{SOM}}$ and $\delta^{13}\text{C}_{\text{NOM}}$ values resulting in the higher estimation of C₃ plants. The higher abundance of C₄ plants estimated from the $\delta^{13}\text{C}_{\text{FAME}}$ values is probably due to the isotopic fractionation (¹³C enrichment of ~2 - 10‰) during the incorporation of plant derived long chain fatty acids into the soil. Various factors such as grain size, vegetation density, sub-aerial exposure and pedogenesis that are inherent to the depositional environment also plays a vital role in controlling the carbon isotopic composition of paleosol components. Considering the uncertainties associated with the paleosol based proxies, it would be misleading and erroneous to report the absolute abundance of C₃/C₄ plants during past vegetational reconstructions. Therefore, the present study recommends presenting the relative change in the abundance of C₃/C₄ plants while reconstructing paleovegetational composition. In addition, the present study underscores the necessity of similar investigations in different climatic zones namely semi-arid, arid, etc. to have a firm knowledge on the factors affecting the isotopic composition of paleosol components and its implications for paleovegetational reconstructions.

Using novel isotopic analysis and U-series dating of terrestrial carbonates to investigate human evolution and climate change in southern Africa

Robyn Pickering¹, Vincent Hare¹, Naomi Levin², David Braun³

¹University of Cape Town, Cape Town, South Africa. ²University of Michigan, Ann Arbor, USA. ³George Washington University, Washington, USA

Abstract

Carbonate research is a staple of stable isotope geochemistry; the combination of U-series dated carbonates from southern African archaeological/hominin sites with promising novel isotopes presents a unique opportunity. Furthermore, as most regional palaeoclimate research has focussed on the last glacial-interglacial cycle (the past 100 ka), previous glacial-interglacial cycles (much of the evolutionary record) are largely neglected. The present situation is ripe for a synthesis of carbonate palaeoclimate records over longer timescales (1 Ma) to answer big-picture questions about local changes in hydroclimate and their relation to the global climate system during the Quaternary. While not yet routine, U-Th dating of pedogenic carbonates is showing great promise, with early indications of closed system behaviour on a small (mm) scale. Careful thin section petrography is a necessary precursor to any dating analyses. The U-Pb chronometer opens up the prospect of dating carbonates older than 500 ka, making investigations over longer, 1 Ma, timescales achievable. This technique has reached a level of maturity where it can be applied both routinely and precisely and there is a considerable collection of cave carbonates already U-Pb dated from South Africa. New excavations of arid, inland sites in the Northern Cape, and renewed interest in sites along the west coast of the Western Cape (both in South Africa), are ideal targets for further U-series dating. Here we exploit an underutilised resource - pedogenic calcrete - from South African archaeological sites, and combine high-resolution U-series dating of these materials with novel stable isotope proxies of temperature ($\Delta 47$) and aridity ($\Delta^{17}\text{O}$), as well as conventional stable isotope analyses ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) to construct a synthesis of regional hydroclimate change over the past 1 Ma.

Abstract

Low- and moderate-magnitude earthquakes in Germany and Lithuania (southern Peribalticum) related to the advance of the Scandinavian Ice Sheet (SIS) are interpreted on the basis of sedimentological and regional stratigraphical studies supported by OSL datings. Almost all seismic activity related to glaciation cycles has thus far been attributed to glacio-isostatic rebound during/after deglaciation. However, the possibility of earthquakes related to ice advance was suggested by Brandes et al. (2011), and recently by Pisarska-Jamroży et al. (2018) and Belzyt et al (2018).

Seismites – layers affected by an earthquake while still unconsolidated – are recognized based on several criteria, including a large lateral extent, continuous deformations and vertical repetition. Such seismites have been recognized within a glaciolacustrine succession in a coastal cliff on the eastern Jasmund peninsula (Rügen Island, NE Germany, see Pisarska-Jamroży et al., 2018), and also in fine-grained floodplain deposits of a meandering river at Slinkis, outcropping in the Dubysa river valley (central Lithuania, see Belzyt et al., 2018).

The seismites at both sites are interbedded between undeformed layers and occur in proglacial sediments overlain by diamictons (glacial tills). Their stratigraphic positions in the successions, supported by OSL dating, unambiguously indicate that the liquefaction-prone deposits were deformed, shortly after their deposition, during phases of SIS advance, just in front of the ice masses.

In both sites, seismites were formed during the Last Glacial Maximum, MIS 2. In Dwasieden site – during Brandenburg/Frankfurt phase of Weichselian Glaciation (according to German stratigraphic scheme), whereas at Slinkis site – during the maximal ice advance of Nemunas Glaciation (according to Lithuanian stratigraphic scheme).

The stable, intraplate tectonic setting of both sites is strong evidence that the deformation of the fine-grained sediments was triggered by displacement of the upper crust of the Earth, induced by ice-mass loading in the moat in front of the advancing ice. This process, most possibly, caused re-activation of favourably-orientated pre-Quaternary faults.

Acknowledgements. The study, forming part of the GREBAL project, has been financially supported by the National Science Centre Poland (No. 2015/19/B/ST10/00661).

Glacial geomorphology and sediments in Puruogangri icecap, central Tibet

Chaolu Yi

Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Abstract

Sedimentary properties in mountain/valley glacier have been studied in details. However, glacial geomorphology and sediments in plateau glacier in semi-arid area are understood little. It is generally believed that this type of plateau glacier is cold-based glacier and is not active in producing glacial landform. We investigated glacial landforms and glacial sediments in the Puruogangri icefield in central Tibet, where the temperature of glacier ice is 7 degree celsius below 0. The moraine is short and small with flat top surface, but subglacial abrasion is still strong enough to produce striations and polished surface on clasts as well as ground silt. We suggest that subglacial thermal heating melts basal ice and produce water film between ice and rock so that ice or clasts can slide on ice-rock interface to produce glacial sedimentary properties as those in valley glaciers.

A new glacial landscape map of the LIS in central Nunavut, Canada: an integrated approach to understand paleo-ice sheet dynamics

Isabelle McMartin¹, Janet Campbell¹, Tommy Tremblay², Pierre-Marc Godbout³

¹Geological Survey of Canada, Ottawa, Canada. ²Canada-Nunavut Geoscience Office, Iqaluit, Canada. ³UQÀM, Montréal, Canada

Abstract

In the former glaciated areas of central Nunavut in northern Canada, large volumes of ground-based and remote surface geology datasets were acquired by government surveys in key regions that are actively being explored for mineral deposits or assessed for infrastructure expansion under changing climates. These comprehensive georeferenced surface earth materials and geomorphological datasets need to be integrated over broad regions to allow interpretation of glacial landscapes and modelling of past glacial histories and transport patterns. A new digital compilation of glacial features and interpreted glacial landsystems was produced for an area covering ~400,000 km² in the Keewatin Sector of the Laurentide Ice Sheet (LIS). The new compilation integrates digitally converted published surficial geology maps, recent framework mapping supported by relative and absolute chronologies, and new mapping interpretations using ArcticDEM (5 m resolution) and LANDSAT8 imagery. It permits the identification and grouping of various glacial features into coherent patterns, including ice streams, ice divides, ice retreat positions, flow sets, palimpsest flows, relict and deglacial cold- and warm-based landscapes, and subglacial meltwater corridors. In addition, the compilation reconciles a number of archived field observations and surface sample compositional databases from years of government mapping. Additional field-based observations as well as samples for age dating and composition were collected in targeted areas in 2017 and 2018 to provide constraints on the glacial history, and help evaluate glacial transport in areas of complex ice-flow dynamics and changing basal ice thermal regimes. The final product will consist of a scalable map with accompanying database of glacial features and landforms (individually identified); a field database including ground and remote stations with field observations, ice-flow measurements and/or glacial sediment samples; an interpretation of glacial landscapes (georeferenced overlays); a bibliography of all published sources; and a nomenclature of the map features.

Characterising the deglaciation and postglacial Tyrell Sea incursion from mapping of deglacial landforms on the western Ungava Peninsula, Nunavik, Canada

Paul Dunlop¹, Martin Roy², Hugo Dubé-Loubert^{2,3}, Marc Antoine Levesque²

¹Ulster University, Coleraine, United Kingdom. ²Dép. des Sciences de la Terre et de l'atmosphère & GEOTOP, Université du Québec à Montréal, , Montréal, Canada. ³Ministère de l'Énergie et des Ressources Naturelles, Val d'Or, Canada

Abstract

The Labrador Sector was an active component of the Laurentide Ice sheet during the last glacial cycle, with significant migrations its ice divide system and marked changes in its subglacial thermal regime. On the Ungava Peninsula, these changes are highlighted by a mosaic of different glacial landforms and terrains that together outline a succession of landform assemblages arranged symmetrically around the former position of the Payne ice divide. The core area spreads along a north-south axis that is underlain by a thin glacial sediment cover pierced by numerous frost-shattered bedrock outcrops and extensive felsenmeer typical of cold-based ice conditions. This central zone is flanked to the east and west by an unmolded till plain, which gradually changes into a fluted till plain that includes drumlins and crag-and-tails that together indicate a radial ice flow from this ice dispersal center. This latter zone comprises several eskers and associated glaciofluvial deposits. This system terminates at the coastal areas where widespread wave-washed bedrock and/or extensive glaciomarine shorelines and deltas were deposited in the postglacial sea. Deglaciation of the Ungava Peninsula was also complex with asymmetric rates of ice retreat between the eastern (slow) and western (fast) margins and large uncertainties persist on the regional pattern of ice margin retreat as well as on the timing of the deglaciation. Deglaciation of the eastern Hudson Bay coast was marked by the postglacial marine incursion of the Tyrell Sea that led to the formation of a spectacular deglacial landscape characterized by large fields of DeGeer moraines, ice-contact deltas and eskers. Here we use these deglacial features to characterize the nature of ice retreat, geometry of the ice margin configuration and relative chronology of ice withdrawal in the region. We present the first detailed glacial geomorphology map of the northwestern sector of the Ungava Peninsula based on interpretations of high-resolution satellite imagery (RapidEye: 5m; Pléiades: 0.5 m) and extensive fieldwork carried out on the deglacial landscape of the Puvirnituk area on the east coast of Hudson Bay. Our mapping results provide a new high-resolution database of individual deglacial landforms that comprises an exhaustive inventory of DeGeer moraines, which document the nature and style of the regional ice retreat pattern. We also sampled large marine ice-contact deltas for cosmogenic dating at two sites, which are part of an East-West sampling transect aimed at constraining the timing of the deglaciation of the Peninsula. Overall, this work provides a new geomorphological framework that improve our understanding of the ice sheet margin evolution during the final stages of the deglaciation of Nunavik.

P-1883

Deglaciation of the Kola Peninsula, Arctic Russia, during the Last Glacial-Interglacial Transition

Benjamin Boyes¹, Lorna Linch¹, Danni Pearce²

¹University of Brighton, Brighton, United Kingdom. ²University of Hertfordshire, Hatfield, United Kingdom

Abstract

During the Last Glacial-Interglacial Transition (LGIT; c. 18-10 ka) the Kola Peninsula, Arctic Russia, was glaciated by the Fennoscandian Ice Sheet (FIS). Ice flowed up into the mountains on the peninsula (Khibiny, Lovozero) rather than down-valley as in typical glacial environments. However, low resolution geomorphological mapping, a lack of sedimentary analyses, and limited dating of glacial landforms and deposits mean deglaciation in the Kola Peninsula, including whether there was a periodic ice standstill during the Younger Dryas (c. 12.9-11.7 ka) cold period, is poorly understood.

This project therefore aims to reconstruct the pattern and timing of deglaciation of the Kola Peninsula during the LGIT. The glacial geomorphology of the Kola Peninsula will be mapped using high resolution imagery (ArcticDEM 2m) to determine retreating ice margin positions. To understand subglacial processes occurring during deglaciation, glacial sediments will be described at macro- and micro-scales. Finally, glacial landforms and sediments will be dated (optically stimulated luminescence and radiocarbon dating) to chronologically constrain deglaciation. This research will: (i) allow evaluation of the style, extent and timing, of deglaciation in the Kola Peninsula, determining whether or not there was a periodic standstill in ice sheet retreat during the Younger Dryas, and (ii) provide crucial empirical evidence to validate numerical model simulations of the FIS, which in turn will further our understanding of glacial/deglacial dynamics in other Arctic, Antarctic and alpine regions.

Abstract

Glacial landform mapping has led to advances in the understanding of landform genesis, palaeo-ice sheet behaviour and glacial processes. However, the availability and utility of hard-won mapping datasets is currently severely limited. This is due, in part, to the disparate storage of data; currently in maps, journal articles and hard-drives around the world, rather than being accessible from a single location. Glacial geomorphological mapping data also lacks a standardised format, may be unevenly spatially distributed and present conflicting interpretations. Here, our aim is to engage the glacial geomorphological community in the launch of an open-access, global, database of mapped glacial landforms. We present progress on collating datasets and digitising available maps. Our procedure for data-quality control and format standardising is demonstrated. The intention is to enable access to the library of existing mapping, enhancing the scope, visibility and accessibility of published work. With this in mind, we welcome submissions to the database, the aim of which is to create a global glacial landform map.

¹Complutense University, Madrid, Spain. ²Castilla-La Mancha University, Toledo, Spain. ³Pontificia Universidad Católica, Santiago de Chile, Chile. ⁴National Research Centre on Human Evolution, Burgos, Spain. ⁵Marcel Chevallier Earth Science Foundation, Andorra, Andorra

Abstract

The Iberian Central System (ICS) is a Mediterranean medium mountain range (with summits reaching altitudes 1700 - 2400 m asl), running 650 km WSW-ENE through the centre of the Iberian Peninsula, from near the Atlantic Ocean coast of Portugal to the eastern edge of the Iberian Meseta in Spain. Due to this trajectory and latitude (40°- 41° N), there are significant contrasts between the subtropical-subpolar and continental-Atlantic environments. For this reason, studying the evolutionary sequence of paleo-glaciers in the ICS may contribute valuable data on climate variability, e.g. paleo-NAO and paleo-AMO effects. This paper presents the evolutionary sequence of paleo-glaciers in the Spanish sector of the ICS, corresponding to the Last Glacial Period (in general MIS2, and locally MIS3).

The procedure to establish this evolutionary sequence has six main stages: (1) Geomorphological mapping; (2) identifying morphostratigraphic indicators; (3) defining morphostratigraphic successions, both sectorial and in synthesis; (4) assigning absolute chronologies using cosmogenic nuclide (¹⁰Be-TCN); (5) defining the evolutionary sequences, both sectorial and in synthesis (regional evolutive model; REM); (6) correlating this REM with similar areas.

The morphostratigraphic indicator of reference, which appears in all the paleo-glaciers, is called here Principal Moraine (PM) and corresponds to the group formed by the two lateral moraines with the greatest dimensions, development and continuity. The indicators in external positions in the valley in relation to the PM, called here Peripheral Deposits (PD), are formed by series of disperse erratic boulders (PD-B) and smaller discontinuous moraines (PD-M). Finally, the indicators in internal positions in the valley in relation to the PM, called here Internal Deposits (ID), are formed by a series of secondary crests on the inner side of the PM, latero-frontal and arcuate moraines, and series of erratic boulders. From an evolutionary viewpoint, these three formations correspond to: (1) PD from the maximum advance stages (PD-B; ~25.0 ka correlated to global LGM, MIS2) and limited retreat (ID-M; after ~24.3 ka and before ~20.6 ka); (2) PM from a re-advance stage and another maximum stabilization stage (later than ~20.6 ka and earlier than ~17.8 ka); and (3) ID from deglaciation stages, showing three stadials in the late glacial sequence dated to minimum ages ~17.5 ka, ~ 13.9 ka and ~11.1 ka (correlating with the Oldest, Older and Younger Dryas stadials). The conclusion which can be drawn from this evolutionary sequence is that glaciation in the ICS is more convergent with glaciation in northern European regions than in the Mediterranean region.

Reconstructing ice sheet decay, sea level changes and glacio-isostatic adjustment using landforms from the Dornoch Firth, Scotland.

Callum Firth¹, David Smith²

¹Canterbury Christ Church University, Canterbury, United Kingdom. ²University of Oxford, Oxford, United Kingdom

Abstract

Glacial, fluvio-glacial and marine/coastal landforms and their associated sediments can be used to reconstruct the dynamics of ice sheets as well as sea-level changes and glacio-isostatic adjustments. Such reconstructions have traditionally been based on field mapping combined with land survey and the logging of sedimentary deposits. More recently mapping derived from remote sensing methods (e.g. Lidar) have been used to identify landforms and to reconstruct ice sheet dynamics, however the applicability of such techniques to appropriately identify palaeo-coastal features has not been tested.

The Dornoch Firth, Scotland, contains a wealth of geomorphological features associated with the retreat of the Late Devensian Scottish Ice Sheet. In the outer Firth there are well defined glacial ridges which are truncated by raised marine ridges and terraces which can be used to define the marine limit. In the central Firth there are glacial features with associated outwash surfaces which grade into deltas that can be related to raised marine terraces which are indicative of an ice still-stand or readvance. Whilst the inner Firth contains a succession of outwash fans/deltas with associated glacial and raised marine shoreline fragments that document the continued fall in sea-level. On the higher ground to the south there are a series of deep meltwater channels which can be traced to outwash deltas associated with a former ice-dammed lake.

The sequence of landforms indicate that as the ice sheet retreated 40km westward relative sea level fell from *circa* 30m OD to 12m OD. The retreat was interrupted by a stillstand or readvance during which sea-level fell 10m and this was then followed by a very rapid retreat of the ice front.

The assemblage of landforms can also be used to evaluate the use of mapping methods based on remote sensing techniques to identify raised marine features and in particular shoreline fragments and deltas.

Reconstructing the Last Glacial Maximum in the Southern Alps: the record of the Adige River Glacial Amphitheatre.

Guido Stefano Mariani¹, Mauro Cremaschi¹, Carlo Baroni², Mattia Marini¹, Andrea Zerboni¹

¹Dipartimento di Scienze della Terra "ardito Desio", Università degli Studi di Milano, Milan, Italy. ²Università di Pisa, Pisa, Italy

Abstract

Glacial amphitheatres at the southern fringe of the Alps have been extensively studied in the framework of Quaternary glaciations. Easy accessibility and the presence of well-preserved complex moraine systems allowed retrieving useful middle- to high-resolution geomorphological and stratigraphical records of Pleistocene glaciations. The Adige River Glacier Amphitheatre (ARGA) is one of the smallest end-moraine systems of southern Alps and lies close to the much larger Garda Lake Glacial Amphitheatre. During most of Pleistocene glacial advances, the two adjoining glaciers merged, thus preventing the Adige Glacier to form proper end-moraine systems for most of its duration. This did not happen during the Last Glacial Maximum (LGM), when the extant glacial amphitheatre was built. From field surveys and dating we produced a detailed mapping of the morphostratigraphic units composing the ARGA. This map represents the first step towards the reconstruction of the evolution of the ARGA system and related landforms. We could recognise five morphostratigraphic phases each responsible for the deposition of a moraine arc. Two major moraine arcs (the outermost ones) aggraded during two positive pulses of the glacier. The innermost three moraine arcs are smaller and less preserved; likely, they correspond to subsequent recessional steps of the Adige Glacier. Flat areas, filled by gravel sediments from meltwater outwash streams, separate moraine arcs. Between the glacier terminus and the innermost moraine arcs several flat terraces consisting of sandy to clayey sediments are recognised as kame terraces, deposited by a proglacial lake formed in the last phase of retreat. At the final collapse of the Pleistocene Adige Glacier, the proglacial lake disappeared, and fluvial erosion started sectioning Pleistocene deposits.

In fact, the ARGA, while being a small LGM glacial system, is well preserved and includes evidence for multistep aggradation of moraines during the advances and regressions of the Adige Glacier during and after the LGM. This interpretation substantially confirms previously reported evidence for a two-fold LGM glacial advance along Southern Alps.

P-1888

Genesis of dead-ice moraines in eastern Poland

Karolina Łabęcka, Sławomir Terpiłowski

Faculty of Earth Sciences and Spatial Management, Maria Curie-Skłodowska University, Lublin, Poland

Abstract

The well-known result of Pleistocene/recent ice sheets (and glaciers) are the landforms called dead-ice moraines, hummocky dead-ice moraines or, most often – hummocky moraines (HM). As a rule, typical hummocky moraines are oval or slightly elongated hills scattered on till plains. In the planform they represent chaotic or faintly oriented pattern, both longitudinal or transverse to ice movement direction. Till is the main deposit of hummocky moraines.

Differentiated genesis of till results in two contrary models of HM development. In 'supraglacial' model the flow till is regarded as mass flows redeposited to the depressions on the ice-sheet surface. Contrary, in 'subglacial' model the basal till is squeezed upwards to ice crevasses.

Dead-ice moraines (DM) are abundant landforms on Polish territory, however they are still poorly understood. We studied DMs in eastern Poland, which are located in glaciomarginal zone of Warthian (younger Saalian) age. This research sheds a new light on the issue of DM origin. Dead-ice moraines are the hills with evident orientation; some of them are elongated perpendicularly ('transverse' DM), whereas other parallel ('longitudinal' DM) to the movement of the ice. All moraines are characterized by the same lithology. Relatively thick glaciofluvial sands are overlain with gravelly-sandy-clayey diamictos of massflow origin (flow till). An important feature is the presence of basal till diapirs in the cores of 'longitudinal' DMs. Substantial difference between both mentioned DM types is that the glaciofluvial deposits and flow tills within 'transverse' moraines are cut by normal and reverse faults, whereas the beds of 'longitudinal' moraines are folded concordantly with underlying diapirs of subglacial till.

Regular pattern of DM planform and their lithology prove that disintegration of stagnant ice sheet was controlled both by the depressions between ice-cored ridges (origin of 'transverse' DM) and ice crevasses (origin of 'longitudinal' DM). At first glaciofluvial sands and flow tills were deposited. Then the deposits subsided due to melting ice walls and ice floors or were uplifted by till diapirs intruding to ice crevasses. These two phases of DM development point to climatic change during the deglaciation. We claim that the second (deformational) phase took place during climate amelioration, when the permafrost declined and the thawed substratum was deformed more easily.

Paleo-ice cap modeling with Parallel Ice Sheet Model (PISM); a case study from Mount Dedegöl, SW Turkey

M. Akif Sarıkaya¹, Adem Candaş^{2,1}, Oğuzhan Köse¹, Ömer L. Şen¹, Attila Çiner¹

¹Eurasia Institute of Earth Sciences, Istanbul Technical University, Istanbul, Turkey. ²Mechanical Engineering Department, Istanbul Technical University, Istanbul, Turkey

Abstract

We used the Parallel Ice Sheet Model (PISM), to simulate a relatively small size ($\sim 300 \text{ km}^2$, $17 \times 17 \text{ km}$) paleo-ice cap on Mount Dedegöl in southwestern Turkey. Modelling small paleo-ice bodies in mountainous terrain is challenging due to the need for detailed ice flow computations in relatively narrow and steep valleys, high-resolution climate estimations, knowledge of pre-ice topography, and proxy-based paleoclimate forcing. PISM, a numerical ice-flow model that approximates glacier sliding and deformation to simulate large ice sheets such as Greenland, was recently adapted also to Alpine environments. The model was forced by modified temperature and precipitation conditions. The best fit results indicate that if temperatures during LGM were $8\text{-}11^\circ\text{C}$ lower than the modern-day temperatures, as suggested by the local proxy data, the precipitation should have ranged between the modern levels up to $\sim 44\%$ wetter conditions. Therefore, we conclude that the local LGM climate was not only colder but also wetter than the present, which is coherent with the other proxy results for the region. Our results also showed that PISM is suitable in high-resolution ($\sim 27 \text{ m}$) ice modeling of mountain glaciers and ice caps on temperate and mid-latitude glaciers. We tested the model sensitivity to multiple climatic and non-climatic conditions and explored paleo-glacier dynamics. Using the current topography may lead to some deterioration in the results, due to the moraines blocking the glacier flow, and thus recommend further studies on this aspect. This work was supported by Tübitak #114Y548.

Using glacial geomorphology to constrain the final deglaciation of the central sector of the Cordilleran Ice Sheet, northern British Columbia

Helen E. Dulfer¹, Martin Margold¹, Julien Seguinot^{2,3}, Jakob Heyman⁴, Arjen P. Stroeven⁵, Zbyněk Engel¹

¹Charles University, Prague, Czech Republic. ²ETH Zürich, Zürich, Switzerland. ³Hokkaido University, Sapporo, Japan.

⁴University of Gothenburg, Gothenburg, Sweden. ⁵Stockholm University, Stockholm, Sweden

Abstract

The Cordilleran Ice Sheet (CIS) repeatedly covered western Canada during the Pleistocene and attained a volume and area similar to that of the present-day Greenland Ice Sheet. The ice sheet had a western marine-terminating margin in the Pacific Ocean, and at maximum extent, an eastern margin that locally coalesced with the Laurentide Ice Sheet. Deglaciation of the CIS following the Last Glacial Maximum (LGM) directly affected atmosphere and ocean circulation, eustatic sea level, and human migration from Asia to North America. However, the subglacial mountainous terrain makes it challenging to reconstruct local glacial dynamics, impeding the reconstruction of ice sheet-wide glacial advance and retreat patterns. Therefore, the central sector of the CIS that covered the mountain systems of northern British Columbia and southern Yukon Territory is one of the least understood areas of any ephemeral Pleistocene ice sheet.

This study uses geomorphological mapping and ¹⁰Be exposure dating to determine the pattern of ice retreat in the Tuya Range of the Cassiar Mountains, northern British Columbia. The Cassiar Mountains are located at the centre of the CIS and previous mapping of glacial lineations indicates that an ice dome existed over these mountains during the LGM. Here we present the first detailed geomorphological map of glacial landforms, including moraines, drumlins, eskers, and meltwater channels, within the Tuya Range. These landforms were mapped using high resolution remotely sensed data and their spatial distribution defines the evolving ice sheet configuration during deglaciation. The meltwater landforms record a regionally uniform westward retreat of the eastern CIS margin towards the Coast Mountains, whilst the morphology of a large valley moraine around Tuya Lake indicates a readvance of ice flow from the Cassiar Mountains in the north. ¹⁰Be exposure dating of stable boulders from this moraine gives ages corresponding to a late glacial re-advance, likely during the Younger Dryas. This provides evidence of an icefield regrowth within the Tuya Range during a climate reversal and shows that the rapid climate oscillations of the Bølling-Allerød (14.6 to 12.9 ka) and Younger Dryas (12.9 to 11.7 ka) had an effect on alpine glaciers and icefields within the Canadian Cordillera.

P-1891

The northwest Laurentide Ice Sheet: interaction with the Cordilleran Ice Sheet and montane glaciers across the Mackenzie Mountains

Benjamin James Stoker, Martin Margold, Zbynek Engel
Charles University , Prague, Czech Republic

Abstract

The northwestern sector of the Laurentide Ice Sheet coalesced with the Cordilleran Ice Sheet over the southern Mackenzie Mountains, and with local montane glaciers along the eastern slopes of the Mackenzie Mountains. According to the published numerical modelling, a rapid ice thinning across this area contributed significantly to Meltwater Pulse 1A. However, little empirical data are available for this region and the NW sector of the Laurentide Ice Sheet is perhaps the one least understood. A detailed reconstruction of the NW Laurentide Ice Sheet has not previously been completed, with the last available studies dating back to the 1990s. The lack of empirical evidence constraining the maximum extent of the NW Laurentide Ice Sheet and its interaction with the Cordilleran Ice Sheet and montane glaciers prevents a better understanding of the contribution of this sector to global deglacial sea level change. Reconstruction of former glacier dynamics and extent has implications also for modern infrastructure projects in the region. Ice-rich mass movements, 'retrogressive thaw slumps', occur primarily in previously glaciated landscapes and are commonly associated with ice-cored moraines. This phenomenon has recently been observed in the Mackenzie Valley further south than previously documented, and a better understanding of the former ice sheet dynamics will allow for the identification of areas susceptible to thaw slumping.

We present the results of glacial geomorphological mapping for an area >400,000 km² in the Northwest Territories, Canada. A combination of the high-resolution ArcticDEM topographic data and PlanetLabs satellite imagery are used for the mapping of glacial landforms along the eastern slopes of the Canyon Ranges and the southern portion of the Backbone Ranges. The maximum ice extents across the region are delineated and the interaction and relative chronology of retreat of the Cordilleran and Laurentide ice sheets and the local montane glaciers from their maxima are reconstructed. This mapping will provide a basis for further work on the deglaciation of the NW Laurentide Ice Sheet, which in turn will inform on the sources of the Meltwater Pulse 1A and on the regional landscape susceptibility to the warming climate.

¹University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, Bergen, Norway. ³University of Buffalo, Buffalo, USA

Abstract

Here we present new results constraining the ice-sheet thinning during deglaciation and the formation of a local ice-cap during the Younger Dryas at the mouth of Hardangerfjorden, southwest Norway. We base our interpretations on a combination of geomorphological mapping, using high resolution (LiDAR) terrain models, together with ¹⁰Be-dating of glacial erratics and lake coring. We have ¹⁰Be-dated erratics in transects from the highest summits (1200-1400 m a.s.l.) and down towards the fjord. Our results suggest that the highest mountain peaks in the area melted out as nunataks some 20 000 years ago due to thinning of the ice-sheet following deglaciation from its Last Glacial Maximum extent. During the Allerød warm period, the ice-sheet retreated into the inner parts of Hardangerfjord before a major re-advance occurred during the Younger Dryas cold period. In our study we revise the extent of the Younger Dryas re-advance by mapping of moraine ridges using LiDAR-data and the use of ¹⁰Be-dating. In addition, we present sediment cores obtained from both inside and outside of the moraines. Based on our results we provide a detailed reconstruction the Younger Dryas ice-sheet geometry in the area, including the identification of a local ice-cap situated on the Ulvanosa/Englafjell massif. We demonstrate that some of the previously assumed early Holocene moraines in the area actually are of Younger Dryas age. Consequently, we reconstruct a less steep Younger Dryas ice-surface profile in the Matrefjord and identify ice-free areas between the larger ice-sheet in the fjords and outlet glaciers from the local ice-cap.

P-1893

Kinetostratigraphy of the Płock Basin, central Poland

Małgorzata Roman

University of Łódź, Łódź, Poland

Abstract

Kinetostratigraphy allows a more systematic approach to the analysis of complex, multi-phase deformed glacial sequences, and enables identification of kinetostratigraphic units associated with the deformation stages caused by subsequent ice-sheet advances from different directions. Three kinetostratigraphic units relating to separate generations of glaciotectionic disturbances have been distinguished in the Płock Basin area, the oldest (I), associated with the Elsterian glaciations, older (II), corresponding to the Saalian and younger (III), representing the Weichselian. Each unit varies in scale, spatial extent and style of structures, and in particular the direction of glaciotectionic compression. Unit I concerns a complex of large-scale concealed thrust structures with a significant amplitude (up to 100-150m) and with a southern vergence. Glaciotectionic deformations involve Neogene deposits and they are not expressed as landforms, however, in the sub-Quaternary surface they form vast elevation-depression pairs. The driving mechanism is interpreted to be gravity spreading in front of the thick ice sheets advancing from the N/NE.

Unit II pertains folds and thrusts with a depth range from a dozen to a few dozen meters in which involved are Pleistocene (Saalian and older) sediments. Their formation was associated with glaciotectionic thrusting from NW towards SE during the Late Saalian ice-sheet advance. Unit II structures constitute the king-pin of the highest moraine ridges, and what is significant, the axes of the structures run obliquely to the orientation of moraine ramparts. The structures of unit II are a survived element, relict of thrust end-moraines, transformed during the Weichselian glacial event and incorporated to younger glacial landforms.

Unit III, best recognized, concerns Weichselian sediments deformed to a varying degree. Structural-kinematic analysis showed significant differences in the development of deformations, allowing to separate two subunits: proglacial (IIIp) and subglacial (III_s). The IIIp subunit concerns compression structures (thrust folds, imbricate thrust fault fans) formed at the forehead of the advancing ice-sheet. Glaciomarginal sediments, previously deposited by the causative glacier, have been strongly shortened. The vertical extent of the disturbances does not exceed several meters, while the spatial extent of the structures is strictly limited to the pre-maximum overridden push-moraines and end-moraines of the Weichselian ice sheet maximum. Subunit III_s represents small-scale deformations, indicative for shearing at the foot of a moving glacier. III_s deformations involve sediments in the till-substratum contact zone and reach shallow, up to 1.5 m below the till floor. Their continuum is a subglacial traction till. Glaciotectionic transport vectors as derived from IIIp compression mesostructures and small-scale III_s shears are concordant and confirmed in till fabric, striations and lee ends orientation of clasts in boulder pavement underlying the till. Glaciotectionites with their inherent till prove a single ice-sheet advance in the Weichselian.

Abstract

The sediment-landform assemblages at the recently deglaciated forefields in front of Svalbard's glaciers have been of interest for numerous studies of past glacier dynamics and paleoclimate reconstructions. However, few studies have concentrated on comparing the terrestrial and submarine forefields to gain a holistic approach of the environment. Detailed geomorphological mapping of the terrestrial and submarine forefields of Protektor-, Harriet- and Kjerulfbreen in Trygghamna, western Svalbard, reveal clear contrast between the terrestrial and submarine environments. Crevasse-squeeze ridges (CSRs) are only observed on land in the forefield of Harriet- and Kjerulfbreen, and recessional moraines are only observed at the sea floor. This suggests differences in dynamic behavior between the polythermal land-based part of the glacier compared to the warm-based marine portion of the same glacier. Furthermore, different factors affect the preservation potential between the two environments; fluvial erosion, burial by supraglacial material and permafrost degradation in the terrestrial environment versus burial by glaciomarine sediments and reworking of material by an active glacier margin in the submarine environment. These could be the reason for the absence of CSRs in the submarine environment and the forefield of Protektorbreen.

The landform assemblage in Trygghamna does not show a good correspondence to the existing surge-type glacier landsystem models. Conceptual landsystem models for surge-type glaciers with combined terrestrial and marine margin, based on geomorphological archive from Trygghamna, are presented. The contrast between them demonstrate how the glaciers behaved differently in the environments during the retreat as a result of differences in the thermal regime. The study emphasizes the importance of incorporating data from both archives to understand and reconstruct past glacier behavior and that the glacier environment and dynamics are highly controlling for the preservation potential of landforms, which needs to be taken into account when discussing the dynamics of the glaciers.

Tasmanian glaciokarst: glaciers restrained karstification on lowlands and enhanced it on uplands

Adrian Slee¹, Peter McIntosh¹, Bianca Burke², Ningsheng Wang³

¹Forest Practices Authority, Hobart, Australia. ²University of Queensland, Brisbane, Australia. ³Victoria University of Wellington, Wellington, New Zealand

Abstract

During the Quaternary Tasmania was the only region of Australia to have substantial valley glaciers that in some locations reached close to present-day sea level. The influence of glacial processes on karst development has been underestimated in previous karst studies. As a significant area of Tasmania's mountains in northwest and southern Tasmania are underlain by limestone and dolomite, glaciokarst has developed. Prominent examples are cirque glaciers formed in sinkholes at Mt Anne and the Cracroft River headwaters and glacial deposits (moraines and erratic boulders) in karstified terrain in the Picton valley and Mole Creek area. More than 25 karst areas containing major dolines and caves have been directly impacted by mid- to late Quaternary glaciations. While the glaciokarst at Mt Anne containing the 380 m deep Anne-a-Kandanda cave and the 700 m deep Lake Timk basin (Kiernan 1990) are well known and documented, many other glaciokarst areas have not been recognised or research on them remains unpublished.

This presentation summarises the extent of knowledge on glaciokarst in Tasmania, and presents new information regarding the evolution of active valley floor glaciokarst in the Mersey River catchment in lowland northern Tasmania and a newly-discovered sub-alpine glaciokarst in the King River catchment in western Tasmania. The Mersey River site demonstrates a complex sedimentary, hydrological and geomorphic history in which karst development has essentially been dormant for several hundred thousand years as a result of burial by deposits associated with lobes of the Mersey Glacier during middle Quaternary glaciations and by more recent MIS7 lacustrine deposits and cold-climate fan alluvium dating from MIS5c to MIS2. In contrast the sub-alpine King River site as with other upland karst landscapes in Tasmania has been impacted by several Quaternary glaciations including cirque and small valley glaciers during the last glacial cycle. Here glacial erosion has enhanced karst development by exhumation of limestone bedrock, enabling sediment-laden subglacial meltwater streams to sink into underlying karst conduits.

Late Quaternary Glacial History of Zemu Valley, Sikkim Himalaya, India

Parvendra kumar^{1,2}, Milap Chand Sharma²

¹Dr Harisingh Gour Central University, Sagar, India. ²Jawaharlal Nehru University, New Delhi, India

Abstract

Glaciers provide a huge repository of landforms that can be used as proxy data source to assess magnitude and frequency of processes over time and space. Zemu glacier (27°45'58.62"N, 88°22'45.95"E), one of the largest (26km) in Eastern Himalaya, descends from the eastern slopes of Kanchenjunga in Sikkim Himalaya, India. Climate is dominated by SW monsoon, followed by winter rain from the South China Sea as well as the Mediterranean Westerly which influence the behavior of glaciers in the region. In such geo-climatic settings, smaller changes in climate will be reflected in the behavior of the glaciers in the region. The present study investigates glacial fluctuations in the Zemu Basin on the basis of deposited glacial landforms. The sequence of moraines provides a fair opportunity to reconstruct the glacial history since the Last Glacial Maximum in the region. Several field studies with GPS and remote sensed data with 3D view of Google Earth have been helpful to understand the geomorphology of the area. Accumulation-area Ratio, Maximum Elevation of Lateral Moraines, Toe to Headwall Altitude Ratio and Area-Weighted Mean methods have been used to estimate the Equilibrium Line Altitudes (ELAs) changes to understand the paleo-environmental conditions. Relative timings of the glacial advances have been estimated on the basis of ELA Change, distance of moraines from the present snout, and their comparison with the established chronology of glacial landforms in the neighboring areas of Bhutan and South-eastern Tibet.

Based on moraines, at least four glacial advances have been recognized in the study area. The maximum extent of Zemu glacier reached Zema, a place 16.2km downstream from the present snout position of Zemu glacier. This glacial extent, covered by climax vegetation and stable slopes along with ELA change of 412m suggests that it must be >20Ka old. A small lateral moraine which terminates at Poke, runs up to Zemu glacier in a broken line. Its 4.38km distance from the present snout position and an ELA change of 320m probably represents a Younger Dryer cooling event (>9Ka). A small advance which seems to be Late Holocene in age formed Yabuk ridge, which is 1875m downstream from the present snout position. An ELA change of 100m is estimated for this stage. Zemu seems to have been in a state of retreat ever since, except for a stand-still position that is 1240m far from the present snout. With an ELA change of 57m, this stand-still position probably indicates an extent during the LIA.

The glacial advances appear to be synchronous with the glacial histories of the neighboring regions. However, to understand the exact timing of glaciation, accurate dates should be acquired through various absolute dating methods.

Keywords: Quaternary, Glaciation, Sikkim Himalaya.

Abstract

During the Pleistocene, extensive and repeated glaciations covered the foreland of the European Alps and carved up to several hundred meters deep trough structures, termed overdeepened valleys. These sediment traps were later – sometimes over the course of multiple subsequent glaciations – infilled with sub-, pro-, or non-glacial deposits. Therefore, overdeepened valleys can serve as excellent archives of pre-LGM glaciations, whose relics were otherwise largely obliterated by the following ice advances. However, timing and processes of formation of pre-LGM overdeepenings in the Alpine foreland are discussed controversially.

To gain insights into the pre-LGM glacial and fluvial history of northern Switzerland and to constrain the process of subglacial erosion, we currently investigate the overdeepened section of the Lower Aare Valley as well as a nearby glaciofluvial paleochannel. The project comprises four scientific drillings and is complemented by field work. Our study area is situated just beyond the local LGM, at the confluence of the rivers Aare, Reuss, and Limmat. There, the valley is deeply incised (>100 m below surface) into the substratum composed of Jurassic limestones.

In 2018, we recovered more than 350 m of drill cores. Here, we present first results of our sedimentological, geotechnical, and geochronological analyses.

From ice-marginal to distal, sediments from filling a fjord-like glacial lake in the Aare Valley (CH) about 220'000 years ago

Michael A. Schwenk, Dimitri Bandou, Patrick Schläfli, Guilhem A. Douillet, Fritz Schlunegger
Institut für Geologie, Universität Bern, Bern, Switzerland

Abstract

Repeated glacier advances affected the Swiss Plateau during the Quaternary. Deeply carved valleys, where the bedrock surface is located far below the current drainage level, are a prominent feature on the Swiss Plateau. How and when the glaciers lead to the formation of so-called overdeepenings is still a matter of debate. Different studies show that overdeepenings in the Bern area contain thick and widespread lacustrine deposits of pre-Eemian age (Preusser & Schlüchter, 2004; Preusser et al., 2005). A coherent geological model of this complex setting is missing. Likely, glaciers carved into pre-existing overdeepening fills and repeatedly dug large troughs.

Furthermore, access to the sedimentary record is limited. Outcrops containing sediments of the last glaciation are scarce and isolated. Access to older sediments is almost entirely limited to excavations and drillings.

Nevertheless, the overdeepenings served as local sedimentary traps while and after they were covered by ice during different glaciations. Hence, these troughs are prone to preserve a coherent sediment succession of a glaciation cycle in an ideal case, and they are therefore worth studying.

In this study, we attempt to resolve the local stratigraphic framework of pre-Eemian lacustrine deposits in the Bern area. In February 2019, we will conduct a ca. 200 m deep scientific drilling in order to link it to existing investigations aided by publicly available drill log data. We will study the lithofacies and use relative and absolute dating methods (palynology, luminescence dating, U-Th dating) to determine the development of a lake throughout a pre-Eemian glacial cycle. Preliminary OSL results of the lacustrine sediments yield a minimum age of 220 ka. This study will provide new insights into the timing, extent and impact of this glaciation as well as its climatic conditions.

Crevasse forms – bridging the gap in glacial geomorphology between East and West

Anna Orłowska

Maria Curie-Skłodowska University, Lublin, Poland

Abstract

Crevasse forms are a group of often-occurring glacial landforms, the origin of which are still variously interpreted by the east and west glacial geomorphologists, regardless their presence in contemporary glaciated areas of the high latitudes or formerly glaciated lowlands of Europe and North America. In the history of their research, they have been related so far to two extreme dynamic states of ice sheet:

1. Stagnant ice (among others Flint 1928; Bartkowski 1967; Johnson 1975; Eyles et al. 1999; Friello & Hanson, unpublished; Godlewska & Terpiłowski 2012; Gruszka et al. 2012);
2. Surging ice (among others Sharp 1985, 1988; Evans & Rea 1999, 2005; Evans et al. 1999, 2007; Christoffersen et al. 2005; Waller et al. 2008; Evans et al. 2016; Sobota et al. 2016).

Scale of deposition of Pleistocene and contemporary glacial landforms may result in misinterpretations of forms developing in ice crevasses. In some cases, despite morphological or geological differences, they are concerned or even named as the same landforms. In this context, the following tasks were executed: 1) review of the published examples of forms interpreted as developed in ice crevasses, 2) comparison of their characteristics and an attempt to explain their origin, and 3) assignment of the analysed forms to specific dynamic states of modern glaciers and/or Pleistocene ice sheets. Based on these studies, the following conclusions were drawn:

- 1) Forms filling ice crevasses are generally ridges, parallel or perpendicular to the direction of ice advance, which are composed of glaciofluvial, glaciolacustrine and glacial (mainly flow till) sediments from supraglacial deposition. These are forms typical of disintegration of stagnant/dead ice, named so far e.g. *kames*, *dead-ice moraines*. A place of their deposition, i.e. the crevasse, develops by ice cracking in the active ice but supraglacial deposition in these crevasses occurs mainly after ice activeness, i.e. when ice becomes inactive.
- 2) Crevasse forms *sensu stricto* are low, narrow sharp-edge glacial ridges subglacially deposited in crevasses during their formation. Such conditions of their development are possible only in surging glaciers. Deposition of such forms occurs from bottom to top of crevasses by squeezing of basal till – hence e.g. *crevasse squeeze* ridges develop.

It is high time glacial landforms developing in ice crevasses of Pleistocene ice-sheets and contemporary glaciers were regulated. This approach can offer an opportunity to limit misinterpretations of crevasse forms *sensu stricto* mainly in the research of Pleistocene glacial landforms, carried in the East.

Morphological analysis of large-scale glacial and glaciofluvial bedrock-incised landforms

Sean M. Gilgannon¹, Darrel A. Swift¹, Stephen J. Livingstone¹, John Menzies²

¹The University of Sheffield, Sheffield, United Kingdom. ²Brock University, St. Catharines, Canada

Abstract

Understanding the controls on focused glacial erosion is important given the potential impact on ice sheet development and dynamics. Previous work undertaken in this area has assumed that large glacial erosional landforms such as troughs and overdeepenings are morphologically distinct from glaciofluvial landforms such as tunnel valleys. However, there are many examples of glacial bedrock incision that are difficult to categorise as either glacial or subglacial-fluvial, and process-based morphological criteria for distinguishing between the two are lacking. We present morphological analyses of overdeepened bedrock-incised landforms present on the Northern Swiss Foreland (NSF), focusing on their cross-profile morphology and comparability to that of similar features in other settings. This work aims to develop criteria that can be used to assess the relative contribution of glacial versus subglacial-fluvial erosion to the formation of such features, and therefore inform understanding and numerical modelling of subglacial conditions and processes.

Ice-cored ridges: topography and melting dynamics based on sedimentary and structural evolution of collapse structures within kame deposits (eastern Poland)

Anna Orłowska¹, Wojciech Włodarski²

¹Maria Curie-Skłodowska University, Lublin, Poland. ²Adam Mickiewicz University, Poznań, Poland

Abstract

The topography and melting dynamics of ice-cored ridges within marginal zones of the Pleistocene ice sheets have been reconstructed based only on simple conceptual and qualitative models supported by geomorphological, sedimentological, and palaeogeographical studies. A novel approach based on detailed sedimentary and structural analysis of two collapse structures affecting the Pleistocene kame deposits in eastern Poland is presented. The high regularity in the geometry of synclines and the patterns of subsidence of the folded strata are interpreted as evidence of topography and melting dynamics of ice-cored ridges. The topography is determined in terms of elongation, orientation and cross-sectional shape of ice-cored ridges. Dynamics of their melting is assessed based on a semi-quantitative model of different relative rates between backwasting and downwasting. The topography of ice-cored ridges, derived independently from the morphology of the related supraglacial landform, is interpreted as an effect of ablation controlled by debris bands within parent ice. The formation of the ice-cored ridges was initiated in subaerial conditions and then continued subaqueously during deglaciation. The reconstructed ice-cored ridges probably represent second order topographic features which were progressively emerged within wide ice-cored depression. The sedimentary evolution of collapse structures in terms of hinge/depocentre migration within them, provides new insight into dynamics of ice melting, to show the predominance of backwasting over downwasting. It concerns the final stage of de-icing which was probably preceded by stage of lowering of the ice-cored topography and progressive emergence of the ice-cored ridges. This approach offers the opportunity to overcome some limitations associated with using the present-day glacier margins as a modern analogue despite the differences in the scale between ice-cored topographic features and Pleistocene supraglacial landforms.

Last Glacial Maximum glaciers reconstruction in the Karkonosze Mountains (Sudetes, SW Poland)

Mateusz Pitura, Artur Sobczyk

Institute of Geological Sciences, University of Wrocław, Wrocław, Poland

Abstract

Karkonosze Mountains represent the highest mountain range within the Sudetes Mts. (Bohemian Massif) and contain one of the best preserved glacial relief among all mid-mountains (Mittelgebirge) ranges of Europe. Geomorphological signatures of intensive recurrent local glaciations (i.a. cirques, niches, moraines), are nowadays the only remnants of past glacial activity, and therefore can be used as natural tracers of glaciers formed during the Last Glacial Maximum (LGM). At the time of the LGM, glaciers have been emplaced in cirques located both on northern (6) and southern (10) slopes of the Karkonosze Mts. By a combination of a high-resolution (ca. 1x1 m) LiDAR DEM, geological data and field observations, integrated within an ArcGIS GlARE python tool, a new numerical model of paleo-glaciers has been proposed. In the beginning, reconstruction of the flowline, ice and moraine boundaries, have been used as proxies for the glaciers' past position. Ice thickness has been calculated based on airborne LiDAR DEM data and reconstructed glaciers' flowline. The total length of all reconstructed glaciers oscillates between 3 to 5 km, and the main type is cirque glacier. The area of glaciated terrain was not large or densely scattered, nevertheless, the quality of erosion, residuum and landforms is uncommon and worth investigating.

The main aim of this project is to reconstruct paleo-glaciers evolved both on northern and southern slopes of the Karkonosze mountain range, at the same time trying to decipher their contribution to the Quaternary relief remodelling, sediment flux and glacial erosion. The result in a form of the detailed Last Glacial Maximum paleoglaciological map of the Karkonosze Mountains should allow to better understand the importance of glaciation as triggering factor of mid-mountain ranges destruction and give an overview on past spatial ice extent.

Sedimentary and seismic stratigraphy of buried glacial landforms at Dogger Bank, North Sea: implications for ice-sheet retreat

Andrew Emery¹, David Hodgson¹, Natasha Barlow¹, Jonathan Carrivick¹, Carol Cotterill², Emrys Phillips²

¹University of Leeds, Leeds, United Kingdom. ²British Geological Survey, Edinburgh, United Kingdom

Abstract

Dogger Bank, in the southern North Sea, is a large shallow bank surrounded by deeper waters, which makes it an ideal site for offshore wind turbine development. Site investigations as part of the Forewind windfarm project have provided an integrated dataset comprising a dense grid of high-resolution 2D shallow seismic survey, geotechnical tests and vibrocores. Calibration between observed sedimentary facies to the seismic stratigraphy allows for robust geomorphological interpretation. This provides vital inputs into ground models for placement of offshore wind turbines.

At the Last Glacial Maximum, Dogger Bank was covered by the British-Irish Ice Sheet. During ice-sheet advance, streamlined subglacial bedforms formed and were subsequently preserved. This implies both fast ice streaming during ice advance, and limited reworking of the bedforms during retreat. During ice sheet retreat, a large terminal thrust moraine ridge formed. The NE-SW trending moraine ridge dammed a large (approximately 750 km²) proglacial lake. Subsequent sedimentation infilled the lake with up to 30 m of glacial outwash sediments. The lake-fill seismic stratigraphy comprises discrete units of low amplitude, chaotic, or moderate to high amplitude, rhythmic seismic facies. A unit of chaotic facies with a lobate geometry thinning towards the southeast is interpreted to be an ice-contact subaqueous fan. This has minor thrust faulting and folding at the toe of the wedge, which suggest gravity-driven mass movement, or deformation due to minor ice margin oscillation. Iceberg scours and a layer of ice-rafted debris at the base of the lake suggest that the ice margin was calving icebergs into the lake. Onlapping the subaqueous fan, rhythmic seismic facies represent lake sediments calibrated to vibrocores as alternating clay and silt laminae, which are interpreted to be varves reflecting annual variation of sediment input. The varves also indicate quiet water sedimentation, which suggests ice sheet retreat and ice-distal sedimentation with a strong density stratification of the water column and a range of overflow and underflows that dispersed sediment in the lake.

This dataset suggests a record of punctuated ice-sheet retreat. After the initial formation of the terminal moraine, an ice-contact lake formed. The ice front then retreated to allow distal lake sedimentation, before sediment supply switched off as the ice retreated further northwards. This stepped retreat occurred after the LGM at around 27 ka and before a ribbon lake formed to the north of Dogger Bank, approximately 60 metres lower in elevation, dated previously to 23 ka. An initial phase of rapid, passive retreat was followed by a slow phase of retreat that allowed approximately 2000 years of lake varves to form. Subsequently, retreat was rapid towards the 23 ka ribbon lake. A negative subglacial slope as the ice sheet retreated northwards may have influenced this rapid phase of retreat.

Luminescence chronology of fluvial and marine records from subsurface cores in Kaveri delta: Implications to deltaic geomorphic evolution

KARTIKA GOSWAMI¹, Manoj Kumar Jaiswal¹, Sivakumar Krishnan², Anbarasu Kumerasan², Senthil Kumar Sadasivam³
¹Department of Earth Sciences, Indian Institute of Science Education and Research, KOLKATA, India. ²PG and Research Department of Geology, National College (Autonomous), Tiruchirappalli, India. ³Geobiotechnology Laboratory, PG and Research Department of Biotechnology, National College (Autonomous), Tiruchirappalli, India

Abstract

Long-term evolution of river deltas is a result of various contributions of external forcings (tectonics, climate, sea level, water and sediment inputs) and internal controls (avulsion, compaction etc). Thus, the deltaic fluvial deposits could be potential proxies to reconstruct past climate as well as to understand the response of river to changes in the sea level that are generally in sync with the changing climate. Presence of the past shoreline signatures in the form of palaeo beach ridges in Kaveri delta suggest a wave dominated delta and thus past sea level variations directly affecting the sedimentary dynamics of the Kaveri river forcing river to either aggrade or prograde. We present the results of luminescence dating of sediments from four sediment cores (VKI, TNR, SY and KKI) of 25 m depth each from the Kaveri delta in south east India. The coring sites are located ~2.5 km, ~11 km, ~17 km and ~20 km away from the present coastline respectively. The sediment cores were analyzed for OSL dating, ¹⁴C dating, lithology and microfossils. OSL dating technique was used to provide robust chronological framework to the cores. This study extends OSL dating to a geographic region not covered in previous OSL dating literature, providing robust chronology for the Kaveri river delta. OSL dating provides an estimate of last daylight exposure of sediments, thus giving last burial ages. The cores represent various stages of fluvial and marine activity in the region over the last 150 ka. The chronology of the core closet to the coast (VKI) reflects eight major phases of increased sea level (142-140 ka, 104-100 ka, ~121 ka, 87-81 ka, 60-57 ka, 9-6 ka, ~5 ka and ~3 ka) partly coinciding with the global climate cycles MIS 6, MIS 5, MIS 3, MIS 1 respectively during the late Quaternary period. During ~121 ka and 9-6 ka, marine transgression reached the core location to leave marine signatures in the forms of foraminifera. VKI core replicates the quaternary sea level curve, showing strong control of the sea in coastal deposition. The bottom most age of this core is much older (~140 ka) than the rest of the four cores (~120 ka) situated further inland. This indicates the coastal land has uplifted in the recent years (somewhere post~50 ka), creating a basin fill situation for sediments to accumulate, as observed from the sedimentation pattern and robust luminescence chronology of the rest of the inland cores. The chronology of the topmost ages of the cores indicates delta has prograded gradually towards the sea during ~27 ka, ~19 ka and ~14 ka. Thus, the present work examines the geomorphic evolution of Kaveri delta, an archive of fluvial and shoreline activities.

The Holocene coastal dunes of the eastern Hengchun Peninsula, Taiwan – A synthesis of their development and palaeo-environmental implications

Lih-Der Ho¹, Christopher Lüthgens², Jia-Hong Chen¹, Shyi-Jeng Chyi¹

¹Department of Geography, National Kaohsiung Normal University, Kaohsiung City, Taiwan. ²Institute for Applied Geology, University of Natural Resources and Life Sciences (BOKU), Vienna, Austria

Abstract

Coastal dunes of the Feng-Chuei-Sha coastal area, Gang-Ko River mouth area and the Giopong-Gangtzie coastal area in the eastern Hengchun peninsula of southern Taiwan provide important opportunities to understand the interactions between the land and sea during the middle to the late Holocene. Our study applied UAV to carry out the landform survey, and developed digital surface model (DSM) for Integrating with the ground penetrating radar (GPR) data to show the relationship between landforms and internal structures of the dunes. Detailed descriptions of the dune outcrops and samples taken from the outcrops for grain-size analysis, radiocarbon dating and feldspar OSL dating allow us reconstruct the landscape evolution of the coastal dunes. Results show that (1) in the context of gradual eustatic sea-level dropping since the middle Holocene around Taiwan, rates of tectonic uplift, ranging from 0.4 mm/yr to ~2 mm/yr, primarily control the timing of coastal dune development in the study areas. The faster is the earlier. (2) The sand accumulation periods of the coastal dunes at ~4 ka to ~2.3 ka, ~1.8 ka to ~1.1 ka, and ~0.7 ka to ~0.4 ka are mainly consistent with the cold/cool climatic periods during the late Holocene. This finding indicates that stronger Asian Monsoon winter winds during the cold/cool periods blow abundant sand from the continuously extending beach toward land, even onto the uplifted marine terrace surface with 70 m in height. (3) Because of the topographic effect, the cliff-top dunes preserved more fine eolian deposit than the other coastal dunes did, and the grain-size changing trends in the cliff-top dune deposit may indicate the changes of the palaeo-wind transportation capacity. (4) Recently, layers of eolianites were observed in the profiles of the coastal dunes. The appearance of the eolianite layers and their implications about palaeo-environmental conditions should be further addressed in the future study.

P-1906

Deciphering Quaternary palimpsest landscapes to constrain 3D (4D) geological models: an example from the Po Plain-Apennines border (N-Italy)

Chiara Zuffetti, Riccardo Bersezio
Department of Earth Sciences, University of Milan, Milano, Italy

Abstract

Palimpsest landscapes represent important archives of the geological evolution of a basin. Deciphering the nature, timing and hierarchy of successive episodes of landscape-changing events in dynamic settings helps to constrain reliable evolutionary models and/or simulations, which incorporate the 4th dimension into 3D geological reconstructions.

The landscape of the Quaternary Po Plain, in the foreland between the Alps and the Apennines, is the surface expression of active thrusting of the Apennines (South) and Alpine glacial cycles (North). Reliable models of this complex, geomorphological and tectono-stratigraphic setting, are of interest for both the Quaternary reconstructions of the basin and the relevant issues in land and resources management.

Aiming to describe the Late Pleistocene-Holocene incremental landscape evolution of the basin, and to develop 3-4D models, we focus on a region close to the Po Plain-Apennines border, where three isolated low-relief hills emerge above the plain as a consequence of N-wards blind thrust-related uplift and wrenching/collapse. The hills expose stratigraphic boundaries and (paleo-) morphological surfaces otherwise buried in the adjacent plain sectors and show the involvement of the Quaternary, mostly alpine-sourced littoral, alluvial and glacio-fluvial succession in Apennine folding and faulting.

The adopted multidisciplinary approach combines different scales of geomorphological, geopedological, stratigraphic and structural field observations corroborated by OSL and ¹⁴C age determinations to feed GIS-assisted, quantitative morphotectonic and stratigraphic analyses. The 3D forward models were processed by interfacing the GIS management with the 3DGeoModeller software.

The results highlight how, where and when climate and tectonic-driven processes fingerprinted the evolution of the hills and surrounding plain landscape. The proto-hills, i.e. paleo-highs uplifted during active Apennine thrusting in the early Late Pleistocene, were the sites for polycyclic loess-soil aggradation. This suite of non-erosional surfaces, characterized by *in situ* paleosols, relates to sites of morphological stability. Valley incision, fluvial terracing, soil truncation and redeposition occurred along the faulted boundaries of the uplifting reliefs and in the intervening structural lows. Late Pleistocene transtensional faulting induced abrupt changes of the drainage network by shifting the base-levels and enhanced reworking of paleosols. These were redeposited in colluvial wedges on the fault-block hangingwalls, the latter highlighted by peculiar alignments of morphotectonic indicators. A latest uplift stage during the latest Pleistocene-Holocene is recorded by the regional entrenchment of the major drainage network of the southern Po Plain, which is affected by several fault-related diversions, river captures and terrace-slope intersections. These cross-cut relationships and the tectonic increments have been converted into modelling rules, which have been incorporated as new routines into the GeoModeller suite.

The work shows that palimpsest landscapes represent the topographic and geomorphological constraints for modelling, where the modelled volumes, assembled by their hierarchy and formative increments, incorporate the evolutionary steps and drivers deciphered from field observations.

P-1907

Preparing climate input data series for the FACSIMILE Rio Bergantes landscape evolution model-data comparison project.

Darrel Maddy¹, FACSIMILE Project Members²

¹Newcastle University, Newcastle upon Tyne, United Kingdom. ²Various, Various, United Kingdom

Abstract

While numerical models can usefully be explored using synthetic climate input data, for the more challenging task of real world simulation, where model outputs are to be directly compared with observed field data, these inputs data series should attempt to more closely reflect actual climate history. The challenge set for the FACSIMILE project was therefore to establish likely timeseries for temperature and precipitation for the Rio Bergantes catchment spanning the modelled 140ka time interval, thus encompassing a full interglacial-glacial cycle.

Not surprisingly proxy climate data spanning this interval at annual resolution is not available. In order to reconstruct these series required the use of multiple proxy records spliced together and resampled using interpolation techniques. As temperature and precipitation are independent variables, that often show only weak correlation, we tried to reconstruct them using different data sources. For temperature a pollen data transfer function was used and for precipitation biomarker records were used as a proxy. Where overlapping data was not available generalised patterns were used to interpolate the missing data. Time series resampling was performed using the Rioja package in R. Modifications to these series will continue as the project moves forward.

The annual data series are used directly in the reduced complexity models e.g. LAPSUS, PARALLEM where appropriate spatially distributed temperature and rainfall are modelled using generalised lapse rates for temperature and modern precipitation gradients across the catchment.

P-1908

Reconstruction of long-term soil erosion and deposition in a mesoscale catchment of the Central German Uplands: A field-based modelling study

Raphael Steup¹, Katja Kothieringer², Timo Seregély², Andreas Schäfer², Markus Fuchs¹

¹Justus-Liebig-University, Giessen, Germany. ²Otto-Friedrich-University, Bamberg, Germany

Abstract

Soil erosion and related sediment deposition caused by climatic variations and human activity are important geomorphic processes in Central Europe during the Holocene. Since the Neolithic Period (c. 5.500 BCE) humans turned natural into cultural landscapes and thus further altered sediment dynamics. In the last decades, many studies have shown the importance of quantifying the contributing parts to the sediment cascade within a catchment to better understand the underlying driving forces on Holocene sediment dynamics. Due to the specific landscape history and often complex responses of geomorphic systems to change (e.g. feedback processes, resilience times, self-organization), the analysis of these underlying forces remains challenging.

Therefore, numeric models are used to provide valuable information on past geomorphic processes, test different scenarios of landscape evolution and complement field-based studies, as long as careful considerations of choosing a model and its limitations (e.g. data availability, calibration, validation and uncertainty) are made (Van de Wiel et al., 2011). When simulating actual landscapes, reference areas with well-established chronostratigraphies and spatially distributed data on long-term erosion and deposition patterns are of great importance.

This approach tries to reconstruct and quantify the sedimentation history of colluvial and alluvial archives in the Weismain river catchment (125 km²), located in the Northern Franconian Jura of the German Central Upland region, by using a combination of field-based methods, laboratory work and modelling setup. The OSL and AMS radiocarbon based chronology shows an increase in sediment deposition since the Early Bronze Age (2100-1550 BCE) for colluvial sites and around 590 CE for floodplain deposits. However, there is a variation in the onset of sedimentation between the individual sites, indicating the need for multiple regional site studies to reconstruct sediment dynamics on a catchment scale.

Widespread lake deposits on interfluves of Middle Pleistocene glaciated plains: problems of age and origin interpretation (Central European Russia)

Ekaterina Garankina¹, Ilya Shorkunov², Vladimir Belyaev¹, Pavel Andreev³, Inessa Karevskaya¹, Alexey Rusakov³, Alina Samus¹, Elena Sheremetskaya¹, Yuliya Shishkina¹

¹Faculty of Geography, Lomonosov Moscow State University, Moscow, Russian Federation. ²Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation. ³Institute of Earth Sciences, Saint-Petersburg State University, Saint-Petersburg, Russian Federation

Abstract

At the Russian Plain, a set of uplands in the marginal zone of Mid-Pleistocene glaciations are traditionally thought to have dominant glacial origin of landscape structure. The entire postglacial sedimentary sequence of interfluve areas is interpreted as mantle loams – relatively thin (2-3 m) cover sometimes correlated with loesses of the southerly regions. While still debatable most agree on its subaerial origin under periglacial conditions involving combination of eolian, cryogenic and shallow pool deposition. However, recent individual investigations show widespread much thicker (up to 8 m) silts to sandy and clayey loams even at the highest interfluves of several uplands. Those infilling depressions of initial glacial and glaciofluvial topography usually have brownish-bluish grey color and contain organic-rich lenses, which frequency increases downwards. Those covering hilltops have lower thickness (<3 m) but are found almost throughout the entire area.

Complicated by various cryo- and pedofeatures and partially destroyed, these sequences are not always recognized in cores and cross-sections. To obtain their reliable stratigraphy, we applied a hierarchical multiscale approach including detailed macromorphological description of sediments followed by comprehensive analyses of grain size, chemical, organic, and spore-pollen contents, microstructures and paleopedofeatures using scanning electron microscopy and energy dispersive spectrometry, and numerical dating of organic-rich lenses.

Revealed microlamination highlighted by color and granulometric variability, general lithological homogeneity and specific structural features allow considering both addressed sedimentary units of lacustrine origin. Stratigraphic (incl. overlying paleopedofeatures of texturally differentiated soils) and geomorphological positions suggest that on hilltops short-lived residual lakes formed during the final stages of Moscow ice cover degradation (MIS6). The accumulation in depressions started later - during the Mikulino (MIS5e) or Early Valdai (MIS5d-MIS4) and, in places, continued till the Late Valdai (MIS2) when was largely substituted by the intensified mass-wasting. Several asynchronous local water table drops and erosion episodes in the Valdai caused substantial reworking of deposits in periglacial environments and local stratigraphic hiatuses.

Thus, for the peripheral areas of uplands in the Mid-Pleistocene glaciation marginal zone, we propose a long-term discontinual postglacial transformation mostly by lacustrine type of exogenesis, which led to a significant flattening of its initially higher-amplitude glacial topography at least during the last glacial-interglacial macrocycle. Nonetheless, resuming the extents of lake basins either causes of their origination is still problematic. High regional base level rises in large proglacial lake systems are occasionally proposed in light of a potential Late Pleistocene ice-damming of the Upper Volga and glacioisostatic effects. However, the existence of such extensive waterbodies is supported neither by the required water sources nor by the regional topography. As for the local agents of widespread distribution of multiple small lake basins, high activity of zoogenic (during interglacials) and slope (during periglacial and transition periods) processes can be suggested.

Comparing differently derived soil depth and bedrock strength inputs for landscape evolution modelling of the Bergantes catchment (Spain).

Wouter van Gorp¹, Jeroen Schoorl², Marco van de Wiel³, Kim Cohen⁴

¹Groningen Institute of Archaeology, University of Groningen, Groningen, Netherlands. ²Soil Geography and Landscape, Wageningen University, Wageningen, Netherlands. ³Centre for Agroecology, Water and Resilience, Coventry University, Coventry, United Kingdom. ⁴Department of Physical Geography, Utrecht University, Utrecht, Netherlands

Abstract

In the field of landscape evolution modelling, initial conditions strongly steer model behaviour and, when modelling actual catchment evolution, influence the validity of model results. One of the important inputs for landscape evolution models is information on soil depth and bedrock strength. These not only control the available initial erodible material, but also control, in combination with climatic and topographical data, long-term weathering rates and depths. Within the scope of the Facsimile-working group (Field And Computer SIMulation In Landscape Evolution), the Bergantes Catchment (Alcañiz province, Spain) is chosen as a test case to compare different Landscape Evolution Models (LEMs) because of its relatively well-known fluvial archive. One of the key questions of the working group is to compare results of different LEM's over a 150ka timespan modelling the same catchment with the same input parameters. These input parameters need to be constrained. This paper investigates the available data of initial soil-sediment depths and bedrock strengths to be used as an initial condition. It will show comparisons of relatively simple, more conceptually constructed input maps, such as a slope related sediment depth map and compare these with more data driven maps, using maps from readily available online soil and geological data. These data can then be used for model sensitivity studies and model to model comparison studies to eventually lead to meaningful landscape evolution modelling of the Bergantes catchment.

Relic cryogenic features on cultivated interfluves and their impact on modern soil redistribution and gully erosion processes (Western European Russia)

Vladimir Belyaev¹, Katerina Garankina¹, Artem Gurinov¹, Nikolay Lugovoy¹, Alexandra Lisova¹, Anna Semochkina¹, Ilya Shorkunov², Irina Streletskaya¹, Elena Sheremetskaya¹, Sergey Kharchenko¹

¹Lomonosov Moscow State University, Moscow, Russian Federation. ²Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation

Abstract

Widespread relic cryogenic features (RCF) in topography and soil structure beyond the present permafrost southern limits are observed in many areas of Europe (Pewe, 1966; Kolstrup, 1986; Jetchik and Allard, 1990; Bertran et al., 2014). It is generally accepted that most of those were formed under the most severe conditions of the last stage of the Late Pleistocene glaciation (Vandenberghé et al., 2014; Andrieux et al., 2016). Recent progress in studies of the RCF has been largely achieved due to latest development of the remote sensing (RS) techniques and especially increasing availability of high-resolution satellite imagery. By present time, morphological classification of RCF has been proposed (Velichko, 2015; Andrieux et al., 2016) and specifics of their zonal distribution more or less established for the Eastern European Plain (Velichko, 1982, 2015). Significant progress has also been achieved in investigations of role of RCF in structure of modern soils (Duchaufour, 1951; Makeev, 2009; Alifanov, 2010, Sycheva, 2012). Several problems still lacking detailed scientific considerations, namely relationships between different types of RCF and modern hillslope processes, soil degradation, sediment export from cultivated slopes into fluvial network.

The research reported here is concentrated on evaluating relationships between different types of the RCF and morphological and geochemical differentiation of soils, intensity and spatial distribution of soil erosion and deposition processes on cultivated slopes. Approaches employed include analysis of the RS data, application of several independent techniques for quantitative assessment of soil redistribution on cultivated slopes and in small catchments, geodetic DGPS surveys, airborne photo by unmanned aerial vehicles (UAV), morphological and geochemical investigation of soil properties and georadar surveys. Several case study sites with various combinations of relic cryogenic feature types, zonal soil types, morphological and morphometric characteristics of cultivated slopes, density and structure of stream network have been selected basing on examination of the RS data and reconnaissance field surveys. Two case study sites located in the Yaroslavl and Kursk Regions respectively have already been studied in more details. Detailed satellite images interpretation allowed distinguishing several types of RCF spatial patterns (similar to determined by Andrieux et al., 2016) including regular and irregular (by size and shape) polygonal networks with rounded outlines due to thermokarstic degradation of the wedges, striped grounds, transition zones between polygons and stripes and individual thermokarstic depressions. Ground control in combination with DGPS survey and detailed UAV photography allowed additional determination of RCFs prominent in the present-day microtopography or only in topsoil and vegetation color. It has been found that for the case study sites microtopographically-prominent RCF exert important influence on spatial pattern of overland flow, especially runoff concentration, and, therefore, on sediment redistribution within cultivated hillslopes. Present gully network also partly inherits downslope parts of polygonal or striped RCFs.

Late-Cenozoic bedrock denudation rates and tors exhumation in the Sudetes (SW Poland) quantified with ^{10}Be and ^{26}Al cosmogenic radionuclides dating

artur sobczyk¹, Régis Braucher²

¹University of Wrocław, Institute of Geological Sciences, Wrocław, Poland. ²CEREGE UM34Aix-Marseille Univ., CNRS, IRD, Collège de France, INRA, Aix en Provence, France

Abstract

To quantify Late-Cenozoic dynamics of relief evolution in the Central European mid-mountain range type as represented by the Sudetes Mts. (SW Poland, Bohemian Massif), we applied cosmogenic radionuclides (CRN) dating technique based on ^{10}Be and ^{26}Al measurements. All samples originated from granite and metamorphic tors, located at different topographic positions (ridge, slope, valley side) and altitudes (ca. 400-900 m a.s.l.). Obtained ^{10}Be minimum exposure ages (assuming null denudation rate) clustered in the range between 17.08 ± 0.53 to 67.08 ± 2.00 ka for tors top surfaces and from 6.84 ± 1.14 to 35.78 ± 18.60 ka for tors bottom surfaces respectively. Estimation of maximum denudation rates (assuming steady-state and infinite time) for outcrops in a valley side position has yielded the value of 24.3 to 37.1 m/Ma, whereas for those occurring in a summit and ridge position shown the value of 9.2 to 15.7 m/Ma. The highest ^{10}Be concentrations were found at subhorizontal top surfaces of the sampled tors occurring at flat summits (planation surface) and in the upper parts of valley slopes. Cosmogenic nuclides derived denudation rates for the Western Sudetes evidence a Plio-Pleistocene (ca. 2.6-1.0 Ma) maximum tors formation period. However, we do hypothesise that they could evolve most intensively mainly during Elsterian (MIS12) and Early Saalian (MIS6) glaciations. Intensification of erosion and deposition processes during the Middle Pleistocene glacial-interglacial cycles are well evidenced with glacial and glaciofluvial sediments reported for the Sudetes area. Performed cosmogenic radionuclides dating, provides a first geochronological insight into the problem of Sudetic tors origin and evolution, which hold inherited non-steady exhumation history.

Human mobility in the Lop Nur region during Han-Jin Dynasties: A multi-approach study

Xueye Wang¹, Zihua Tang¹, Dong Wei², Xiaoguang Qin¹

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²Jilin University, Changchun, China

Abstract

The Lop Nur region, as the junction of the Silk Roads, played an important role in human migration and cultural communications between the East and the West, north and south Eurasia during Han-Jin Dynasties. However, the extent and intensity of human mobility in this region during Han-Jin Dynasties remain unclear. Here we present a multi-approach (wood species identification, strontium and oxygen isotopes of tooth enamel and historical documents) to investigate the extent of human mobility in the Lop Nur region. From a Han-Jin Dynasties cemetery in the Lop Nur region, two particular tree species which are not common in the region have been identified among wooden objects, suggesting a human migratory behavior in the Lop Nur region. Strontium isotope and oxygen isotope data show that at least 8 out of 27 individuals are identified as immigrants, and the great isotopic variation indicates that these immigrants have diverse origins. Furthermore, exotic mortuary object, such as lacquerware originated from eastern China, indicates the existence of long-distance exchange. In context with historical documents, we infer that the Lop Nur region was once the political, economic, and cultural meeting place of various societies, and also a communication corridor on the Silk Roads in Han-Jin Dynasties.

Middle Pleistocene rocky shores and rock-boring biota at Kuromatsunai, southwestern Hokkaido, Japan

Akihiko Suzuki¹, Takamasa Iwabuchi¹, Takafumi Enya²

¹Department of Earth Science, Sapporo Campus, Hokkaido University of Education, Sapporo, Japan. ²Hokkaido Museum, Sapporo, Japan

Abstract

Rocky-shore habitats are often well preserved in the geological record, and are well suited for interfacing with reconstructions of paleoecological, paleogeographic and paleoenvironmental changes. Hard bottom environments often bear rock-boring trace fossils produced by boring organisms, such as bivalves, gastropods, brachiopods, barnacles, polychaete annelids, sponges and bryozoans. In general, these trace fossils are used as indicators of ancient rocky shores and are useful for reconstructing paleoenvironmental conditions.

In Hokkaido, the shallow-marine facies that are rich in rock-boring biota were primarily deposited during the Pleistocene. We studied rock-boring bivalves and their clavate borings in the Setana Formation in the Kuromatsunai area, southwestern Hokkaido. The Setana Formation contains well-preserved molluscs that have been dated to approximately 0.95 to 0.83 Ma based upon microbiostratigraphy using planktonic foraminifera and nannofossils. In the Soibetsugawa section of the Kuromatsunai area, the basal part of the Setana Formation unconformably overlies a basement comprised of a conglomerate of Pliocene siltstone deposits. Many wave grooves and tidal pools are apparent on the basement surface. Boring bivalves are dominant in conglomerate clasts and are absent from the basement layer.

The rock-boring bivalve, *Nettastomella japonica*, and the clavate borer, *Gastrochaenolites orbicularis*, are dominant in clastic sediments. Moreover, rocky-substrate molluscs, such as mussels, limpets, and chitons, are also recognized. These molluscs are considered to be semi-autochthonous in origin, and are presumed to wave-cut platforms associated with boulder beaches on ancient rocky shores.

The paleoecological characteristics of the molluscan and ichnofossil assemblages in the studied section reflect changes in the sedimentary environment during a sea-level transgression during the Pleistocene. Wave-cut platforms bearing wave grooves and tide pools were created during the initial period of the transgression. Subsequently, *N. japonica* and *G. orbicularis* assemblages found in the conglomerate during the late transgression reflect the semi-autochthonous occurrence of these taxa on unstable substrates.

Bioerosion of rocky marine surfaces is well suited to revealing geological episodes, such as oscillations of sea level, erosion/sedimentation rates and the intensity of physical disturbance. The Setana Formation is assigned to the interglacial stages of the middle Pleistocene (ca. 0.95 to 0.83 Ma) based on microbiostratigraphy, and is likely correlated with a marine isotope stage of 27 or 25.

²Nagasaki University, Nagasaki, Japan. ³School of Environmental Sciences, University of Liverpool, Liverpool, United Kingdom.

⁴Department of Archaeology and Anthropology, University of Cambridge, Cambridge, United Kingdom

Abstract

The Niger Delta is ideally located in a region of great sensitivity to climate change and sea level fluctuations and offers the possibility to provide insights on Late Quaternary environmental change in Equatorial West Africa. In comparison with other major tropical deltas, this deltaic system's response to past climate change and sea level fluctuations during the last 20 ka is poorly understood due limited studies in the basin. This presentation documents the detailed analyses of a multi-proxy dataset collected from three gravity cores obtained from the shallow margin of the Niger Delta in an effort to fill this scientific knowledge gap. The dataset included sedimentology, grain size, geochemistry, calcareous nannoplankton, foraminifera, and palynomorphs. The study hypothesised that the dynamics of the Intertropical Convergence Zone (ITCZ) and sea level fluctuation played a major role in shaping the landscape in the Niger Basin and adjacent coastal regions. The palynological sequences defined in the three gravity cores show very similar fluctuations; afro-montane forest (Podocarpaceae), freshwater swamp (Cyperaceae), savannah (Poaceae) and lowland rainforest (Polypodiaceae) dominated the late glacial and deglaciation periods, followed by the development of mangrove vegetation (Rhizophoraceae) during the interglacial in Early to mid-Holocene. In addition, high values of charred grass cuticles and Ti/Zr ratio are observed during the late glacial, whereas high values of Fe/S ratio and planktonic foraminifera correlate with the expansion of mangrove vegetation during the interglacial period. These records suggest dry conditions and lower sea level during the late glacial and deglaciation periods, and warm conditions leading to the rise of the sea level during the interglacial. These extraneous controls on the environment confirm a direct link between the vegetation dynamics (pollen), and sediment supply in the Niger Delta sedimentary paleoenvironment from ~ 20 to 6.5 ka. The sequential record links the evolutionary stages of the littoral margin of the Niger Delta to the deltaic landscape and sequence architecture with two brief time-bound regional stages based on evidence derived from the integrated multi-proxies. Thus, the controlling factors that accommodate the two complete stages of evolution at different periods has resulted in an improved understanding of the paleoenvironmental dynamics of the passive margin of the Niger Delta during the Late Quaternary.

A preliminary study on sedimentary facies from a sediment core of Nakdong river delta, Korea

Seok Hwi Hong^{1,2}, Gwang-Soo Lee¹, Jin Cheul Kim¹, Hyun Ho Yoon^{1,2}, Dong-Geun Yoo¹

¹Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of. ²Chonnam National University, Gwangju, Korea, Republic of

Abstract

A vibro-core (16ND-C02) was obtained from the Nakdong river delta in 2016. Based on the sediment composition and texture, and color, the deposits can be divided into eight sedimentary facies. In ascending order these are: a) weathered rocks, b) basal gravelly sand, c) massive sand, d) thin laminated silty mud, e) bioturbated mud, f) bioturbated sandy mud, g) alternated muddy sand and, h) cross bedded sand. The distribution of the facies is significantly variable in the core. These facies can be then grouped into three units: 1) fluvial deposits, 2) marine deposits, 3) delta deposits. Each unit is separated by sharp and unconformable erosion surfaces. The lowermost Unit 1 is about 25 m thick and comprised massive gravelly sand and gravels. The presence of massive sand suggests that Unit 1 is a fluvial deposit, which evidently formed during the lowstand sea level during the glacial period. OSL dates of the base of Unit 1 is 76.7 ± 7.5 ka. Unit 2 consists of thin silt lamina that vary systematically in thickness, suggesting tidal influences. OSL dates of this unit range from 10.9 ± 0.7 to 9.0 ± 0.6 . The presence of weakly tidal signatures suggest that Unit 2 is estuarine deposit. Unit 3 is composed of bioturbated mud and cross-bedded sands. This unit contains either shells or foraminifers or any other marine indicators. It is mostly oxidized and weathered. The OSL dated age of Unit 3 ranges from 6.6 ± 0.4 to 1.1 ± 0.1 ka, the deposits belonging to the Holocene. The depositional record of the most recent sea-level highstands (Holocene period) is well preserved. During the late Holocene sea-level highstand, the stratigraphic pattern consists of the deltaic sequence, formed as a seaward progradational pattern.

Re-evaluation of a 19 ka BP meltwater pulse in the Northern Hemisphere: new data from offshore northeast Ireland (Kilkeel)

S. Louise Callard¹, Ruth Plets², Antony Long¹, Andrew Cooper², Robin Edwards³, Daniel Belknap⁴, Joseph Kelley⁴, Rory Quinn²

¹Durham University, Durham, United Kingdom. ²Ulster University, Coleraine, United Kingdom. ³Trinity College Dublin, Dublin, Ireland. ⁴University of Maine, Orono, USA

Abstract

It has previously been hypothesized that glacial and glacimarine deposits infilling incised river channels exposed in coastal cliff sections at Kilkeel (Northern Ireland), provide evidence in support of a major meltwater pulse at 19 ka BP (MWP-19ka), marking the end of the global Last Glacial Maximum (gLGM). This is the only site that constrains both the timing and magnitude of MWP-19ka in the Northern Hemisphere. We present new offshore multibeam bathymetry and sub-bottom data, sediment cores and radiometric dates that question the MWP-19ka hypothesis at this site. Geophysical data reveal a drumlinized landscape with no evidence of a river channel network incised during an interval of low relative sea level (RSL). Instead glacimarine muds accumulated within inter-drumlin troughs during a single period of higher than present RSL during deglaciation. A subsequent RSL fall, to c. -20 m below present, likely caused by glacio-isostatic rebound, is indicated by evidence of a wave ravinement and planation of now-drowned drumlins. The site provides no evidence for MWP-19ka and should not be used to inform oceanographic, ice sheet and sea-level models for this period.

P-2005

Reconstructing the coastal response to Last Interglacial sea-level rise in the southern North Sea

Natasha Barlow, Victor Cartelle
University of Leeds, Leeds, United Kingdom

Abstract

Global temperatures during the Last Interglacial were $\sim 1^{\circ}\text{C}$ warmer than pre-industrial values and $3\text{-}5^{\circ}\text{C}$ warmer at polar latitudes, during which time global mean sea level was 6-9 m above present, far above that experienced in human memory. Though the drivers of warming during the Last Interglacial are different to those of today, it is the amplified warming at polar latitudes, the primary locations of the terrestrial ice masses likely to contribute to long term sea-level rise, which makes the Last Interglacial an interesting analogue for improving understanding of future climate and sea-level change and associated landscape response. However our understanding of Last Interglacial sea level change is primarily limited to tropical and sub-tropical latitudes and it is important to understand the response of temperate estuarine settings to rising sea level.

A new project focuses on specifically targeting palaeo shorelines sequences buried within the southern North Sea, preserved beyond the limit of the Last Glacial Maximum ice sheets, to reconstruct the rate and nature of transgression of the basin during the Last Interglacial. There is a broad understanding of the Last Interglacial sedimentary sequences of the southern North Sea, but not the flooding of the former terrestrial landscape. Geophysical data has been used for a long time in 'deep time' offshore Geology, but recent advances in higher resolution data collection makes it possible to identify shallow late-Quaternary stratigraphic units. A wealth of new offshore geophysical and borehole data has become available as a result of significant investment into energy sources in the North Sea region and is providing a driver for Holocene-focused research, establishing a methodological framework that can be applied to older sequences.

The offshore sedimentary archives offer significant advantages over the geomorphologically restricted onshore records, with the ability to trace the transgression in 3-dimensions over a much greater area. Furthermore, the offshore record should capture the earliest flooding of the Last Interglacial North Sea basin, when the far-field data suggests ice sheet melt was at it maximum, during the peak in global warmth during the Last Interglacial. This has the potential to allow us to 'fingerprint' the source of melt (Greenland and/or Antarctica) during the interglacial sea-level highstand.

P-2006

Rate of sea-level rise as a control on shoreline preservation

Andrew Cooper^{1,2}, Andrew Green²

¹Ulster University, Coleraine, United Kingdom. ²University of KwaZulu-Natal, Durban, South Africa

Abstract

The recorded preservation of submerged shorelines as geomorphological features on continental shelves indicates the implausibility of standard models of coastal response to sea-level rise (e.g. the Bruun Rule and its derivatives). The distribution and preservation of Late- and Postglacial shorelines at specific periods and at specific sea-levels in the United Kingdom, South Africa, Brazil, the Mediterranean and the Gulf of Mexico, for example, points to an important role for the *rate* of sea-level rise rather than simply the *amount* of sea-level rise as a constraint on shoreline evolution. We present a model for shoreline preservation that involves a slowing or halt in sea-level rise (a stillstand or slowstand) during which mature shoreline features develop. These are then preserved if subsequent sea-level rise is rapid enough for the surf zone to translate across the shoreline without totally reworking it. Evidence from several locations suggests that this has occurred several times since the LGM and that sea-level surges associated with meltwater pulses are a key factor. During intermediate rates of sea-level rise, shorelines are reworked and not preserved except under exceptional circumstances associated with local topography, energy levels and sediment volumes. Our findings are important not just for former shoreline preservation but also for predicted future shoreline response to sea-level change.

P-2007

The evolution of a submerged glacial and deglacial landscape from east Ireland (Dundalk Bay and Carlingford Lough).

S. Louise Callard¹, Ruth Plets², Andrew Cooper², Antony Long¹, Joseph Kelley³, Daniel Belknap³, Robin Edwards⁴, Rory Quinn², Derek Jackson²

¹Durham University, Durham, United Kingdom. ²Ulster University, Coleraine, United Kingdom. ³University of Maine, Maine, USA. ⁴Trinity College Dublin, Dublin, Ireland

Abstract

During its final deglaciation, the Irish Ice sheet (IIS) underwent different phases of advance and retreat that have often been linked to global climatic events as opposed to local scale ice-sheet dynamics. Two important readvance phases are known locally as the Clogher Head and Killard Point stadials, with evidence of both in Dundalk Bay and Carlingford Lough (east coast Ireland, C. Lough). Associated with these readvance phases are multi-meter scale relative sea-level oscillations. However, the offshore extent of these advances is unknown and there is large disagreement between the empirical evidence of relative sea level and the modelled sea-level response for this region. This contribution presents the analysis and interpretation of marine geophysical data, eight vibrocores and six radiocarbon dates from offshore C. Lough to investigate the evidence of these readvance phases and the associated sea-level response.

The bathymetric and radiocarbon evidence suggests initial ice-sheet retreat was northwards, with ice-free conditions offshore C. Lough sometime before 18.7 ka cal BP. The core stratigraphy indicates this early retreat was set in a glacial marine environment. A large arcuate moraine ridge in Dundalk Bay and a series of smaller ridges at the mouth of Carlingford Lough are evidence of a readvance of the IIS eastward. The composite nature of these features suggests an oscillating margin and possibly suggest that the IIS was not solely dependent on external forcing factors but also sensitive to local ice-dynamics. The outer most moraines indicate that the maximum extent of ice advance in the region is more restricted than previously thought. We correlate these features with ice margins mapped onshore and are likely correlative to the Clogher Head and/or Killard Point Stadial, a period spanning 18.2 to 16.5 ka BP.

The cores collected in this study currently lie in a dynamic marine setting where evidence of sea-level minima has not been preserved. The lack of primary sea-level index points restricts us from constraining the sea-level models for this region. However, the seismic data display a consistent ravinement surface down to -40 m, suggesting sea level dropped to around -30m when wave base erosion is taken into consideration. A date above the ravinement surface of 13.2 ka cal BP indicates the timing of the sea-level lowstand occurred prior to this date. In Dundalk Bay the moraine crest is 12 m below sea level and would therefore have been sub-aerial during this lowstand. The sea-bed geomorphology behind the moraine suggest this acted as a barrier, possibly damming a lake and/or providing a suitable environment that preserves evidence of an intertidal setting that is not preserved seaward of this feature.

P-2008

Late Holocene mangrove dynamics and coastal environmental changes in the Sundarbans, Ganges-Brahmaputra delta, India

Shilpa Pandey

Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

Mangroves are halophytes occur on intertidal shorelines in the tropics and subtropics. Mangroves constitute an expressive ecosystem in the east coast of India and one of the best examples of mangrove forest is located on the coastal area of the Ganges-Brahmaputra delta, India. A 4.6 m sediment core from mangrove region of southwestern part of the Sundarbans, Ganges-Brahmaputra delta has been studied through pollen analysis in order to reconstruct mangrove dynamics and coastal environmental changes during Late Holocene. Pollen and stratigraphic data indicate dominance of mangroves between 4000 to 3500 cal yr BP. A contraction of the mangrove area and an expansion of midland and aquatic vegetation occurred between 3500 to 2500 cal yr BP. The reappearance of mangroves at the study site occurred with a return of brackish water estuarine environment between 2500 to 900 cal yr BP. This trend continued until the present. Occurrence of *Casuarina equisetifolia* and *Palmae* pollen in good percentages from a few surface samples from the upper section of the core also indicate anthropogenic activities during the recent past in this area.

Coastal processes of the Eastern Gulf of Finland: recent dynamics and driving forces

Alexander Sergeev¹, Daria Ryabchuk^{2,3}, Olga Kovaleva², Vladimir Zhamoida², Igor Neevin²

¹A.P.Karpinsky Russian Geological Research Institute (VSEGEI), St. Petersburg, Russian Federation. ²A.P.Karpinsky Russian Geological Research Institute (VSEGEI), St. Petersburg, Russian Federation. ³St. Petersburg State University, St. Petersburg, Russian Federation

Abstract

Littoral zone lithodynamics, together with geology, morphology and tectonics control the main features of coastal processes as well as the size, shape and development of erosion/accretion formations. Therefore the study of recent coastal processes provides another valuable proxy for modelling of shoreline displacements.

The eastern Gulf of Finland coastal zone is characterized by intense coastal processes. Upper part of geological sequence consists of easily erodible Quaternary deposits represented by Holocene marine sands and Late Pleistocene sandy and clayey loam. Due to the complicated interplay of eustatic and isostatic processes, there have been several pronounced sea-level variations during the Holocene. Evidence of many phases of these variations is well-preserved in the modern landscape at different elevations both onshore (relict lagoon systems and sand spits at altitude +5 – +20 m) and offshore (submarine terraces at water depth -5 – -20 m). Sand, gravel and pebble material from glacial and glaciofluvial landforms were the main source of sediments for the Holocene coastal accretion bodies. Conservation of big sediment volume in relict coastal landform together with very low (from 0 to +3 mm/year) rates of uplift at a near zero rate of recent sea-level change caused sediment deficit, which is one of the important driving forces of coastal erosion.

Annual coastal monitoring carried out by VSEGEI since 2000, has shown the highest intensity of coastal dynamics are confined to the easternmost part of the Gulf of Finland. The most extreme erosion events occur when long-lasting western or south-western storms, high water level, and the absence of stable sea ice take place simultaneously. Such situations are recently more frequent due to climate change. Along the northern coast (Kurortny District of St. Petersburg), the average rates of coastal retreat is about 0.5 m/year, but within some coastal segments they reaches 2 m/year, and can be up to 5 m per one strong storm.

Southern coast of the Gulf (near Bolshaya Izhora village) is one of the most dynamic coastal area. The coastal zone here is steadily developing along the principle of longshore sand waves, moving eastward along the coastal line with an average speed of 25 m/year. From 2011 to 2018, the movement of the coast projection (waves) is 180 m.

Comparative analyses remote sensing data (started from the WWII Aerial Photos of August 15, 1939) has shown that the same phenomenon of longshore sand waves is observed within coastal zone of Kotlin Island. It is resulted in western coast retreat (rates 1.2–2 m/year) and sand spits forming in the east.

This research undertook in frame of project № 17-77-20041 of Russian Science Foundation.

Abstract

Posidonia oceanica is a long-living marine phanerogam in which a significant part of the production is stored on seabottoms as an organic bioconstruction (mat). In principle, seagrass mats are reliable archives of long-term environmental change; although palaeoecological approaches using seagrass archives are still rare, particularly those using fossil pigments. Competition for light and/or nutrients between algal organisms and the seagrass have been observed at decadal scales and symbiosis between cyanobacteria and *P. oceanica* has recently been suggested to play a key role in the production of these seagrass meadows. Planktonic and epiphytic communities as well as *P. oceanica* production have also been observed to change with water depth. The aim of this study is to elucidate how primary producer communities interact and change in *P. oceanica* meadows at millennial scales: are cyanobacteria or others organisms linked to seagrass production? Which factor(s) regulate(s) main changes in assemblages? To answer these questions, sediment cores were obtained from two bays of Cabrera island (Balearic Islands, Spain), including a transect of cores from different depths. All cores were sectioned, dated using ¹⁴C and ²¹⁰Pb, analysed for biomarker pigment composition using high performance liquid chromatography, analysed for the elemental chemical composition, grain size was also determined using a laser-based particle analyzer and Fourier Transform Infrared Spectroscopy was used to get absorbances of biogenic silica. Diverse pigments derived from cyanobacteria, diatoms, chlorophytes, cryptophytes and dinoflagellates were preserved in sediments. In each core, changes in the relative abundance of carotenoids from cyanobacteria (canthaxanthin, echinenone) and diatoms (diatoxanthin) reflected changes in the seagrass ecosystem production. Higher seagrass production, indicated by seagrass debris and biogenic silica in sediments, was associated with elevated abundance of cyanobacteria. This higher production state seems to depend on external contributions of nutrients, specifically iron, to the aquatic system. Periods of clear cyanobacteria dominance go from 1000 to 500 cal. yr BP and from 300 to 125 cal. yr BP, both coincident with enhanced aeolian dust from Sahara, a known significant source of nutrients to the Mediterranean waters. From 300 to 125 cal. yr BP, agricultural activities in the island could have also enhanced the arrival of terrestrial nutrients to the aquatic ecosystem. Pigment assemblages associated with lower seagrass production states were composed mainly of diatoxanthin from diatoms. A pattern in assemblages along a depth gradient reveal that cryptophytes (alloxanthin) and cyanobacterial pigments (echinenone) were both associated with shallower and more productive waters while at deeper stations, dinoflagellates (diadinoxanthin) were more abundant. Fluctuations in pigment composition in seagrass soils records reveal that primary producer assemblages and seagrass production in the *P. oceanica* ecosystem are mainly associated with water depth and iron inputs (either from atmospheric or terrestrial sources).

Paleoenvironmental Changes Based on Geochemical and Palynofacies Analysis of the sediment cores from Lagoa Salgada, southeast Brazil

Sabrina Barroso Silva, João Graciano Mendonça Filho, Sinda Beatriz Vianna CARVALHAL-GOMES, Joalice de Oliveira Mendonça
Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract

Lagoa Salgada is a seasonally brackish to hypersaline coastal lagoon located in Rio de Janeiro State, southern Brazil. It sets in the context of the coastal plain of the Paraíba do Sul river with its formation associated with sea level fluctuation in Quaternary. This study aims to provide a high resolution of the Lagoa Salgada paleoenvironmental evolution by the study of the organic matter (OM) associated with the sedimentation.

In order to do it, eight sediments cores were described. These sediments were characterized mainly by coarse and fine sand, sandy mud and mud. LS15 is the deepest sediment core of 212 cm and in a previous study it was constructed a chronological model resulting in a period between 6.300- and 1.300-years cal. BP.

The cores LS-01, LS-02, LS-03, LS-09, LS-11, LS-13, LS-14 and LS-15 were sampled at intervals of 10 cm, totalizing 96 intervals. They were submitted to the analysis of Total Organic Carbon (TOC) aiming to quantify the OM in the sediments. Except for LS14, the same sampling intervals were submitted chemical isolation of OM. All these 77 intervals were studied by Palynofacies analyses. Geochemical data indicates high heterogeneous content with TOC values varying from 0.04 to 9.45wt%. Carbonate content ranges from 3 to 90%. Both results show an increase in the top area, reaching the highest values in the upper mud.

The kerogen assembly is complex for sand and sandy mud sediments with a high allochthonous contribution. For this reason, the results of 34 intervals were submitted to cluster analysis by applying R-Mode and Q-Mode. The rise in the amounts of the Phytoclast Group (0 to 39.68%) is related to an input from the river bringing these compounds derived from terrestrial macrophytes. Dinocysts (0 to 13.09%) from species *Operculodinium centrocarpum* and the genus *Spheniferites* spp are the main marine contribution. The occurrence of peaks was related to transgressions. The occurrence of freshwater microplankton - *Botryococcus* and *Pediastrum* - indicates moments of lower salinity. Sporomorphs has a great occurrence and the appearance of the family *Amaranthaceae* is recurrent. This family is associated to arid environments and altered human settlements due to their high temperature tolerance. Amorphous organic matter (AOM) occurs in all sampling intervals (10.19 to 100%), and even though they are from distinct origins, they are always autochthonous. The AOM dominates the palynological assemblage of the top intervals and its origin is related to the activity of autotrophic and photosynthetic bacteria. Moreover, Phytoclasts and Palynomorphs are extremely rare in these intervals which are related to the closure of this coastal lagoon. Through these results, it is possible to characterize the evolution of the paleoenvironment of Lagoa Salgada over the 6340 years BP.

Autogenic and allogenic processes involved in the formation of *Posidonia oceanica* environmental record.

Nerea Piñeiro-Junca^{1,2}, Carmen Leiva-Dueñas², Oscar Serrano³, Miguel Ángel Mateo^{2,3}, Antonio Martínez-Cortizas¹
¹University of Santiago de Compostela, Santiago de Compostela, Spain. ²Centro de Estudios Avanzados de Blanes, Blanes, Spain. ³Edith Cowan University, Perth, Australia

Abstract

Posidonia oceanica is a highly productive marine plant that promotes sedimentation leading to the formation of a well-stratified soil (mat), whose upper part can be equated to a Histosol. Similar to continental peatlands, the value of the mats as late Holocene environmental archive has been explored, most particularly over the last decade. However, knowledge on soil formation and dynamics is scarce and mainly refers to the epipedon. On this study, we determined the chemical composition (by XRF) of a core (470 cm long) sampled in Portlligat bay (NE Spain), which spans the last 4000 yr. We aimed to reconstruct autogenic and allogenic factors involved in *P. oceanica* mat formation and dynamics. Using principal component analysis, we have been able to identify four processes: organic vs inorganic matter accumulation, carbonates production, deposition of fine particles and metal accumulation. Organic matter (OM) is mostly composed by plant remains, which are deposited at the surface as the plant grows avoiding burial. Its decomposition essentially occurs in the epipedon (upper \approx 40 cm, last 300 yr BP), being very slow below it – i.e. the proportion of organic vs inorganic matter remains almost constant with depth except for punctual increases in mineral matter which reflect past inputs of continental material. Carbonate content seems to be controlled by biocalcifier organism's production, but changes at the top of the core are controlled by OM content. Fine grain size particles deposition is promoted by *P. oceanica* canopy and arid periods. Metallic elements showed two different accumulation records, and are splitted between two components, related to anthropogenic and natural sources. Change point modeling enabled to identify eight main periods: 4000-3600, 3600-3050, 3050-2200, 2200-2000, 2000-800, 800-250, 250-40 and <40 cal BP, involving changes in one or more of the process identified. Several paleoproxies have also been previously studied in the same core, which allows us to discuss the causes of the changes.

P-2201

Mammalian fossils from Hualong Cave, a recently recovered Middle Pleistocene human site in Anhui, China

Haowen TONG

Key Laboratory of Vertebrate Evolution and Human Origins, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China

Abstract

The Hualong Cave of Dongzhi in Anhui Province is located on the southern bank of the Yangtze River, and it was recovered in 2004; several excavations since then have resulted in the discovery of several human remains and numerous mammalian fossils. Currently 43 mammalian species, including indeterminate species, belonging to 24 families and 8 orders have been identified. The fauna is dominated by artiodactyles. The majority of the fossils are bone fragments with very few gnawing marks of rodents, dental specimens are relatively few, and complete bone is scanty. The Hualong Cave fauna is similar to those of Nanjing Man site and Hexian Man site in the following aspects: 1) With human remains; 2) Absence of relict elements of Neogene fauna; 3) Containing the common elements of *Ailuropoda-Stegodon* Fauna of southern China, e.g. *Ailuropoda*, *Stegodon*, *Megatapirus* and *Arctonyx*; 4) Some boreal elements are also presented, but Hualong Cave bears no more than *Cricetulus*, *Lasiopodomys brandti*, *Ursus arctos*, *Sus lydekkeri*, *Cervus (Pseudaxis) grayi* and *Sinomegaceros* sp., and the latter represents the southernmost occurrence of its kind; 5) Containing *Stegodon* instead of *Elephas* as in other Late Pleistocene fauna in southern China; 6) Containing rich postcranial bones, which is different from other cave sites which mainly bear isolated teeth specimens. Based on the faunal composition, the Hualong Cave fauna can be correlated with the fauna of Hexian Man Site, whose geological age should correspond to late Middle Pleistocene.

Silvicolous Neanderthals in the far West: the mid-Pleistocene palaeoecological sequence of Bolomor Cave (Valencia, Spain)

Juan Ochando¹, José Carrión¹, Ruth Blasco², Santiago Fernández¹, Gabriela Amorós¹, Manuel Munuera³, Pablo Sañudo⁴, Josep Fernández Peris⁵

¹University of Murcia, Murcia, Spain. ²CENIEH, Burgos, Spain. ³University Polytechnic, Cartagena, Spain. ⁴Universidad Rovira i Virgili, Tarragona, Spain. ⁵SIP, Valencia, Valencia, Spain

Abstract

A palynological study of archaeological layers from the Neanderthal site of Bolomor Cave, eastern Spain, is presented. Vegetation landscapes for the interval MIS 8 to MIS 5 are described. The sequence, regardless its chronology, is dominated by trees, mainly *Quercus* and *Pinus*, accompanied by a diversity of deciduous, Mediterranean, and thermophilous woody species. It is worth stressing the continuous occurrences of *Olea*, *Fraxinus*, *Pistacia*, *Myrtus*, *Phillyrea* and Cistaceae, and the abundance of evergreen *Quercus*, thus suggesting the existence of a Mid-Pleistocene glacial refugium for mesothermophytic vegetation. To our knowledge, no similar record of forest landscape has been described so far in glacial context for Neanderthals, which bears archaeological and anthropological implications. The record of past vegetation in Bolomor parallels the palaeontological findings, especially concerning the mammal fauna, suggestive of forest landscapes.

P-2203

Late Pleistocene age, size, and paleoenvironment of a caribou antler from Haida Gwaii, British Columbia

Rolf Mathewes¹, Michael Richards¹, Thomas Reimchen²

¹ Simon Fraser University, Burnaby, Canada. ² University of Victoria, Victoria, Canada

Abstract

The basal portion of a fossil caribou antler from Graham Island British Columbia, Canada is the only evidence of large terrestrial vertebrates older than the Fraser (late-Wisconsin) glaciation on Haida Gwaii (former Queen Charlotte Islands). This antler has been radiocarbon-dated three times by different laboratories and all ages fall within the mid-Wisconsin Olympia Interglaciation (Marine Isotope Stage 3; MIS 3). We suggest that the latest date, using ultrafiltration of bone collagen is closest to the true age at $43,200 \pm 650$ BP (48,200-45,200 cal BP). Previous paleoecological analysis using pollen and plant macrofossils from Graham Island reconstructed a vegetation cover during MIS 3 consisting of mixed coniferous forest with non-forested openings, similar to cool subalpine forests of the northeast Pacific region today. These conditions are consistent with environments that support Woodland Caribou today, and likely also the closely related extinct endemic Dawson caribou subspecies of Haida Gwaii. Morphometric comparison of antlers from Woodland and Dawson Caribou suggest that they are more similar than previously interpreted, and raise questions about the inferred differences between the mainland and island subspecies.

Abstract

The site of Fuente-Nueva 3 (Guadix-Baza Basin, Southern Iberian Peninsula) records, together with the very close site of Barranco León, the oldest evidence of human presence in western Europe, as is evidenced by one deciduous human tooth and thousands of Mode 1 or Oldowan lithic artifacts. The age of this site has been established by different methods at ca. 1.2-1.5 Ma. The small vertebrate assemblage from this site includes anurans, squamates, insectivores, rodents and lagomorphs. Anurans are represented by four species (*Discoglossus* cf. *jeanneae*, *Pelobates cultripes*, *Bufo bufo* s.l. and *Pelophylax* cf. *perezi*), while squamates include four lizards (*Chalcides* cf. *bedriagai*, *Timon* cf. *lepidus*, indeterminate small lacertids and cf. *Dopasia*) and five snakes (*Coronella girondica*, *Natrix maura*, *Natrix natrix* s.l., *Rhinechis scalaris* and *Malpolon monspessulanus*). The insectivores (Lipotiphla) are represented by shrews (*Crocidura* sp., *Sorex minutus*, *Sorex* sp., *Asoriculus gibberodon*) and aquatic talpids (*Galemys* sp.). Rodents are represented by arvicolids (*Allophaiomys* aff. *lavocati*, *Allophaiomys* sp., *Mimomys savini*), murids (*Castillomys rivas*, *Apodemus mystacinus*) and glirids (*Eliomys* sp.). Lagomorphs are represented by the species *Oryctolagus* cf. *lacosti*. The Mutual Ecogeographic Range method has been applied to the paleoherpetological assemblage in order to quantify paleotemperatures and paleoprecipitation for the Fuente Nueva 3 site. In this way, the Mean Annual Temperature is calculated in 16.4°C while the inferred value of the Mean Annual Precipitation is 738 mm. In comparison with the current climatic data from the vicinity village of Orce, the Mean Annual Temperature is much higher (+2.6°C) than at present and the total amount of rainfall are also higher (+432 mm) than at present in the Guadix-Baza Basin. Those results indicate a warm climate, with a lower atmospheric temperature range. More specifically, summers should be warmer and winters rather milder, and rainfall should be higher than at present but with an irregular distribution, with four dry months during summer and early autumn. The data reported here clearly support the idea that the early hominin occupation of Europe was strongly constrained by climatic and environmental conditions, rather than by physiography or cultural factors. This paper is part of projects SGR2017-859 and CGL2016-80000-P.

Diet and living environment of extinct *Stephanorhinus kirchbergensis* on the basis of palaeobotany research

Anna Hrynowiecka¹, Renata Stachowicz-Rybka², Magdalena Moskal-Del Hoyo², Krzysztof Stefaniak³, Adam Kotowski³

¹Polish Geological Institute - National Research Institute, Marine Geology Branch, Gdańsk, Poland. ²W. Szafer Institute of Botany, Polish Academy of Sciences, Kraków, Poland. ³Department of Paleozoology, Institute of Environmental Biology, University of Wrocław, Wrocław, Poland

Abstract

In western Poland (near Gorzów Wielkopolski) almost complete remains of a rhino *Stephanorhinus kirchbergensis* were found in lake sediments. From the rhino's teeth, it was possible to extract material that probably corresponds to its last meals. 11 samples of sediments filling of teeth caverns and 6 sediment samples directly adjacent to the jaw were analysed.

Results of pollen, macrofossil and cladoceran analysis of 6 "jaw" samples show dominance of *Carpinus* and *Corylus* communities as the rhinoceros' living environment, which is tantamount on the end of the Middle Eemian Interglacial (MIS 5e). The abundance and variety of remains of aquatic plant species, especially *Trapa* sp., characteristic for sediments of the Eemian Interglacial *Aldrovanda* sp. or *Najas marina* indicate a warm climate and shallowing lake.

Pollen analysis of 11 "teeth cavern" samples indicates that the majority of samples consists of lake sediment that penetrated into the spaces inside the teeth post mortem. Only four samples differ in their pollen composition indicating mainly *Betula* and *Corylus*, as the source of food of the *S. kirchbergensis*. The intriguing discovery was *Taxodium* sp. pollen in amounts up to 4%. This species has not been found yet in the Eemian Interglacial sediments.

The analysis of plant macro-remains allowed to determine only a small fragment of heavily damaged seed scales of *Betula* sp. Fragments of wood were also found. The majority of them represented twigs of 1-2 mm in diameter and were in a bad preservation state due to chewing, permitting only a determination up to the level of angiosperms. However, wood of *Corylus*, *Carpinus* and cf. *Viscum* were identified.

Based on research of woody plant remains found in the teeth of this rhinoceros, and on the basis of the construction of the teeth, it is considered that the rhinoceroses of the *S. kirchbergensis* species nourished themselves with hard branches and twigs of trees and shrubs, deciduous vegetation, woody and shrubby, hence called them a "forest rhinoceros".

Abstract

Research in Africa and Europe shows that vegetation and climate change takes an important role in Pleistocene human migration and adaptation. The scene, however, is obscure in East Asia. Recent decades, hominin fossils and abundant *in-situ* Paleolithic artifacts buried in the loess deposits are discovered in Qinling Mountains (QM), making it an ideal area for this study. Here the vegetation cover and monsoon climate change since ca. 1.2 Ma in QM were reconstructed by pollen analysis. Our results show that the arboreal coverage was relatively higher during interglacial periods than those in glacial periods, consistent with the East Asian summer monsoon change indicated by magnetic susceptibility of loess-paleosol sequences. The site density and artifact abundance suggest that early human preferred warm- humid interglacial climate and open forest/ forest steppe vegetation. Before ca. 0.3 Ma, human, termed *Homo erectus*, might not adapt to the relatively cold temperature in the northern QM during glaciation, and they had to migrate to southern QM, where probably acted as the “source” refuge. Since ca. 0.3 Ma, the broadleaf trees and summer monsoon became retreated, with significantly increasing fluctuation. Along with the worse environment, human evolved into early *Homo sapiens* and changed their adaptation routine in glacial period. The further weakening of Asian summer monsoon and expansion of grassland since ca. 0.07 Ma enhanced their adaptability to grassland and cool climate, and promoted them to migrate to the open plain areas. The migration, adaptation and evolution of Pleistocene human in East Asia were significantly affected by both the glacial-interglacial change and stepwise trend in vegetation and climate.

Abstract

La Puebla de Valverde (Teruel, Spain) fossil locality is one of the most relevant mammal-bearing deposits of the European Early Pleistocene. It is interpreted to be located between the Reunion event (2.27-2.14 Ma) and the Olduvai chron (1.95-1.78 Ma), and represents therefore an association that lived just prior the emergence and diffusion of *Homo*. It has also produced one of the greatest concentration of continental mammalian diversity of the epoch, with a fossil record that comprises 19 macromammalian taxa including also cercopithecoid primates. As such, we consider La Puebla de Valverde as an extraordinary example for gaining an updated knowledge and better understanding about the environmental context that prevailed in Western Europe and that favoured the early occupation of *Homo* in this area. Here, we aim at investigating the diet and ecology of large herbivorous mammals through their long- (molar mesowear) and short- (dental microwear texture analysis) term tooth-wear patterns and hypsodonty to reconstruct climate and habitats of this site in a period for which there exists still a dearth of palaeoenvironmental information. Our preliminary palaeoecological data show La Puebla de Valverde as a complex site, probably composed by steppe-like and open woodland landscapes with a strong development of graminoids. Evidence of this is provided by a considerable dietary breadth found among the large herbivorous-faunas here recorded, with perissodactyls (equids and rhinos) being more engaged in grazing, and ruminants (deer and bovids) being more opportunistic groups, some of which had a significant browse component. Our results provide thus firm evidence that environmental heterogeneity and a wide spectrum of available food resources could have been factors favouring the settlement of early species of *Homo* in Western Europe.

Epivillafranchian-Galerian hyenas from Italy

Sardella Raffaele^{1,2}, Bellucci Luca^{3,2}, Mecozzi Beniamino^{1,2}, Iurino Dawid Adam^{1,2}

¹Dipartimento di Scienze della Terra, Sapienza Università di Roma, Roma, Italy. ²PaleoFactory lab, Sapienza Università di Roma, Roma, Italy. ³Polo museale, Sapienza università di Roma, Roma, Italy

Abstract

The Villafranchian/Galerian transition can be considered one of the most controversial issues in the European biochronological framework. At the Jaramillo Subchron a marked faunal turnover occurred. In Europe the term Epivillafranchian was adopted for this transitional faunas and recently it has been formalized (Bellucci et al 2015). The period 1.2 – 0.7 ma was characterised by the shift of the climate from 41 ky obliquity orbital cycles to a highly non-linear system dominated by 100 ky periodicity with asymmetric glacial/interglacial cycles. This period is characterised by significant fluctuations in $\delta^{18}\text{O}$ values, in contrast to those recorded from the earlier part of the Matuyama magnetochron. A special relevance in defining the biochronology of this faunal turnover is related to the hyenas, and the fossil record coming from Italy is of particular interest. In the Italian fossil record, the large mammal assemblage of Slivia, referred now to the Epivillafranchian, includes the latest occurrence of the giant hyena *Pachycrocuta brevirostris*. The FO of the giant hyaena (*Pachycrocuta brevirostris* event) is the bioevent that marks the Late Villafranchian (Rook and Martínez Navarro 2010) and this carnivore is a common element in the Late Villafranchian and Epivillafranchian assemblages of Europe. The *Crocuta crocuta* bioevent represents a further renewal in European faunas, when most of the Villafranchian large carnivores became extinct. The *Crocuta crocuta* bioevent is documented in the lower unit TD 4/5 at Atapuerca (Spain) (García and Arsuaga, 2001), and the occurrence of the spotted hyaena is documented also at Casal Selce (Rome, around 0,7 Ma) (Sardella and Petrucci 2012).

The effects of climate change upon peatlands: past and future perspectives from a Welsh raised bog.

Luke Andrews¹, Richard Payne¹, James Rowson², Nancy Dise³, Maria Gehrels¹, Simon Caporn⁴

¹University of York, York, United Kingdom. ²Edge Hill University, Ormskirk, United Kingdom. ³Center of Ecology and Hydrology, Edinburgh, United Kingdom. ⁴Manchester Metropolitan University, Manchester, United Kingdom

Abstract

The effects of future climate change are projected to be most severe in the northern hemisphere, where the majority of peatlands (>75-85%) are located. Peatlands represent important long-term terrestrial stores of carbon (C), containing an estimated 600GT C despite only covering 3% of total land area globally. Pristine peatlands act as net sinks of atmospheric CO₂ and sources of CH₄. How projected future changes in temperature, precipitation and other environmental variables will affect the carbon balance of peatlands is poorly understood and results carry large uncertainties due to the complex nature of the peatland carbon cycle.

Two methods are widely used in order to help understand future the carbon dynamics of peat bogs under climate change. Experimental studies measure greenhouse gas fluxes under manipulated climatic and environmental conditions and palaeoecological studies, examine the effects of past climate change upon carbon accumulation throughout the peat profile. However, results from these two approaches can contradict each-other, with many palaeoecological studies suggesting carbon accumulation increases during warming periods, and many warming experiments observing greater carbon loss with increased temperature.

The aim of this project is to link contemporary experimental and palaeoecological approaches to understand peatland response to climate change. Our study focuses on a raised bog, Cors Fochno in Ceredigion, Wales which is the site of a long-term climate manipulation experiment. The contemporary greenhouse gas budgets for these experimental plots are compared to long-term carbon accumulation and how this has responded to Late Holocene climate variability. To understand how the climate manipulations are represented by palaeoenvironmental proxies surface a time-series of surface samples is being analysed. Finally, a high-resolution multi-proxy palaeoenvironmental reconstruction spanning the past 1000 years will be compared with reconstructions derived from short-cores from each plot covering the duration of the experiment from each treatment, to see how faithfully climate manipulation mirrors real periods of climate change.

Understanding the future role of peatlands in carbon sequestration and storage is of vital importance for modelling future climate change.

Ecological climatology along an elevational transect in the outer belt of the European Alps: comparing modern pollen deposition, vegetation, climate

Giulia Furlanetto^{1,2}, Lorena Garozzo², Michele Brunetti³, Cesare Ravazzi²

¹Univ. of Milano - Bicocca, Dept. of Environmental and Earth Sciences, Milano, Italy. ²CNR – IDPA, Lab. of Palynology and Paleocology, Milano, Italy. ³CNR- Institute of Atmospheric Sciences and Climate (ISAC), Bologna, Italy

Abstract

In mountain areas, climate parameters vary strongly with elevation, largely determining the vegetation cover. In turn pollen rain reflects both vegetation cover and climate-triggered pollen production at different elevations. Analyses of modern pollen deposition is essential for a better understanding of fossil pollen sequences in a particular region, and thus for pollen-based palaeoenvironment and palaeoclimate reconstructions. This study analyzes the relationships among modern pollen assemblages, vegetation and climate along an elevational gradient in the outer belt of the European Alps. Modern pollen assemblages have been studied in pollen traps and moss samples from different vegetation communities along an elevational transect (stretching from 1240 to 2390 m asl), as well as the vegetation using the Braun-Blanquet system. Moss samples are assumed to record an average of several years of pollen deposition and can be profitably used as analogues for fossil pollen assemblages; while pollen traps can be expressed as Pollen Accumulation Rates (PAR) and used as a modern reference to estimate past plant population densities. Results of Canonical Correspondence Analysis (CCA) demonstrated a general good agreement with previous studies, which identified elevation as the main gradient in the variation of modern pollen and vegetation assemblages in mountain areas. *Alnus viridis*, the main woody species forming the dwarf forests in the timberline ecotone, shows a specific elevational PAR arrangement under modern climate conditions. The highest PAR values are observed in sites from river corridors and waterfalls with mountain alder scrub. Results of pollen analysis show an uphill transport of strong pollen producers (e.g. *Pinus sylvestris/mugo*, *Picea*, *Castanea*, *Corylus* and *Ostrya*) by wind to subalpine and alpine zones leading to wider pollen belts with less defined boundaries than vegetation. Thus, if it is possible to identify the major vegetation types by means of their modern pollen deposition, it becomes more difficult to identify specific thresholds (e.g. treeline). To overcome these limitations, potential indicator pollen taxa of alpine/subalpine belts (*Vaccinium*, *Rhododendron*, *Loiseleuria*) documented in this study could be useful for this purpose.

Continental molluscs as indicators of hydrological changes during the Late Quaternary in plain rivers

Maria Pisano^{1,2,3}, Maríel Samanta Luengo^{1,2,3}

¹Universidad Nacional de La Plata, La Plata, Argentina. ²Conicet, La Plata, Argentina. ³CEIDE, Universidad Nacional de La Plata, La Plata, Argentina

Abstract

Molluscs have conquered successfully different types of continental environments, both terrestrial and aquatic, have an important record in Quaternary sediments and are usefulness as paleoenvironmental and paleoclimatic indicators. Salado River in Buenos Aires province, Argentina, like all river of plains is a system highly sensitive to environmental changes, both during periodic episodes of intense rains, as it happens today, as dry conditions that causing great economic loss in one of the most important agricultural areas of Argentina.

However, alternation of dry and wet periods is not recent and analysis of the mollusk assemblages allow to know these type of event also during Late Quaternary in the region. Mollusks assemblages have been subjected to an integral analysis, taking into account composition and dominance species changes and their taphonomic characteristics in more than 15 localities throughout of the principal course where sediments have been accumulated during last 13,000 years BP.

Knowing the composition of the communities and habits that species present today, associations show three types of main variations. First, *Heleobia parchappii* plays is the dominant specie in all studied assemblages, analyzing the co-dominant species can be recognized two principal groups: one composed of aquatic gastropods such as *Biomphalaria peregrina*, *Uncancylus concentricus* or *Pomacea canaliculata*, and another with species of hydrophilic or terrestrial habits as *Succinea meridionalis*, *Miradiscops brasiliensis* or *Gastrocopta nodosaria*. These compositional changes, especially the presence of associations of first type from 6000 years BP, allow reconoced an improve in the availability and development of bodies of freshwater.

When analyzing the number of recovered specimens, the density of the individuals recovered it varies from 0 to 10000 individuals, and the alteration of the external surface of the shells has allowed to recognize differents events. Accumulations with high densities of individuals, mainly of *H. parchappii*, and low values of taphonomic alteration (fragmentation scarce, good preservation of color and ornamentation original) would allow to recognize assemblages that have not been transported outside their original habitat and that have been accumulated during an extraordinary flood event.

Conversely, the presence of poorly preserved associations conserved, with evident signs of dissolution and loss of original ornamentation represent shells that have remained exposed more time, probably during drought periods, favoring a greater alteration of the surface in the shells.

Therefore, these changes could be related to the residence time of the remains near the water-sediment interface and the differences in the sedimentation rate of the different exposure cycles suffered by them.

Thereby, integral analysis of the mollusk assemblages from different perspectives (ecological, taphonomic, actalist) has allowed to recognize different events of flood and drought that have occurred in the region in a cyclical way, not only at present but throughout the Late Quaternary.

Abstract

The recent increase in the size and severity of wildfires in the Mediterranean Basin has prompted concern about the future of biodiversity and ecosystem functioning in this plant diversity hotspot. Are fire regime changes unprecedented or have they occurred in the past? What were past fires' effects on ecosystem dynamics, particularly in terms of key biodiversity indicators? Using strict data-quality criteria, we selected palaeoecological records (pollen and charcoal) from the Mediterranean Basin and analysed rates-of-change, richness and turnover in response to fire regime shifts through the last 10,000 years. Event sequence analysis showed that fire regime changes and major fire peaks initiated biodiversity change significantly more often than by chance ($p < 0.05$). Fire regime changes were associated with non-forest turnover, while major fire peaks were associated with richness changes and forest turnover. The timing of fire-led biodiversity changes was non-random and suggests a strong link to the intensification of human activities since the Neolithic. These results reinforce the idea that Mediterranean biodiversity carries a strong legacy of prehistoric fire and land-use change. Palaeoecological records help to pinpoint the likely biodiversity trajectories of future fire, helping to validate ecological theories and paving the way for a more far-sighted approach to land-use policy and management.

Conifer refugia and beech expansion in the North Hungarian Mountains during the Holocene

Zsuzsanna Anna Pató¹, Tibor Standovár¹, Mariusz Gałka², Gusztáv Jakab^{3,4}, Mihály Molnár⁵, Enikő Katalin Magyari⁶
¹Eötvös Loránd University, Faculty of Biology, Department of Plant Systematics, Ecology and Theoretical Biology, Budapest, Hungary. ²University of Lodz, Department of Geobotany and Plant Ecology, Faculty of Biology and Environmental Protection, Lodz, Poland. ³Szent István University, Faculty of Agricultural and Economics Science, Szarvas, Hungary. ⁴Hungarian Academy of Science, Department of Bioarchaeology and Environmental Archaeology, Budapest, Hungary. ⁵Hungarian Academy of Sciences, Institute of Nuclear Research, Hertelendi Laboratory of Environmental Studies, Debrecen, Hungary. ⁶Eötvös Loránd University, Department of Environmental and Landscape Geography, Budapest, Hungary

Abstract

We investigated the stand-scale vegetation changes and the Holocene history of a beech dominated forest in the North Hungarian Mountains. Although several studies provide a broad overview about the vegetation changes in the Carpathian Basin during the Holocene, there is a lack of spatially explicit information about how climate change and human presence influenced the forests in the last several thousand years. Stand-scale paleoecological methods give information about local vegetation changes and long-term ecological processes; however, suitable sites are rare in Hungary due to the temperate continental climate and the relatively low altitude.

We examined the sediment of a small forest hollow (Pisztrángos-hollow, 690 m, 0.15 ha). The site is located in the central part of Mátra Mountains, on the north-facing slope of Kékes (1014 m) in close proximity of the Kékes Forest Reserve, one of the last primary deciduous forests in Europe. The full length of the sediment was 240 cm, we analyzed it at 4 cm resolution for pollen and plant macrofossils. The investigated sediment profile was exceptionally rich in plant remains, and showed a unidirectional vegetation trajectory. The site is dated back to 15,425 Cal yr BP, when an open boreal forest and wet tundra-like habitats are indicated by cold tolerant herbs and *Picea*, *Larix decidua* and *Pinus* remains. Closed forest cover developed around 14,600 Cal yr BP, when boreal European larch - Swiss stone pine (*Larix-Pinus cembra*) forest surrounded the site. This vegetation type remained stable during the early Holocene, up to 7700 Cal yr BP. Between 7700 and 2700 Cal yr BP we observed a hiatus followed by a mixed temperate deciduous forest with *Fagus sylvatica* and among others *Quercus* and *Carpinus betulus*, similar to the current forest cover. The human influence is visible through the presence of cereal pollen from 175 Cal yr BP, the modern deforestations and artificial plantations showed up from 110 Cal yr BP.

The most interesting finding of our study is the relatively long lasting presence of the Swiss stone pine in the Holocene at relatively low altitude (690 m), as it is not the member of the present natural vegetation, and has never been found in Holocene sediments in Hungary before. If our study area was a cold conifer refugium during the Holocene, it is possible that it can play the same role for present day beech forests which are threatened by recent climate change in Hungary.

Palaeoecology is ecology: the new Palaeoecology Special Interest Group of the British Ecological Society

M. Jane Bunting¹, Althea Davies²

¹University of Hull, Hull, United Kingdom. ²University of St Andrews, St Andrews, United Kingdom

Abstract

Palaeoecology is outside the toolkit of many ecologists and often not well integrated with modern ecological research, to the detriment of both ecology and palaeoecology. As Quaternary scientists, INQUA attendees are well aware that given the rates of ecosystem processes and varied species lifespans, ecological dynamics play out over a range of spatial and temporal scales, including those well beyond a human lifetime. The current 'planet-wide experiment' of climate change and the accumulation of evidence from long-term monitoring data over the last few decades emphasise that the timescales needed to understand the effects of ecological and environmental change extend over decades, centuries and millennia, but ecologists still often overlook or are unaware of the insights available from sedimentary records, and regard "long term" data as monitoring series of a few decades. On the other hand, ecology is a rapidly developing and diversifying field, yet engagement with organisations like the British Ecological Society is low amongst palaeoecologists.

In August 2018, a new Special Interest Group within the British Ecological Society was launched, which aims to:

- improve the use of the long timeseries derived from palaeoecological data within the wider ecological community
- bring the latest ecological understanding to palaeoecologists' attention.
- serve as a forum for palaeoecology in Britain and beyond, since the research community is currently spread across multiple different organisations

The BES now recognises palaeoecology as a suitable field for grant support and palaeoecological perspectives are increasingly represented in BES journals. It also provides funding and professional administrative support for SIG events including training, conferences and field based meetings.

This poster will introduce attendees to the British Ecological Society and to the SIG, identify upcoming SIG events, and explain how interested attendees can join the SIG or otherwise become involved in its activities.

Abstract

The processes by which climate change impacts organisms are crucial for understanding community dynamics and even species extinctions. However, such understanding is mainly based on modern observations and therefore the nature of the processes on long timescales is mostly unknown, owing to the paucity of long, direct and continuous records. Egg sequences spanning numerous interglacial-glacial transitions are particularly valuable since the vast majority of animals are oviparous and hatching is sensitive to climate change and thus closely related to community dynamics. Here we present egg records of one of the representative oviparous invertebrates, land snails, from the Chinese Loess Plateau (CLP), covering the last 1,300,000 years (1,300 kyr) that include all the largest-amplitude interglacial-to-glacial transitions. The results show that 20 stages of high egg abundance occur during 17 interglacial-to-glacial transitions. Within each stage, egg abundance reaches peaks when snail abundance is low or decreasing, and vice versa, revealing a near-inverse relationship between egg and snail abundances. The maximum egg abundance within each stage mainly occurs near glacial inceptions or glacial maxima. The 10 largest-amplitude changes are characterized by an over 95% increase in egg abundance and an equivalent reduction in snail abundance. These results indicate that climate impacts on hatching are consistently responsible for large-amplitude oscillations in snail communities over the past 1,300 kyr. Earth's obliquity minima and Arctic amplification, associated with glacial expansions, would have induced strong cooling at high northern latitudes and therefore strengthened the Siberian High and the occurrence of severe seasonal climatic events over the CLP, causing high hatching failures and thereby reductions in snail abundance. Conversely, weakness of severe climatic events would favor hatching successes and thereby increase snail abundance. Our findings stress the importance of hatching in snail community dynamics on long timescales, which may have implications for other invertebrates with similar biological characteristics to land snails.

Peat loss and renewed accumulation in a rewetted, former drained fen

Dierk Michaelis¹, Almut Mrotzek¹, Anke Günther², John Couwenberg¹

¹University of Greifswald, Greifswald, Germany. ²University of Rostock, Rostock, Germany

Abstract

The interdisciplinary project WETSCAPES studies turnover processes in drained and rewetted peatlands in Northeastern Germany. The project aims to support climate and water protection and to provide a basis for **sustainable (wet) peatland cultivation**. The main objective of the project is to understand the development and functioning of drained peatlands after rewetting.

For high resolution analyses we sampled peat monoliths from pairs of drained and rewetted sites in a percolation mire, in a coastal wetland, and in two adjacent alder carrs. The monoliths were cut into 0.5 cm contiguous slices which were subsampled for a set of analyses: micro fossils (palynomorphs), macro fossils, microbial DNA (methanogens, [de]nitrifiers) and soil chemistry (elements, carbon species).

Here we present the results from a percolation mire that was deeply drained for agriculture in the late 1960s. Slight human-induced changes in the hydrology of the mire system date back to at least 1744 (Succow 1969), but significant peat losses likely only occurred after deep drainage in 1967. The site was rewetted in 1997 and is now water-logged during the whole year. Vegetation is dominated by sedges (*Carex spec.*). The monolith of 55 cm includes about 10 cm of newly formed material (litter, roots and radicles) underlain by a 25 cm thick layer of compacted and highly decomposed, amorphous peat material (the former cultivated grassland soil). Below this layer lies the well preserved original peat; the top of this original peat has been radiocarbon dated to ~3.700 cal. BP. These different layers as well as the rewetting event show clear differences in the micro and macro fossil record. Recent roots and radicles are found throughout the profile.

Based on the radiocarbon date, the bulk density, and ash and carbon content of the peat samples, we calculate the loss of peat and carbon during the 30 years of intensive agriculture. Gas flux measurements have shown that the site today is again a net C sink. We try to reconcile the measured fluxes with the newly accumulated carbon in the profile. Together, these data help to better understand the C dynamics of rewetted fen peats.

Temporal scale changes in species distribution in boreal peatlands: Store Mosse, South-central Sweden (preliminary results)

Eleonor Ryberg^{1,2}, Malin Kylander¹, Minna Väiliranta³, Johan Ehrlén⁴

¹Stockholm University, Dept of Geological Sciences, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm, Sweden. ³University of Helsinki, Dept of Environmental Sciences, Helsinki, Finland. ⁴Stockholm University, Dept of Ecology, Environment and Plant Sciences, Stockholm, Sweden

Abstract

Boreal peatlands play an important role in the global biogeochemical cycle of carbon with an estimated third of global soil carbon stored in northern peatlands. Peat is made up of decomposed plant material, making it especially suited to macrofossil analyses. *Sphagnum* mosses can tolerate nutrition-poor and highly acidic environments and, as a consequence, they tend to dominate in boreal peatlands. As such, it is important to understand what factors drive changes in the *Sphagnum* species distribution on longer time scales than that traditionally used in ecological studies as this can impact peatland carbon storage (or release) in the changing climate of the future.

This project aims to assess the internal successional processes and biotic interactions and external climate drivers (humidity, solar irradiation, nutrient supply) of *Sphagnum* species over time in the peat paleo-record, by reconstructing temporal changes in species distribution, identifying the main factors controlling species distribution on multi-decadal to millennial scales, and testing whether current spatial distribution of *Sphagnum* species can be explained by models of temporal distribution of *Sphagnum* in peat cores. It involves three bogs in South-central Sweden: Store Mosse, Dala Mosse, and Draftinge Mosse. By comparing and contrasting across these three sites as well as with relevant published paleoclimate studies, we will examine potential drivers of changes in species distribution in peatlands.

Store Mosse, which is the first focus site of the project, has been studied previously for macrofossils (Svensson, 1988) but the age control in this study was poor (only four ¹⁴C dates). Since then, several detailed paleoclimate studies have been made (Kylander et al., 2013, 2016, 2018) which provide information on major environmental changes at the site over the last 9000 years. A set of triplicate sequences were collected using a Russian corer in November 2018 which exceed these previous studies in depth, reaching to nearly 7 m. Here we present a preliminary age model and plant macrofossil analyses from what will be our "high resolution" sequence from Store Mosse.

Abstract

The Arctic is currently experiencing dramatic ecosystem changes, with immediate effects on ecosystem services connected to food production, climate regulation, natural resources and cultural integrity. Understanding the relative impacts of climate, herbivory and human management on ecosystems, in particular on vegetation, is of paramount importance for their long-term sustainability and conservation, as well as for its inhabitants. Arctic and Subarctic communities, whose livelihoods are closely linked to their environment and who directly depend on the herding and hunting of large herbivores, will have to adapt to the effects of climate warming and vegetation changes. Building relevant scenarios requires understanding the relative roles of climate, herbivory and increased anthropogenic pressures as large-scale drivers as well as on local scales relevant to the communities. Well-informed ecosystem management and species conservation is however precluded by the scarcity of long-term (millennia) data sets spanning ancient and contemporary climatic and land use events. Palaeorecords offer a unique possibility to fill this gap as they provide data on long-term ecosystem development, historic events of climate change and land use modification. In the BiodivERsA project "Future ArcTic Ecosystems (FATE): drivers of diversity and future scenarios from ethno-ecology, contemporary ecology and ancient DNA" we are therefore conducting a comprehensive inter- and transdisciplinary study using sedimentary ancient DNA, current ecological observations and anthropological investigations of indigenous and local knowledge and interpretations. By coupling indigenous and local knowledge with scientific analyses and interpretations, fine-grained and broad spatio-temporal scales, and qualitative and quantitative data sets, we will create scenarios that support decision-making in the face of accelerating socio-ecological transformations throughout the circumpolar North.

To reconstruct past vegetation changes over large spatial (circumarctic) and temporal (Last Glacial Maximum until today) scales, and investigate to what extent changes are driven by herbivory or by climate, we will analyse sediment core DNA for plants, mammals and fungi. This will generate datasets with a high taxonomic resolution for vegetation and herbivores, allowing us to make detailed inferences about questions of palatability and potential toxicity to herbivores, as well as refine reconstructions of past ecological conditions. The data on past diversity changes will be integrated with data from modern ecological experiments to evaluate the stability of biotic interactions through time and space and to parameterize species distribution models, which will be used in ecological forecasting. We here present our approaches for biodiversity reconstruction using sedimentary ancient DNA along with an evaluation of the taxonomic resolution and explanatory power of our molecular methods.

P-2219

An assessment of some of the constraints of pollen-based vegetation studies in Tropics and an experimental method to understand them

Navya Reghu, Prasad S, Ramesh B.R., Anupama K

Laboratory of Palynology and Paleoecology, Department of Ecology, French Institute of Pondicherry, Pondicherry, India

Abstract

While entomophily is the major mode of pollination in tropics, the pollen of anemophilous plants are generally over represented and are the major pollen components of the pollen retrieved from the lake sediments (Bush and Rivera, 2001). This can bias the interpretation carried out by a palyno-paleoecologist in inferring the past vegetation.

In a tropical context ecological associations of pollen taxa are important in delineating the actual landcover and an indicator taxon identified to the species level is quite significant. The present study was conducted primarily to investigate the pollen dispersal-deposition mechanism of a key taxon present in south east India i.e., *Hardwickia binata*, the Indian Blackwood, which is endemic to Peninsular India. This tree is an indicator of dry deciduous forests. The pollen of this taxon could be identified up to the species level because it is the only species of the genus *Hardwickia* in India.

The lesser occurrence of *Hardwickia* pollen in the modern pollen samples and its frequent presence in the pollen samples extracted from the lakes and marine sediment cores directed this assessment. The dispersal-deposition function of the *Hardwickia binata* pollen from its tree was studied by collecting and analyzing the surface samples during the flowering seasons and non flowering seasons at a distance from 0m to 75 m. The surface soil samples were collected at equal intervals of every 3 months during one year. The samples were extracted and assessed at a distance of 5 m, 10 m, 20 m, 35 m, 55 m and 75 m by fixing the *Hardwickia* tree as the centre point.

This study provided two major inferences: (i) *Hardwickia binata* pollen are not predominantly dispersed by wind. (ii) Despite the seasonal changes in flowering pattern of different plants in SE India, the pollen composition of the surface samples collected during an interval of 3 months each in a year, remained almost the same.

Fine resolution pollen analysis arises out of attempts to bridge the gap in time scale that has separated paleoecology (few thousand years) from field ecology (few decades). An important point is the sampling resolution: even a single sample (typically 10-20 years worth of lake mud) would average out all the data of field ecological studies (Green & Dolman 1988). From our study, we conclude that pollen grains indicate vegetation patterns, not on a seasonal basis, but on a longer time basis. This can be perceived as a constraint if we are looking at seasonal or annual patterns.

P-2220

Holocene hydroclimate variability in the glacial highlands of Costa Rica: Evidence for abrupt climate change at 5.2 ka BP

David Porinchu¹, Jiaying Wu²

¹University of Georgia, Athens, USA. ²Florida International University, Miami, USA

Abstract

The vulnerability of high-elevation regions, such as the Cordillera de Talamanca in Costa Rica, to global climate change is extremely high, due in part to vertical amplification of warming. Developing a long-term perspective of climate variability for Central America broadly, and Costa Rica more specifically, through paleoclimate and paleoenvironmental studies, will improve our understanding of the mechanisms driving hydroclimate variability and climate change in the Neotropics.

We make use of an existing chironomid-based calibration set from Costa Rica together with subfossil chironomid remains, sediment geochemistry and charcoal extracted from a 5.75 m sediment core recovered from Lago Ditkebi, in Chirripó National Park, Costa Rica, to reconstruct Holocene hydroclimate variability and paleoenvironmental change in southern Central America. Chronological control for the Lago Ditkebi sediment core is based on eight AMS ¹⁴C dates obtained on charcoal and aquatic moss. Geochemical analyses of the lake sediment recovered from Lago Ditkebi included total organic carbon (C%), total organic nitrogen (N%) and stable carbon isotopes ($\delta^{13}\text{C}$). Variations in the signature of $\delta^{13}\text{C}$, together with the chironomid-based estimates of thermal conditions and the charcoal-inferred reconstruction of the local fire regime, enable the development of an integrated multi-proxy record of regional hydroclimate and environmental change spanning the past ~8100 years.

A holistic consideration of the multi-proxy record developed for Lago Ditkebi, indicates that the glacial highlands of Costa Rica were characterized by: 1) relatively cold, dry conditions and limited fire activity between ~8100 and 5270 cal yr BP; 2) persistent elevated temperature, relatively wet conditions and frequent, high-severity fires between ~5270 and 2820 cal yr BP; and 3) cool, dry conditions, and frequent low-severity fires between ~2820 cal yr BP and the present. Macroscopic charcoal analysis, which indicates that wildfires periodically burned throughout the Holocene, document the occurrence of a sudden and severe fire event at ~5270 cal yr BP and elevated fire frequency between ~3300 and 1600 cal yr BP. Concurrent maxima in C/N, charcoal accumulation rates and the abundance of *Polypedilum* N type, a thermophilous chironomid taxon, provides evidence of the occurrence of an abrupt climate change event at ~5200 cal yr BP characterized by elevated temperature and increased lake levels. A 1.5 cm-thick layer of large macroscopic charcoal and the presence of multiple large woody charcoal fragments (~0.25 cm²) also support the inference that this fire event was the most intense and severe of the entire record. The evidence of an abrupt climate event at ~5200 cal yr BP at Lago Ditkebi, Costa Rica corresponds well with existing records from elsewhere in the low latitudes and provides additional support for the existence of a global-scale event at ~5200 cal yr BP.

Middle-Late Holocene palaeoenvironmental change and anthropogenic impact in tropical Southeast Asia: a multi-proxy lacustrine record from Tasik Chini, Malaysia

Jack Lacey¹, John Boyle², Charlotte Briddon³, Stefan Engels⁴, Mushrifah Idris⁵, Melanie Leng¹, Melody Li⁶, Suzanne McGowan³, Keely Mills¹, Virginia Panizzo³, David Ryves⁶, Muhammad Shafiq⁵, Christopher Vane¹, Lara Winter⁶
¹British Geological Survey, Nottingham, United Kingdom. ²Department of Geography and Planning, University of Liverpool, Liverpool, United Kingdom. ³School of Geography, University of Nottingham, Nottingham, United Kingdom. ⁴Department of Geography, Birkbeck, University of London, London, United Kingdom. ⁵Tasik Chini Research Centre, Faculty of Science and Technology, Universiti Kebangsaan Malaysia, Bangi, Malaysia. ⁶Centre for Ecological and Hydrological Science, Department of Geography, Loughborough University, Loughborough, United Kingdom

Abstract

Tropical areas are currently experiencing rapid environmental change due to the combined effects of climate change and human impact on the landscape. Climate variations in Southeast Asia play a key role in the global hydrological cycle, but past changes in the Asian monsoon system and its effects on local ecosystems are poorly constrained due to a shortage of well-dated palaeoenvironmental records that can provide a longer-term perspective on environmental change. This study investigates sediment cores from Tasik (Lake) Chini situated on the Malaysian Peninsular and provides the first lacustrine record of palaeoenvironmental change from the area. The flood pulse wetland is one of the few lake basins in the lowlands of this region and is of great ecological importance, contributing to the site's UNESCO designation. Tasik Chini comprises twelve interconnected basins with a hydrology dependent on monsoonal rainfall, therefore the lake is highly sensitive to variations in hydroclimate. Here, we provide new information on past environmental changes at Tasik Chini using the carbon isotope composition ($\delta^{13}\text{C}_{\text{org}}$) and Rock-Eval pyrolysis of sedimentary organic matter, diatom assemblage, elemental analysis, and chlorophyll and carotenoid pigments. An established chronology based on ^{14}C and ^{210}Pb dating shows that the cores span the last ca. 4.8 ka, covering the lakes inception as a permanent water body as well as a transition to higher sedimentation rates since the late 19th century. The multi-proxy record indicates large changes in organic matter production and preservation, hydrology, and water quality over the lake's history with the most pronounced variations occurring during the past 150 years, especially since the 1950s. Together, these proxies demonstrate major shifts in the Tasik Chini ecosystem that were most likely driven by a dynamic monsoonal system during the Middle to Late Holocene, and more recently initiated by anthropogenic catchment land use changes. This rare wetland record offers the potential to better understand past hydroclimate development in Southeast Asia and provide context for the human impact-related changes that have occurred, and are likely to continue, in this rapidly developing region.

P-2222

Pollen-based vegetation and climate reconstruction over the mountains of Equatorial Africa over the last 90,000 years

Kenji Izumi^{1,2}, Anne-Marie Lézine³, Masa Kageyama¹

¹Laboratoire des Sciences du Climat et de l'Environnement/IPSL, CNRS-CEA-UVSQ, Université Paris-Saclay, Saclay, France. ²University of Bristol, Bristol, United Kingdom. ³Laboratoire d'Océanographie et du Climat, Expérimentation et Approche Numérique/IPSL, Sorbonne Université, CNRS-IRD-MNHN, Paris, France

Abstract

The inverse modeling through iterative forward modeling (IMIFM) approach was adopted to reconstruct the last 90,000-year climates (mean annual temperature, total annual precipitation, and a plant-available moisture index) at western Equatorial Africa using a pollen sequence from the Lake Bambili on the Cameroon highlands. The pollen sequence provides the first and exceptional high-resolution record of vegetation change in the tropical mountains of Africa over the last 90,000 years (Lézine et al, in press). Pollen data and reconstructed biomes have shown the extreme instability of the Afromontane environments with phases of expansion of different kind of mountain forests alternating with phases of the expansion of savanna and grasslands (Lézine et al., 2013; Izumi et al., 2016; Lézine et al., in press) in response to the glacial-interglacial climate and atmospheric CO₂ concentration changes.

The IMIFM approach, which originated as an inverse-modeling approach, has been developed to consider vegetation responses to changes in atmospheric CO₂ concentration as well as to climate changes. It is based on an equilibrium vegetation model (BIOME4 or/and BIOME5-beta) and overcomes some debated issues of conventional statistical approaches for reconstruction (e.g., modern analog, regression and response-surface techniques). After the Last Glacial Maximum, warming and wet conditions and higher CO₂ concentration promptly established the Afromontane forest and keep it over the Holocene, whereas cold and dry conditions and lower CO₂ concentration promoted the expansion of savanna and grasslands. Compared to climate reconstructions using other data, our climate reconstructions show smaller amplitude. In this study, we also compare our results for Bambili to climate reconstructions over the Equatorial Africa during the last deglaciation (22,000-9,000 years ago) using pollen records from the eastern Congo basin (e.g. Burundi Highlands, Rukiga Highlands and Rwenzori Mountains) in order to discuss the large-scale vegetation and climate changes over the Equatorial Africa.

A continuous tropical record of glacial-interglacial cycles spanning more than 600 ka from Lake Junin, Peruvian Andes

Mark Abbott¹, Donald Rodbell², Arielle Woods¹, Sophie Lehmann¹, Christine Chen³, David McGee³, Robert Hatfield⁴, Joseph Stoner⁴, Mark Bush⁵

¹University of Pittsburgh, Pittsburgh, USA. ²Union College, Schenectady, USA. ³MIT, Boston, USA. ⁴Oregon State University, Corvallis, USA. ⁵FIT, Melbourne, USA

Abstract

Lake Junin (11.0°S, 76.2°W) is a shallow (12 m), high-elevation intermontane lake (4080 m asl) located in the inner-tropics of the Southern Hemisphere. It is dammed by coalescing alluvial fans that are >250 ka formed by glacial debris from low gradient watersheds with headwalls under 4700 m. The lake was drilled by the Lake Junin working group funded by NSF and ICDP in 2015 and over 100 m of section was recovered, spanning over 600 ka based on an age model produced with radiocarbon, U/Th, and paleomagnetic measurements. Sedimentary and moraine evidence indicates that during cold phases glaciers advanced down valleys and approached the edge of the lake, but did not overrun it, whereas during warm phases ice disappeared from the watershed. This limits clastic sediment inputs during interglacial periods, allowing for the precipitation of lacustrine carbonates and the formation of peat deposits during arid phases when lake level is lower. The sedimentary record from Lake Junin provides a detailed record of glacial-interglacial cycles that is characterized by three distinct facies: 1) a clastic-rich, fine-grained facies representing periods of glaciation, 2) an authigenic lacustrine calcite facies that is precipitated from lake water during interglacial periods, and 3) an organic-rich peat facies that forms during times of low P/E, representing periods of low lake level.

Stable isotope measurements of oxygen and carbon on Holocene lacustrine carbonates document changes in the strength of the South American Summer Monsoon (SASM), indicating dry conditions during the early Holocene with precipitation increasing toward the present as Southern Hemisphere summer insolation increased, thereby enhancing monsoon circulation. Oxygen and carbon isotope values are highly correlated throughout the Holocene, supporting sedimentary evidence that Lake Junin is sensitive to changes in hydrologic balance. Although lacustrine carbonates are not precipitated continuously throughout the sedimentary record, where they are present, precessional-scale variability in oxygen isotope values is clear and the amplitude of the signal suggests major changes in the SASM over time. Interestingly, the range of oxygen isotope values during previous interglacial periods is considerably greater than during the Holocene, indicating more variable SASM strength and suggesting that tropical circulation/convection was significantly enhanced in the past.

9000-year multi-proxy record of climate and vegetation change from north-central Cuba

Matthew Peros¹, Anna Agosta G'meiner¹, Nadine Kanik², Bill Buhay³, Shawn Collins¹, Eduard Reinhardt⁴, Felipe Matos Pupo⁵

¹Bishop's University, Sherbrooke, Canada. ²Western University, London, Canada. ³University of Winnipeg, Winnipeg, Canada. ⁴McMaster University, Hamilton, Canada. ⁵Coastal Ecosystem Research Center, Cayo Coco, Cuba

Abstract

Relatively little is known about the climate and environmental history of the Caribbean region. Here we provide a continuous 9000-year long sedimentary record obtained from a karst sinkhole, known as Cenote Jennifer, located on the island of Cayo Coco offshore north-central Cuba, which represents one of the longest and most detailed Holocene paleoenvironmental records for the Caribbean region to date. The sinkhole is 14 m deep and consists of an anoxic bottom which has resulted in the excellent preservation of macrobotanical remains such as leaves, twigs, and bark, and thousands of cm- to sub-mm scale sedimentary laminations. The Cenote Jennifer core was dated by AMS and Pb-210 techniques and analyzed for a range of proxy indicators such as pollen, microcharcoal, grain size, elemental composition by XRF core scanning, O and C isotopes on bulk organic matter, and O and C isotopes on benthic foraminifera. The results of the multi-proxy analysis show that Cenote Jennifer is highly sensitive to both regional- and local-scale environmental and land-use changes. Key findings include: (1) the presence of the 8.2 kyr event; (2) a possible rapid sea level rise event 7600 years ago; (3) a long-term shift from dry to wet to dry conditions during the mid-Holocene; (4) the presence of a severe drought around 1000 cal BP that may correspond to a similar event associated with the Maya Collapse; and, (5) a dry Little Ice Age. In addition, significant deforestation is recorded for the historic period and there is circumstantial evidence for prehistoric maize agriculture beginning as early as 2500 cal BP. The record at Cenote Jennifer provides a continuous and highly detailed window onto the Holocene in the Caribbean and highlights the utility of karst sinkholes as repositories of long sedimentary records.

Geoarchaeology of western Sicily, tracing the footsteps of the Elymi

Chad Heinzel¹, Giuseppe Montana²

¹University of Northern Iowa, Cedar Falls, USA. ²University of Palermo, Palermo, Italy

Abstract

This research employed geomorphic and archeometric techniques to investigate human-environmental interrelationships in western Sicily. Sicily contains a wonderfully diverse geoarchaeological record landform sediment-assemblages and Prehistoric to Historic settlement patterns. The Chuddia River Valley (230 m) between Monte Polizzo (700 m) and Montange Grande (750 m). The southern slope of Montange Grande contained coalescing clast-supported alluvial fans: Verme, Ardigna, Armata, and Lentini. The Armata Fan contained a well-developed paleosol, (A-horizon, 7786 to 8033 cal. yrs BP), indicating a locally stabilized landscape prior to Neolithic occupation. The Lentini Fan contained a complex geoarchaeological sequence. A younger organic-rich channel has scoured and deposited angular limestone particles in a series of eight stacked channels. These eight channels contained diagnostic artifacts including equine skeletal fragments and fossil land snail shells. These data suggest landscape destabilization began shortly before, 7113 to 7294 cal. yrs BP.

Twenty-five stratigraphic sections along the banks of the Chuddia River show a well-preserved record of alluvial sedimentation, diagnostic artifacts and pollen. Chronologic data from radiocarbon analysis of charcoal and diagnostic artifacts from within these sediments indicate three primary periods of sedimentation within the valley, 2340 to 2491 cal. yrs. BP, 1298 to 1429 cal. yrs. BP, and 646 to 735 cal. yrs. BP. These sedimentation periods correlate well with major periods of anthropogenic occupation within the Chuddia River Valley suggesting human-induced landscape changes. These data imply a direct correlation between erosion, deposition, and the growth/decline of the Elymian presence at Monte Polizzo. Pollen analyses from Chuddia River, dating back to 3500-4000 BP, reveals *Olea*, cereals, legumes and several indicators of human activity. This supports the archaeological data showing settlement in the area of Monte Polizzo during the Early Bronze Age. *Juglans* were not recorded in the pollen record from Chuddia River sediments, which may indicate that walnut was not growing in the vicinity of the site. High values of *Isoetes* within the valleys basal fluvial stratigraphic units indicates the presence of water at least during parts of the year. Also the alga *Botryococcus* indicates the presence of water.

Recent archeometric results from Monte Polizzo's cultural material provided evidence towards a local Archaic ceramic production center. A comparison between the indigenous and experimental ceramics revealed that the local potters preferred clays from the Terravecchia Formation. The mineralogical, textural and chemical composition of the Terravecchia Formation's clay correlated well with the recovered indigenous ceramic artifacts recovered from Monte Polizzo (92%). The remaining 8% were interpreted to be imported from the Sicani Mountains. These data facilitate human-environmental interpretations that when used carefully may help us learn from the past and may provide guided insight to the present and future.

P-2226

Polished stone tools from the Caribbean Lowland of Colombia, evidence of an advanced lithic industry and large-scale ecological changes

Juan Gonzalez, James Hinthorne
University of Texas Rio Grande Valley, Edinburg, USA

Abstract

Large numbers of highly polished stone tools occur throughout the Caribbean Lowlands of Colombia. Despite their remarkably large quantities and the impressive craftsmanship they display, the stone tools have gone unnoticed by archaeological surveys. In an area where the surface geology is dominated by thick sequences of pelagic turbidites, reef limestone and sandstone rocks, the presence of stone tools made exclusively from high-grade metamorphic and igneous rocks implies that these were likely imported as finished products. This study reports on an assemblage of over 300 tools collected by farmers as surface finds in the area centered on the Gulf of Morrosquillo in the central lowlands. Using a combination of geological and archaeological evidence, these tools are traced to the Sierra Nevada de Santa Marta (SNSM), a 5800 m high coastal massif, located 300 km to the north, that served as the enclave of the Taironas for 1000 years (AD 600 to 1600). An abundance of high-quality raw materials in the SNSM enabled the development of an advanced and highly specialized lithic industry. Production at a large scale and a well-organized distribution system are required to rationalize the large volume of lithic tools. Ecologic implications of such an industry include increased land clearance, the expansion of agricultural land and management of drainage systems, as were recorded in early European chronicles.

Drainage basin and valley systems in the nature management history

Danila Badyukov, Oleg Borsuk
Moscow state university, Moscow, Russian Federation

Abstract

River valleys and drainage basins were purposefully brought under cultivation in various natural environments since the Holocene. In the process of the cultivation the man-induced changes in landscapes triggered a response in erosional-channel systems; the response differed notably in different parts of the system (closely to the head, in the middle and lower reaches, at the river mouth) according to the principle of the relative importance of factors. The human activity impact is traced geographically - from small river drainage basins to large ones and chronologically - from the Neolithic revolution to the present days. Methods and techniques are considered that were developed by various cultures and civilizations in the process of their adaptation to the hydrological regime (in particular, to liquid and solid runoff fluctuations). Particular attention is given to hydrotechnical constructions having been used on our planet in different historical epochs.

Hydrological change and human activity during Yuan–Ming Dynasties in the Loulan area, northwestern China

Kangkang Li^{1,2}, Xiaoguang Qin², Lei Zhang³, Zhaoyan Gu², Bing Xu²

¹University of Chinese Academy of Sciences, Beijing, China. ²Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ³Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China

Abstract

Human activity on arid lands has been related to oases evolution. The ancient Loulan, an important transportation hub of the ancient Silk Road, developed on an ancient oasis on the west bank of the lake Lop Nur in Xinjiang, China. Previous studies and historical documents suggest that the region has experienced dramatic natural environmental and human activity–related changes over time, transitioning from a particularly prosperous oasis to a depopulated zone with harsh environment after about 1500 a BP (before present, where present = AD 1950). Based on systematic radiocarbon (¹⁴C) dating for natural plant remains and archeological sites in the Loulan area, it was revealed that the region re-experienced oasis environment from 1260 to 1450 cal. AD, corresponding to the Yuan–Ming Dynasties, which is the climate transition stage from the ‘Medieval Warm Period’ to the ‘Little Ice Age’, encompassing a series of pulse-like flood events which cannot be identified from lacustrine deposition due to the limits of sampling resolution and dating. It was found that humans re-occupied the Loulan area and built canals to irrigate farmlands during the period. The more habitable hydrological conditions that resulted from these environmental changes present one major reason for the re-emergence of human activities in the Loulan area.

The LGM and Heinrich Event I on the Iberian Peninsula: A regional climate modelling study for understanding human settlement patterns

Patrick Ludwig¹, Yaping Shao², Martin Kehl³, Gerd-Christian Weniger⁴

¹Institute of Meteorology and Climate Research, Karlsruhe Institute of Technology, Karlsruhe, Germany. ²Institute for Geophysics and Meteorology, University of Cologne, Cologne, Germany. ³Institute of Geography, University of Cologne, Cologne, Germany. ⁴Neanderthal Museum, Mettmann, Germany

Abstract

The spatial distribution and dating of archaeological sites suggest a poor occupation of southern Iberia by hunter-gatherers after the Last Glacial Maximum (LGM) and during Heinrich event 1 (H1) compared to Northern Iberia. The H1 was a period of cold and arid climate conditions and is suspected to have played an important role in the population dynamics in Europe at the end of the Pleistocene. In this study, the potential influence of climate change on the human settlement patterns in Iberia is analysed based on regional palaeoclimate modelling. Here, the WRF model is used to simulate continuous time slices of 30 years of climate conditions representative for both the LGM and H1 at high spatial resolution. The model results indicate that, apart from a general decrease in temperature, a considerable decrease in precipitation over southern Iberia occurred during the H1, that agrees with the available climate proxy data. The analysis of ombrotypes unveils extremely arid conditions, particularly over southern Iberia and during the growing season (summer), which could have constrained the availability of food and water to the inhabitants. The total area in Iberia that can be characterized as ultrahyperarid in summer enlarged from 2% (13 K km²) during the LGM to 22% (148 K km²) during the H1. Likewise, the reconstruction of vegetation types shows an increase of non-arboreal (open shrubland, grassland) types at the expense of arboreal types in southern Iberia for H1. Thus, the different climate conditions and changes in palaeovegetation between the LGM and H1 probably played a major role in the decrease of the hunter-gatherer populations in southern Iberia.

Connections and interactions in the Danube Delta: searching for avulsions and waterways changes since the Greek colonization until the present

Luminita Preoteasa¹, Alfred Vespremeanu-Stroe¹, Anca Dan^{2,1}, Laurențiu Țuțuianu¹, Sabin Rotaru^{1,3}, Liviu Iancu¹

¹University of Bucharest, Bucharest, Romania. ²AOROC-CNRS Ecole Normale Supérieure, Paris, France.

³GEOECOMAR, Bucharest, Romania

Abstract

This research is focused on Danube delta connectivity aiming at deciphering the ancient fluvial and maritime waterways following their specific dynamics during successive historic periods starting with the Greek period (7 c. BC) – or since the first indices (indirect) of fluvial navigation in the delta - until the end of the Middle Age in the region (17th c. AD).

The confrontation of ancient sources (maps and texts), archeological findings, as well as paleogeographical reconstructions of the Late Holocene Danube delta led us to the formulation of a first working hypothesis according to which the first Greek colonies were founded on open coast shoreline (or in its proximity) and declined once with shoreline progradation and their subsequent decoupling from the sea, followed by the concentration of the main navigation along the southern Danube arm called Peuce or Hierostoma in Antiquity (and Sf. Gheorghe in the present) which was also coincident with the Roman limes) during Roman times, until the 7th c. AD and transportation pathways relocation on the northern Danube arm, Chilia, during the Genovese supremacy (ca. 12-14 c. AD) within the Black Sea basin and during Ottoman period (ca.13-19 c. AD).

Our new geo-scientific data (e.g. absolute ages, textural, bio-stratigraphic), as well as new archaeological findings, complement this picture with further pieces of evidence attesting natural waterscape configuration during different historical periods and changes of the deltaic dynamics which influenced the navigation network during the last 2500 years. The newly discovered antique ceramics found downdrift of the former mouth of the southern Sulina branch (Împuțita) which was active during 2100-1300 years ago contribute to the reconfiguration of the existing knowledge about the waterways used by our ancestors. Moreover, these new data shed new light on the existing knowledge about certain parts of the Danube delta evolution (e.g. Chilia arm) in that it proves the latest deltaic lobes developed at a slower pace sometimes earlier than previously reported and add information about delta system inhabitation and services (e.g. Sulina branch).

Mapping the paleogeographic evolution of the Central Asia and human migrations during Late Quaternary

Margarita Shangina¹, Redzhep Kurbanov^{1,2}, Svetlana Shnaider³, Tamara Yanina¹, Kseniya Kolobova³, Krivoschapkin Andrei³

¹Moscow State University, Moscow, Russian Federation. ²Institute of Geography RAS, Moscow, Russian Federation.

³Institute of Archaeology and Ethnography of the Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation

Abstract

The development of the ancient societies of the Early, Middle and Late Paleolithic in Central Asia was determined by the evolution of the natural environment. The dynamics of landscape components and various natural barriers predetermine the direction of migration from adjacent regions. Currently, two main directions of migration are reconstructed: the southern (India and Pakistan) and the south-western (Iranian plateau and the Middle East). There are numerous natural barriers that form serious barriers: high mountains system for the southern route in the cooling phases of climate. In the south-west of this territory it was the dynamics of the level of the Caspian Sea and aridization of the territory of modern Iran and Turkmenistan.

One of the most important geological phenomena in the region of Central Asia is transgressive-regressive dynamics of the Caspian Sea, which, is due to the complex combination of climatic, geological and other natural phenomena. In all stages of transgressive-regressive dynamics, the greatest influence was exerted on the coastal relief. The coastal plain areas decreased in the transgressive stages, and increased in the regressive stages. The area of the Caspian Sea was rapidly decreasing, and it could decay into two levels in the southern and northern basins since the most significant regressions. An extensive meridional land corridor was created in the entire eastern tip of the Caucasus, which also contributed to the mutual infiltration of flora and fauna.

Hypotheses about the infiltration of the Early Paleolithic industries into the Eastern Caspian and North Caucasus regions under conditions of deep sea regression are associated with this process.

The appearance of the earliest stone industries on the territory of the Afghan-Tajik Depression is associated with paleo-migration of population from the South - from Pakistan, India; or from the south-west - from Iran, Turkmenistan

We have attempted to analyze the main stages of the migration of the ancient man in the Quaternary. For the main periods, a series of Paleolithic monuments are identified, for which paleogeographic conditions are determined. Special attention is paid to the development of objects that created natural barriers not only on the periphery of Central Asia, but also between regions (Pamir on the East and Caspian Sea on the West, development of the Aral Sea basin and evolution of main river systems of Amudarya and Syrdarya). We will present new data on the chronology of the Paleolithic of Central Asia and paleogeographic reconstructions in a form of series of maps.

The changing role of wild boar in Ireland during the Mesolithic-Neolithic transition

Jonathan Small¹, Laura Basell¹, Paula Reimer¹, Janet Montgomery²

¹Queen's University, Belfast, United Kingdom. ²Durham University, Durham, United Kingdom

Abstract

Much has been made of the social, economic and symbolic importance of red deer in people's lives from the Palaeolithic through to the Neolithic. Their ecology and significance during prehistory has been extensively discussed and studied through faunal, technological and ethnographic analyses, and studies of genetic and isotopic variation. In Ireland however, flora and fauna during the Mesolithic (the period of Ireland's earliest widespread settlement by humans) were characterised by a restricted range of species compared to Britain and Continental Europe. Large terrestrial prey species, including red and roe deer were absent. Instead, wild boar dominate the mammalian faunal assemblages at both Early Mesolithic sites, (such as Mount Sandel and Lough Boora) and Later Mesolithic sites, (such as Ferriter's Cove and Derragh Island). It has been postulated that the first wild boar were brought to Ireland by humans, and thought that boar were eaten and their hides, fat, bones, teeth and tusks used; but relatively little research has been conducted on the precise nature of boar-human relationships in an Irish prehistoric context¹.

In order to contextualise the arrival of wild boar after the LGM in Ireland, a brief review of the relationship between wild boar and humans in the European Late Upper Palaeolithic, Mesolithic and Neolithic will be presented in this poster. This will be followed by preliminary results from ongoing isotopic analyses of Mesolithic and Early Neolithic wild boar teeth². These analyses should permit the identification of the seasonal locations of boar, allowing insights into the relationship between boar and human landscape-use and human hunting strategies. Understanding wildlife movements during the Holocene can help in understanding the role of human agency in shaping evolutionary processes as well as the changing nature of the historical relationship between humans and animals. Ultimately this research aims to move beyond basic conceptualisations of boar simply as a subsistence or economic resource, to consider boar diets, mobility and their broader ecological niche. This will form a basis for more nuanced considerations of boar-human relationships through time which might include practical aspects such as a) the relationship between settlement proximity and boar access to atypical food sources, and b) the impact of the introduction of domesticated pigs on 'wild' populations; as well as more challenging considerations such as c) how these animals and their remains were viewed by Mesolithic and Neolithic people and d) the degree to which such objects made from them reflected and constructed human-animal relations.

Neolithic arable farming on the SW Baltic coast: insights based on crops, weeds and stable isotopes from Oldenburg sites

Dragana Filipovic¹, Stefanie Klooss², Wiebke Kirleis¹

¹Institute for Pre- and Protohistory, Kiel, Germany. ²Arch•aologisches Landesamt Schleswig-Holstein, Schleswig, Germany

Abstract

The Neolithic sites located in the c. 20km-long Oldenburg depression (Oldenburger Graben) in northern Germany yielded significant amounts of crop products and by-products, demonstrating that arable farming was the mainstay of subsistence economy. The Oldenburg depression represents remnants of a fjord that, by 3000 BC, was completely separated from the Baltic Sea. The Neolithic settlements, which were occupied both before and after 3000 BC, were located on former islands and along the shore of a lowland lacustrine environment into which the fjord was transformed. The depression received freshwater from numerous small streams flowing down the low slopes and creating brackish conditions. In such a hydrologically rich environment, was the area within and near the Neolithic settlements suitable for crop cultivation? This poster sheds light on the nature of Neolithic crop cultivation in the Oldenburg micro-region using selected ecological information on potential arable weeds and the ratios of stable carbon and nitrogen isotopes in the remains of major crops – emmer and barley. It appears that the two crops were grown in dissimilar conditions and were managed to varying levels. This may be understood as an adaptation to the potentially challenging farming environment.

Abstract

The publication of a bear patella that was butchered during the Late Upper Palaeolithic at Alice and Gwendoline Cave, Co. Clare marked a significant advance in the search for the Palaeolithic in Ireland (Dowd and Carden 2016). Nevertheless, not a single stone or bone tool can with certainty be said to represent a human occupation of this island prior to the Holocene and the origin of human settlement here is thus far from resolved. The find makes a compelling case for the need to undertake new fieldwork at cave sites with good potential for yielding Palaeolithic archaeology and/or faunal-bearing Pleistocene deposits. Such evidence can also help to refine windows of opportunity for when people were potentially in Ireland, and can be used to help evaluate models of terrestrial ice cover extent and the timing of the existence of land bridges between Ireland and Britain/mainland Europe.

Many caves in Ireland were excavated in the nineteenth century but we believe that much more work needs to be done to explore for new caves and re-evaluate existing ones. Here we report the preliminary results of new fieldwork undertaken at Ballynamintra Cave, Co. Waterford. This cave was chosen because excavations in the late 1870s in the main entrance passage yielded faunal-bearing stratified Pleistocene/Holocene deposits. We confirmed that Pleistocene deposits do survive in the cave and we discovered remains of dog, wolf, fox, hare, giant deer and brown bear, all of which are undergoing a range of environmental and genetic analyses. Outside of the cave entrance, the removal of an area of roof collapse revealed that the cave once extended outwards by as much as ten metres. Furthermore, an entirely new cave was found beneath the collapsed debris, which we have yet to explore. We thus have a cave with intact deposits that are coeval in age with Upper Palaeolithic sites in Britain and mainland Europe. We believe that further fieldwork at similar caves in Ireland will eventually lead to the discovery of decisive cultural evidence for an Irish Palaeolithic. It is only a matter of time.

Late Pleistocene and Holocene human-environment dynamics in the Stormberg highlands: site formation and palaeoenvironments at Grassridge Rockshelter, South Africa

Christopher Ames^{1,2}, Carlos Cordova^{3,4}, Luke Gliganic⁵, Jerome Reynard⁶, Robyn Pickering⁷, Judith Sealy⁷, Emma Loftus⁸, Marion Bamford⁶, Jayne Wilkins⁷, Ayanda Mdludlu⁷, Benjamin Collins^{9,7}

¹University of Wollongong, Wollongong, Australia. ²University of Victoria, Victoria, Canada. ³Oklahoma State University, Stillwater, USA. ⁴Kazan Federal University, Kazan, Russian Federation. ⁵University of Innsbruck, Innsbruck, Austria. ⁶University of Witwatersrand, Johannesburg, South Africa. ⁷University of Cape Town, Cape Town, South Africa. ⁸University of Cambridge, Cambridge, United Kingdom. ⁹University of Manitoba, Manitoba, Canada

Abstract

Grassridge Rockshelter is located in the high elevation grassland foothills of the Stormberg Mountains in the Eastern Cape of South Africa. This places Grassridge at an important biogeoclimatic intersection between the Drakensberg Mountains, the South African coastal zone, and the interior arid lands of southern Africa. Evaluating occupational pulses in this boundary region sheds light on the timing and nature of adaptation and mobility in the highland grasslands, as well providing insight into socio-cultural exchange networks across biogeoclimatic zones and their relationship to palaeoenvironmental changes.

Grassridge Rockshelter was first excavated in 1979 by Dr Hermanus Opperman. The approximately 1.5 m stratigraphic sequence was initially divided into two major occupational components: a 50-70 cm thick Later Stone Age component dating between 7-6 ka, and an underlying 50-80 cm thick Middle Stone Age component dating to 36 ka. Our team revisited the shelter between 2014-2019 to relocate the original excavation, reanalyse the stratigraphy, and carry out new excavations. Here we summarize our findings and present the results of a multi-proxy site formation analysis and palaeoenvironmental reconstruction of the shelter's stratigraphic sequence. We combine new optically stimulated luminescence, uranium-series, and radiocarbon age estimates with sedimentological, microbotanical, zooarchaeological, and technological analyses to evaluate the relationship between human occupation and environmental change at the site.

Our stratigraphic reanalysis indicates a complex history of geogenic, anthropogenic, and biogenic inputs. The sequence is interspersed with pulsed human occupation spanning the middle Late Pleistocene through the middle Holocene, including multiple new phases of occupation in addition to those identified by Opperman. Occupational intensity is similar throughout the sequence until a dramatic increase in artefact density and sediment accumulation rate in the middle Holocene. There is also evidence for considerable palaeoenvironmental changes during the last glacial maximum, which corresponds to the development of a thin flowstone followed by a millennial-scale depositional hiatus in the shelter stratigraphy. We conclude by placing the results from Grassridge within the regional record to discuss patterns of Late Pleistocene and Holocene human-environment dynamics within the high elevation Stormberg grasslands, and how they relate to the broader record of prehistoric occupation in the high mountains and plateaus across sub-Saharan Africa.

Microblade remains from the Xishahe site, North China, and its implication for the origin of microblade technology in Northeast Asia

Ying Guan

Key Laboratory of Vertebrate Evolution and Human Origins of Chinese Academy of Sciences, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China. CAS Center for Excellence in Life and Paleoenvironment, Beijing, China

Abstract

This study discusses the earliest microblade sites in China and the development of microblade technology in Northeast Asia. The Xishahe site has been discovered in the Huli river terrace deposit in the Nihewan Basin, North China. Dating results indicate that the site was used from about 29-28 ka cal BP, while the microblade remains are from about 27 ka cal BP. The discoveries at the Xishahe site provide some of the earliest radiocarbon dates of microblade technology in China, showing that their appearance and disappearance are highly related to climate change. Although microblade technology has been discovered at the Xishahe site, the technique is different from other younger microblade sites in China, specifically from the mature wedge-shaped core technique. Further, although the microblade cores are well shaped, with platform preparation, and can successfully produce parallel flaking, the overall shape of the cores is varied, lacking high-level standardization. An obvious technological divergence can be seen before and after the Last Glacial Maximum, which lasted from about 24 ka cal BP to 18 ka cal BP.

Leaving an imprint: The long term effect of historic mining on a mountain landscape

Liam Reinhardt¹, Michael Ellis²

¹University of Exeter, Penryn, United Kingdom. ²British Geological Survey, Keyworth, United Kingdom

Abstract

Mining is globally one of the most significant means by which humans alter landscapes; we do so through erosion (mining), transport, and deposition of extracted sediments (waste). The iconic Dartmoor mountain landscape of SW England (~700km²) has experienced over 1000 years of shallow (Cu & Sn) mining that has left a pervasive imprint on the landscape. The availability of high resolution digital elevation models and aerial photographs, in combination with historic records of mining activity, make this an ideal location to characterise the impact of mining over an entire mountain landscape during the past millennia.

Spatial scaling analysis (curvature & semi-variance) was used to quantify the signature of historic mining and to determine how it differs to 'natural' landforms such as mountain Tors. Other forms of historic activity such as peat cutting and quarrying were also investigated. The existence of ~500 years of historical archives also makes it possible to distinguish between the imprint of differing forms of mine technology and their spatio-temporal signature. Interestingly higher technology 19th C mines have left a much weaker imprint on the landscape than lower technology medieval mining; though the former had a much greater impact in terms of heavy metal contamination

Abstract

Permanent ice patches from mountain environments in North America, Europe, and Japan are emerging as valuable archaeological and paleoenvironmental archives. These alpine ice patches have survived perennially for thousands of years, preserving fragile archaeological and biological artifacts and documenting the history of ancient hunters in alpine environments. Permanent ice patches also have the potential to preserve paleoclimate information in the chemical records recorded in the ice. Here, we present a highly resolved 10,000-year ice-core record of northern Rocky Mountain, wintertime climate recovered from an ice patch located on the Beartooth Plateau, Wyoming and compare it with a record of past vegetation and disturbance derived from analysis of plant macrofossils, pollen and charcoal from 29 organic layers in the core. Plant material from each of the 29 organic layers was radiocarbon dated to develop a robust chronology for the 5.5 m-long ice core and pollen and macrofossils were analyzed from each of the organic layers. Water isotopes ($\delta^{18}\text{O}$, $\delta^2\text{H}$) and ice accumulation rates from an ice core from the ice patch suggest a pronounced cooling in the region during the mid-Holocene, consistent with climate inferred from stable isotopes from a speleothem record from the Wasatch Mountains, Idaho and population declines in the nearby Bighorn Mountains. Additionally, radiocarbon dates and a floating chronology of cross-sections of 27 large diameter whitebark pine (*Pinus albicaulis*) trees found entombed in an adjacent ice patch reveal the trees established over 250 meters above current treeline during a warm and dry interval then died as conditions abruptly cooled and became wetter c. 5.3 kcal yrs BP, documenting a period of rapid climatic change. Our findings suggest that these small alpine ice patches preserve regionally-representative climate records that document a sustained 800-year period of peak Holocene warmth centered at 4,100 cal BP followed by a rapid cooling leading to a prolonged era of cooler and wetter winters. The ice-patch records suggest rates of winter temperature changed at the onset and termination of this 1,500-year cold period were as high as observed rates of modern warming. The well-dated ice-patch climate records are consistent with reconstructions of environmental change and closely parallel archeological indices of human activity in western Wyoming throughout the Holocene, with activity suppressed during both especially warm and cold climate periods. The chemical record and diverse assemblages of plant, geologic, and archaeological material contained within ice patches provides a wealth of information about past climate and environmental conditions and archeological resources, presenting an unprecedented opportunity to document and evaluate human use of the alpine during periods of rapid climate and environmental change.

Development of Epipaleolithic in high-altitude Central Asian Mountains (Alay site)

Svetlana Shnaider^{1,2}, Redzhep Kurbanov^{3,4}, Saltanat Alisher-Kyza¹, Ksenia Kolobova¹, Aida Abdykanova⁵

¹Institute of Archaeology and Ethnography SB RAS, Novosibirsk, Russian Federation. ²Novosibirsk State University, Novosibirsk, Russian Federation. ³Institute of Geography RAS, Moscow, Russian Federation. ⁴Moscow State University, Faculty of Geography, Moscow, Russian Federation. ⁵American University of Central Asia, Bishkek, Kyrgyzstan

Abstract

The Alay site represents the earliest, high-altitude human-occupation site currently known in western Central Asia. Recent recovery and analysis of a lithic assemblage from Alay underlines the importance of this site and its role in the cultural and technological development in later Eurasian prehistory. During the field work we described the geomorphological position of the site, obtained a new series of absolute dates (radiocarbon and OSL). This data and analyses of satellite images allowed us to reconstruct the palaeogeographic conditions during which this high-altitude site was occupied by humans. The main factor that dominated the geomorphological evolution of the Alay depression was glaciation of the southern ridges with highest peaks (Lenin and Dzherzhinskiy). Study of the history of the Pleistocene glaciations of the Pamirs and the high-mountainous Western Asia testifies to the synchronous development of the region's mountain glaciers (Stübner et al, 2017; Zech, 2012). However, an important factor in the evolution of the natural environment was the general trend of increasing climate aridity, which was expressed in asynchrony with the global climate cycles. In this regard, the maximum spread of glaciation, expressed in the remaining moraines, occurred at the end of MIS-4 - the beginning of MIS-3, and apparently for high-altitude glaciers, apparently earlier (MIS-4). The further expansion of the glaciation, despite the greater cooling, was limited by the lack of moisture, an increase in aridity and the influence of the Siberian anticyclone (Abramowski et al, 2006). Thus, geomorphology, stratigraphy and geochronology (new luminescence ages) of the region allow us to estimate the age of the Alay site for a period of time after the LGM, in the warming stages of the Allerød (about 14-12 thousand years ago). We will present new geoarchaeological data for this important site and recently obtained luminescence and rock-surface ages that form chronological basis for our environmental reconstruction.

New tools for Quaternary Geomorphologists

Malcolm McClure
IQUA, Dublin, Ireland

Abstract

Public awareness of the Quaternary is handicapped by the absence of any remnants of the thick *mer de glace* and pervasive large icebergs that occasionally covered much of northern hemisphere. Teachers substantiate that chilling image by citing evidence of erosion and deposition as its proxy. To reduce the resulting complexity, they sometimes infer that those processes developed on stable, fixed topography not greatly different from our current familiar surroundings. Anomalous features are attributed to changing sea levels or to sudden melting of the ice sheet. Questions about possible crustal movements are avoided, or adjourned for future consideration by interdisciplinary researchers.

That synoptic picture remained adequate while the public still considered hills and mountains the epitome of venerable stability. —However, careful structural interpretations of representative Irish hills now imply major disruptions of pre-Pleistocene peneplains during the past 3 million years. Isostatic movements produced horsts, grabens, swelling and tilting of the present topography, raising the crust onshore and sinking it offshore wherever thick Pleistocene sediment accumulated. These renewed geological insights need wider dissemination to the public and require a thorough review of their broader implications for Quaternary science.

This preliminary study gives notice of eight places that experienced local differential crustal movements during the Quaternary:

1. Drumlin at Moolagh, Donegal, down-faulted by 26 metres
2. Drumlin swarm east of Donegal Town, tilted *en masse* 1:75 to southwest
3. Sybil Head to Signal Hill at Ferriter Cove, Kerry, raised 160 metres above the Irish peneplain and tilted 1:10 to southeast
4. Croaghleheen mountain, Donegal, a dome that swelled 280 metres above the Irish peneplain
5. Glencolmcille peninsula, Donegal, a horst raised 400 metres above Irish peneplain
6. Three Rock Mountain, Dublin, part of the Wicklow horst raised 300 metres above the Irish peneplain and tilted to the southeast
7. Basal Pleistocene unconformity at Croghan Hill, Offaly, raised by at least 50 metres above the Irish peneplain unconformity
8. Ox Mountains Horst, Sligo & Mayo, raised by 400 metres above Irish peneplain and tilted to southeast.

These examples draw attention to a new set of conceptual tools that could serve future geomorphologists in lieu of continuing reliance on changing eustatic sea levels.

Late Glacial Journeys: using Citizen Science and 3D-terrains to inform pathways of hunter-gatherer migration. A case study from East Midlands-UK

Leanne Hughes¹, Daryl Garton²

¹British Geological Survey,, Nottinghamshire, United Kingdom. ²Beeston, Nottingham, United Kingdom

Abstract

As geospatial technologies develop and become more widely integrated in traditionally non-geoscience subjects, the use of these methods in archaeological research has increased. This has led to opportunities for incorporating geospatial techniques in archaeological outreach and engagement. Historic models of understanding human migration and occupation have relied on 2D maps and terrain defined by contours – an interpretation and context not easily visualised by the non-expert. In this study the authors used an immersive 3D terrain visualisation in ‘GeoVisionary’ to allow volunteers to create a Least Cost Path analysis of human migration between sites of known Late Upper Palaeolithic human occupation in the East Midlands, UK. The quasi-formal group demonstration and ease of route creation in the 3D visualisation software GeoVisionary allowed for a dynamic route to be generated, edited and updated based on paleo-landscape evidence gathered. Compared to contour based route methodologies, there was a greater level of engagement among the volunteers when utilising the 3D visualisation software than other methods.

P-2242

Making the Quaternary relevant through outreach and fieldwork learning approaches

Elvaída Agnes Twesigye, Charles KakuhiKire
Kyambogo University, Kampala, Uganda

Abstract

The Quaternary Period, comprising the Holocene and Pleistocene Epochs, encompasses the last 2.6 Million years during which time Earth's climate was strongly influenced by bipolar glaciation and the genus Homo first appeared and evolved. Climate conditions required a diet heavy in animal protein so they were sophisticated hunters, although recent discoveries indicate they also cooked and ate plant materials, and eventually developed farming which has had an impact on the environment. The classification and interpretation of the youngest stratigraphic sequences, variously known as Pleistocene, Holocene or Quaternary, have been a matter of much debate. Climate change during the Quaternary has produced a geological record dominated by sediments deposited under glacial, periglacial and temperate environmental conditions that are fragmented. This has raised concerns of climate change impacts on the natural environment. The Quaternary Period is characterised by very variable climatic conditions oscillating between interglacial and glacial stages. These repeated and extensive cold stages have included some intense glaciations and these have wiped much of the preceding record leaving the world with a heavily glaciated landscape with many features of uncertain age. Due to the important role quaternary plays in peoples' lives and the significant impact of humans on the environment, there is a great and growing need to improve links between quaternary science, education, and society. Traditionally, education was responsible for passing on the grand narratives of the society, the frameworks for thinking and being, and practices which yielded ways of organising, thinking, saying and doing. However, today with the knowledge society, education is not only about passing on past knowledge and practices, but importantly about entrusting the future to the next generations, equipping them with capacities to survive, organise, think, plan, and act. Education inspires progress in society but at the same time it must respond with foresight to society by developing adequate strategies for quality learning. In order to promote the development and delivery of quality learning in formal and informal Quaternary education, it is important to make it relevant to society through outreach settings and fieldwork learning methodologies to motivate the assimilation of aspects of Quaternary history, biology and geology and its influence on the modern world. These methodologies include: field trips, research and publication of field guides, consultation with stakeholders, holding field meetings with the community, project based learning, use of guest speakers, use of primary sources, and establishment of centers of excellence in quaternary science. These methodologies give insight into the richness that is aligned to teaching and learning of quaternary science. This paper critically examines the mentioned methodologies with particular emphasis on creating awareness and relevance of quaternary period in education, and to facilitate future debate and application of quaternary science in society.

Short outreach documentary on earthquake geology: increasing the seismic risk awareness through active learning

María Ortuño¹, Eulàlia Masana¹, Zoraida Rosellò², María Romero³, Raimon Pallàs¹, Jaume Bordonau¹

¹Universitat de Barcelona, Barcelona, Spain. ²Azora Films, Barcelona, Spain. ³Observatori de la Vida Quotidiana (OVQ), Barcelona, Spain

Abstract

People usually become aware of earthquakes after suffering their catastrophic consequences. However, most people facing a damaging earthquake have not experienced any moderate-large seismic event before. This is especially relevant in areas of slow deformation, where time lapse between damaging earthquakes might take decades or centuries. How to sensitize people to potential earthquakes is a major challenge for the Civil Protection and scientific community devoted to Earthquake Risk Reduction. Aiming to increase the Seismic Awareness in the Iberian Peninsula, the active tectonics and paleoseismology team of the RISK-NAT group (UB), and Azora Films have produced a short documentary starting with the following premises: **i)** effective learning occurs when the examples provided are part of our daily lives and our surrounding landscape; and **ii)** learning through games and experiments will help people acquire the desired knowledge and life skills to increase their seismic preparedness. For instance, a seismic crack on a wall of a building that is on the way to school will make us more aware of our seismic exposure than watching a film about earthquakes in a remote part of the world. In addition, making reference to the mountain that we see through our window as the result of repeated seismic movements may help us grasp the idea that earthquakes might happen at any time and that we need to be prepared to reduce the risks they involve. These concepts are reflected in the documentary, in which the main character is an 8-year old girl who experienced the Lorca earthquake (Mw=5.2, 11st May of 2011, southeastern Spain) when she was one-year-old. The story starts as she wakes up after a nightmare with the quake. She wonders if “forgetting about something means that such a thing will not happen again” and she feels highly determined to know more about that event, how earthquakes happen and what she can do about them. Then, her mother takes her to meet her aunt, a paleoseismologist with whom she makes a trip to the world of earthquake geology. The film shows how the tectonic plates move through repeated earthquakes and how this process happens at different scales, including the close example of faults around her city. The adventure ends in a ludic visit to the paleoseismological excavations of the Risknat group near her locality. Through games and experiments with other children of different ages, she learns how the landscapes change earthquake after earthquake, why living on the valley sedimentary infill means that the ground might vibrate more strongly than in other places and how to protect her when land starts to shake. This film is part of a broader outreach initiative on earthquake awareness (included in the PREVENT project), which will be available at www.latierratiembla.net.

Poetry as a tool for Quaternary science outreach

Hywel Griffiths

Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom

Abstract

The potential of poetry for effective science communication is increasingly being recognised, with poetry workshops and residencies included in a number of recent international conferences and collaborations between scientists and poets and other creative writers becoming more common. Reading, composing and/or performing a poem, through the use of imagery, simile and metaphor can inspire interest in scientific ideas and communicate them to new audiences. More work is needed, however, to understand what the most effective approaches are.

Wales's Irish Sea coasts and estuaries include numerous landscapes and landforms of significant interest to Quaternary scientists (e.g. floodplains, moraines, sand dune complexes), especially as records of glaciation, changes in sea level, and historical storminess and flooding. They have also been key features of the country's historical and cultural history and have provided locations for enduring myths, poems and songs. Their essential ecological and geomorphological roles are increasingly recognized by stakeholders and the general public, especially in the context of coastal flood mitigation, but the potential and significance of coastal geomorphology as archives of environmental change is less commonly recognised.

Through illustrations, photographs, prose and particularly poetry, the people of Wales have creatively represented and interpreted Quaternary coastal landscapes for centuries, providing us with clues to the nature of historical and contemporary human-environment relationships. Here I present an overview of the way in which Welsh coastal landforms have been 'mapped' in Welsh poetry from the medieval period to the present and analyse the effectiveness of two of my own poems inspired by coastal Quaternary geomorphology. Welsh poetry has frequently emphasised the dynamic nature of the coast and the illustrate the rich, long-term creative perspective that Quaternary science provides to poets. I suggest that collaboration between poets and Quaternary scientists could be a valuable and effective tool to increase public interest in and understanding of the value of the field.

From achievement of fieldworks to textbook in elementary schools: Introduction of Liu Tungsheng to Chinese public

Zihua Tang, Jing Wu, Qiang Liu
Institute of Geology and Geophysics, CAS, Beijing, China

Abstract

Over the past half century, the paleoenvironment group at the Institute of Geology and Geophysics (IGGCAS) plays a leading role in Quaternary research of China, where a globally well-known Quaternary scientist LIU Tungsheng once worked for. Based on his outstanding loess research, Prof. Liu persistently focused on the interactions of paleoclimate and past/modern human activities, and was awarded by the Tyler Prize for Environmental Achievement in 2002 and the State Preeminent Science and Technology Award of China in 2003. After he passed away in 2008, we gradually introduce the Nihewan basin, a cornerstone of Chinese paleolithic archaeology where once he worked, to the public via study tours, involving participants into geological sampling, stone tool making, and archaeological survey. Meanwhile, Liu's former office has been transformed into a memorial room, where the visitors have opportunities to approach his field notebooks from his college days, various samples he collected worldwide over 30 years, and his rich publications since 1940s. Moreover, we also facilitated Prof. Liu Tungsheng, as an outstanding representative of modern scientists, into a state-compiled textbook for elementary school pupils in China. To date, Prof. Liu is survived by his disciples scientifically and his achievements are understood by the public increasingly, as well as Quaternary researches.

"Once upon a time... a scientific fairy tale" – storytelling to share knowledge about climate and ocean sciences

Gema Martínez Méndez¹, Sandy Boehnert², Rebecca Borges³, Hadar Elyashiv^{2,4}, Valeriia Kirillova⁵, Chelsea Korpanty², Andrea Orfanos Cheuqelaf⁶, Dharma Reyes Macaya², "Once Upon a Time" teams 2016/17 and 2018/19²

¹Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany. ²MARUM, Research Faculty, University of Bremen, Bremen, Germany. ³Leibniz Center for Marine Tropical Research, Bremen, Germany. ⁴Dr. Moses Strauss Department of Marine Geosciences, Leon Charney School of Marine Sciences (CSMS), University of Haifa, Haifa, Israel. ⁵Alumni MARUM, Research Faculty, University of Bremen, Bremen, Germany. ⁶Institute of Environmental Physics, University of Bremen, Bremen, Germany

Abstract

Humankind is known for practicing storytelling during the Quaternary through various forms of art. Storytelling is therefore one of the oldest ways of sharing and transmitting knowledge and values. It is a worldwide phenomenon, with no political or cultural boundaries. Then why not use it to tell a broad audience about the Quaternary (and beyond)?

Sharing scientific knowledge with the lay public is challenging, even more when there is a desire to inspire change and raise awareness about environmental aspects. The "Once upon a time" team, an international group of marine science PhD and postdoctoral researchers at institutions mainly in Bremen, has applied the longstanding method of storytelling using their personal research, scientific curiosity and environmental concerns. The "Once upon a time... a scientific fairy tale" project was organized in 2016 within the framework of the competition "Show your Science" sponsored by the German science communication foundation "Science in Dialogue" (Wissenschaft im Dialog) with the aim of producing an e-book with stories with scientific content. The project was one of the winners of the competition. In 2017 the first "Once Upon a Time..." volume was published with 12 stories and poems which relate to various marine science themes – from marine biology, ecology, and geology to human interactions with the oceans. The volume was published as an illustrated and free to download e-book in German, English and Spanish. After the competition ended, the team continued working in various directions. Volume I is being translated to Chinese, Filipino, Portuguese and many more languages, to be accessible to as many people as possible. We also perform readings of our stories in schools, art exhibitions and outreach events of our institutions to promote the e-book and generate a genuine dialogue with the public. A second volume of new stories and poems is in progress. Importantly, the group is seeking international collaboration with teachers, citizens, and scientists from other disciplines to improve the pedagogical content and to expand the scope and readership of the "Once Upon a Time..." scientific story network.

P-2247

Resilience, stability and abrupt changes of ecosystems in tropical South America during the late Quaternary

Hermann Behling, Lisa Schueler
University of Goettingen, Goettingen, Germany

Abstract

Detailed records on vegetation and environmental changes during the late Quaternary provided insights on past ecological response on environmental changes. Several examples of resilience, stability and abrupt changes from South America will be presented. Studies from lowlands, highlands and mountains reflect interesting ecological responses to climate change, fire and human impact. Results from continental as well as marine records show that the response of ecosystems on large-scale climate change can be abrupt in decades or within centuries. Studies from different regions indicate how tropical ecosystems evolved to what they are today. Furthermore, they show how sensitive ecosystems are to climate change and how ecosystems responded to natural and anthropogenic environmental changes during the past. This knowledge will help us to understand how ecosystems might change under the ongoing Global Change.

P-2248

Resilience versus vulnerability in desert human societies – are they prone to a permanent risk of collapse?

Yoav Avni¹, Noa Avriel-Avni²

¹Geological survey of Israel, Jerusalem, Israel. ²Dead Sea and Arava Science Center, Mizpe Ramon, Israel

Abstract

The great challenges of living in arid and hyper-arid regions around the world are permanent shortage of water, limited food resources and inherent uncertainty regarding water availability, in terms of its quantity and spatial distribution. These challenges dictate the main weaknesses of desert societies that, according to the existing paradigm, are prone to suffer from a permanent risk of collapse.

However, in the Middle East deserts, human societies are known since prehistoric times traversing the entire hyper-dry Holocene. This fact suggests that the simple common paradigm ascribing high vulnerability to desert societies needs to be re-examined.

As desert societies glob-wide deeply assimilated the inherent difficulties imposed by the desert climate into their survival strategies, they developed special behavioral and social structures to cope with the environmental challenges. These strategies included high geographic and social flexibility, high mobilization, low population density and a robust economy. In terms of Social-Ecological systems, these nomadic and semi-nomadic desert societies lived within systems of flexible geographical boundaries. Therefore, their collapse is difficult to define, compared to sedentary societies. The definition we are suggesting here is this: the abandonment of a large portion of the desert region by its inhabitants and the inability of desert nomadic society to return to this region over a considerable long time. This extreme event is supposed to be far beyond the regular desert oscillations.

If this collapse did occur among desert societies, it was most likely the consequence of the fixation of the once nomadic societies to a certain location within their original large wandering region, or the outcome of the inability of the desert environment to support the increasing number of its inhabitants, both human and their livestock.

However, as reflected in the history and archeology of desert societies in the Middle East - a region in which nomadic and semi-nomadic desert societies are known throughout the entire Holocene - this type of collapse was never documented. On the contrary, in the large region including the Sinai Peninsula, the Negev desert, southern Jordan and northern Arabia, such desert societies are known almost continuously during the last 5-6 millenniums, indicating their high resilience throughout historical times. This long-term survival suggests that, contrary to the common paradigm, human desert societies demonstrated a much more robust structure, based on their extensive knowledge of local geodiversity, hydrology and natural resources and their social and geographical flexibility. All these together resulted in a good adaptation to the desert climate.

Regarding our question - are human desert societies prone to a permanent risk of collapse? We think that, in general, they are probably not. However, we call for a re-evaluation of the existing paradigm in light of glob-wide studies of specific desert societies.

Lake ecosystem shift caused by social-economic transitions: case from Yangtze River Basin, China

ke zhang¹, xiangdong Yang¹, Giri kattel², Qi Lin¹, Ji Shen¹

¹State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China. ²Environmental Hydrology and Water Resources Group, Department of Infrastructure Engineering, The University of Melbourne, Melbourne, Australia

Abstract

Globally, many freshwater lakes have undergone rapid degradation over the past century. Lake scientists and managers are struggling with enhancing lake ecosystem resilience to cope with escalating anthropogenic pressures. A better knowledge on how lakes and social systems evolved up to the present is vital for understanding, modeling and anticipating the current and future ecological status of lakes. By integrating paleoenvironmental, instrumental and documentary sources at multi-decadal scales, we demonstrate how typical shallow lake socio-ecological systems evolved over the last century in the Yangtze River Basin, a biogeographic region containing hundreds of shallow lakes. We find that an abrupt ecological shift, expressed as a significant reorganization of lake aquatic species and communities, occurred around the AD 1970s. Land reclamation, hydrological modification, and pollution seem to have acted directly and synergistically to cause this shift. We argue the lake socio-ecological systems went through three stages as society transformed from a traditional agricultural to an urbanized and industrialized society. The dominant feedback has changed from conventional farmer-ecosystem feedback to newly formed socio-economic and ecosystem feedback, due to increasing population, social wealth and resource demand during the last decades. Our results highlight the importance of accounting for the long-term dynamics and feedbacks between ecological, social and economic changes when defining safe operating spaces for sustainable freshwater ecosystem management.

A 260 000-year reconstruction of diatom community dynamics in Lake Chala, a tropical crater lake

Heidi Tantt¹, Christine Cocquyt², Dirk Verschuren¹, Elie Verleyen¹

¹Ghent University, Ghent, Belgium. ²Botanic Garden Meise, Meise, Belgium

Abstract

Lake Chala is a c. 90 m deep meromictic, oligotrophic crater lake near Mt. Kilimanjaro in equatorial East Africa. This sub-humid tropical region experiences two rainy seasons separated by a long dry season in June-August, when deep mixing fuels the epilimnion with nutrients resulting in increased phytoplankton primary production. Within the ICDP DeepCHALLA project, a 215-m long continuous sediment sequence was obtained, which provides a unique opportunity to study long-term climate dynamics and aquatic ecosystem response during the past c. 260 000 years. Here we analyzed fossil diatom assemblages to reconstruct temporal dynamics in the lake's diatom community structure with millennial-scale resolution. A minimum of 400 valves were counted and identified with best-possible taxonomic discrimination from sediment samples taken at c. 800-yr intervals throughout the last glacial cycle (back to c. 160 kyr BP) and at c. 1600-yr intervals throughout earlier lake history. At the base of the sequence (c. 260 kyr BP) the diatom community is dominated by a small cyclotelloid diatom resembling the tychoplanktonic *Discostella stelligera*; we tentatively interpret this to reflect open-water conditions with near-presence of littoral habitat during the early filling stage of lake ontogeny. High proportions (20-50%) of an *Encyonema* species c. 240-230 kyr BP indicates increased prevalence of benthic habitats, possibly because of a pronounced low-stand at the time when the central ash cone on the basin floor was still free of overlying sediments. Other prominent but short-term appearances of benthic species occur at c. 140 kyr BP (*Gomphonema* sp., up to 100%) and c. 130 kyr BP (*Epithemia* sp., 20%). At all other times between c. 230 and 140 kyr BP the diatom community is dominated by fluctuating abundances of small, medium-sized and long *Nitzschia* species. After that time the diatom community starts to resemble the present-day community with dominance of the planktonic *Afrocybella barkeri* and *Nitzschia fabiennejansseniana*, which currently bloom at the end of the long dry season when the lake is deeply mixed. Between c. 110 and 90 kyr BP, i.e. broadly during the pronounced low-stand attributed to MIS5 African megadrought, all small *Nitzschia* species are lacking and *A. barkeri* reaches a relative abundance of up to 100%. An as yet undescribed second *Afrocybella* species replaced *A. barkeri* during the Last Glacial Maximum (c. 22-17 kyr BP). Superimposed on these long-term changes in diatom functional groups, we found many strong but short-term fluctuations in the appearance of different small *Nitzschia* species, which may reflect stochastic colonization and extinction events rather than marked climate-driven fluctuations in the abiotic environment of Lake Chala. This may also apply to the occasional appearances of *Aulacoseira* species; alternatively they indicate periods of increased water-column turbulence that allowed these typically strongly-silicified, fast-sinking cells to remain in suspension.

Climate-vegetation turnover relationships in at the Pleistocene-Holocene transition

Alistair Seddon^{1,2}, Allison Stegner³, Marc Macias-Fauria⁴, John Williams³, Kathy Willis⁵

¹University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, Bergen, Norway. ³University of Wisconsin-Madison, Madison, USA. ⁴University of Oxford, Oxford, United Kingdom. ⁵University of Oxford, Oxford, USA

Abstract

Regime shifts are large, abrupt, and persistent transitions in the function and structure of ecosystems and may become more in the face the projected climate changes expected by the mid-21st century. Regime shifts in vegetation can either be driven by a large, extrinsic-forcing variable (e.g. abrupt climate changes at the Younger Dryas resulting in widespread- and abrupt vegetation changes), or represent a non-linear response to a climate forcing (e.g. a critical transition between alternative stable states resulting from a positive feedback). Depending on a combination of historical disturbance regimes, and the contemporary vegetation structure and functioning, recent research from satellite data indicates that contemporary biomes can be more or less sensitive to climate variability. As a consequence, different ecosystems may exhibit different sensitivities to climate driven regime shifts in the 21st century.

Regime shifts are also commonly identified in palaeoecological records, and long-term ecology may therefore provide a useful set of tools to understand the factors leading to abrupt changes in ecosystems. Specifically, periods of abrupt warming in the past can be used as natural experiments to learn about how different ecosystems respond to climate change. Here, we investigate the patterns and drivers of abrupt vegetation change in Northern Hemisphere biomes across a period of abrupt climate warming at the Pleistocene-Holocene boundary. Our analysis is based on the following questions: i) which biomes demonstrate higher or lower sensitivity to climate and other land-use changes? ii) can we identify periods when the relationship between ecological turnover and climate change is linear or non-linear? These questions are relevant for predicting the type and nature of abrupt ecosystem change as a result of the projected changes in the 21st century.

Ecosystem responses to abrupt climate change: insights from the Mediterranean

Amy McGuire¹, Katherine Roucoux², Ian Lawson², Christine Lane¹

¹University of Cambridge, Cambridge, United Kingdom. ²University of St Andrews, St Andrews, United Kingdom

Abstract

Palaeoenvironmental sequences from the Mediterranean have, for many years, been a cornerstone of our understanding of ecological responses to Quaternary climate change. Lake Ioannina, North West Greece, is one such archive, with a record which spans the last 245 kyr (Tzedakis, 1994; Roucoux et al., 2008). Previous work at the site identifies less pronounced vegetation responses to sub-orbital climatic change to those identified in pollen records elsewhere in the Mediterranean, with the suggestion that local conditions buffered the extreme effects of Quaternary climate variability (Tzedakis et al., 2002). New work, presented here, seeks to test this hypothesis. Two visible tephra layers, the Pantelleria Green Tuff (~45 ka BP) Campanian Ignimbrite (~39 ka BP) provide a temporally well-constrained “window” for palaeoecological study at decadal resolution. These tephra isochrons facilitate precise correlation of the Ioannina pollen record with key local and regional archives of palaeoecological change such as Lago Grande di Monticchio (Italy), Lake Ohrid (Albania), and Tenaghi Philippon (Greece). Such tephra correlations allow comparison of the nature of vegetation response at different sites to the same climatic oscillations with less ambiguity than work reliant on traditional geochronological approaches. In doing so this work will provide an insight into differences in ecological resilience (see: Davies et al., 2018) to millennial scale climatic variability between multiple Mediterranean ecosystems.

Abstract

Fire is the most frequent disturbance in the Ericaceous belt, the dominant plant community of the Afrotropical environment (3300-4000 m asl). By resprouting after fire, *Erica* establishes a fire-trap feedback in which a positive relationship exists between certain fire regimes and *Erica* spp. occurrence. However, present-day human activities in the Bale Mountain National Park (BMNP, Ethiopia) constitute a fire and grazing regime that may have a negative impact on the resilience of the Ericaceous ecosystem. Current knowledge of *Erica*-fire relationships is based on modern investigations, lacking a longer time perspective that can shed light on potential baseline conditions for the fire-trap. We hypothesize that fire has always existed in the BMNP, and has a long-lasting influence on the *Erica* vegetation. To test this, we aim to: 1) identify the fire history of the BMNP at millennial time-scales through a 14 kyr-long charcoal and pollen record from Garba Guracha, a lake at 3950 m above sea level (asl); and 2) describe the long-term bidirectional feedback between wildfire and *Erica*, which defines the ecosystem's resilience. Applying transfer functions to our charcoal record, we reconstruct the fire magnitudes in terms of burnt area, number of fires per year and fire radiative power. We fit a generalised least squares (GLS) model on lagged data to establish the effect of fire on *Erica* species and vice-versa. Our results indicate that fires have always occurred in the BMNP, with a particularly intense early Holocene burning phase equivalent in magnitude to the present-day fire regime. Our model proves that the bidirectional relationship between fire and *Erica* is positive; *Erica* presence is in part explained by fires that occurred in previous centuries and decades. Similarly, *Erica* fuel accumulation at decadal to centennial scales reinforces fire occurrence. We find that the Ericaceous belt is thus a long-term fire resilient ecosystem and that fire should be integrated in landscape management at the BMNP.

Exploring vegetation resilience of the Subantarctic Patagonian communities by ecological modeling and the analysis of Holocene records.

Gonzalo Sottile^{1,2}, Marcos E. Echeverría^{1,2}, Marcela S. Tonello^{1,2}, M. Virginia Mancini^{1,2}, Pablo E. Meretta³

¹Instituto de Investigaciones Marinas y Costeras, Universidad Nacional de Mar del Plata, Facultad de Ciencias Exactas y Naturales, Laboratorio de Paleoecología y Palinología, Funes 3250, Mar del Plata, Argentina. ²Consejo Nacional de Investigaciones Científicas y Tecnológicas, CONICET, Mar del Plata, Argentina. ³Instituto de Investigaciones Marinas y Costeras, Universidad Nacional de Mar del Plata, Facultad de Ciencias Exactas y Naturales, Grupo de Biodiversidad de invertebrados marinos, Mar del Plata, Argentina

Abstract

Subantarctic Patagonian ecosystems might experiment important changes under future climate warming. The precipitation and temperature gradient at the southernmost Andes determines a clear zonation of High Andean dwarf shrubs communities, mid-altitude *Nothofagus* forests and shrub-grass communities in the lowlands. In this research we show how ecological and paleoecological methods provide interesting results to study Subantarctic Patagonian vegetation long-term ecological resilience. We focus on the analysis of modern and paleo vegetation arrangements and diversity patterns variability. First we explore modern patterns of vascular plant taxonomic and functional diversity through generalized linear models. Second we evaluate modern vegetation diversity representation by pollen diversity collected at moss polster samples. Third we interpret past vascular plants diversity patterns and past vegetation changes during the last 12.000 cal yrs BP through the analysis of pollen, charcoal and macro-remains of a peat bog at Parque Nacional Los Glaciares, Santa Cruz, Argentina (50.26°S; 72.85°W). We identified 4 different vegetation arranges during the Holocene: High Andean grass-dwarf shrubland, dwarf shrubland, forest and grassland. We evaluated past vegetation and diversity changes related to past disturbance regime (fire occurrence and tephra deposition) and climate variability (mean annual precipitation and temperature). The analysis of the proxy record and the comparisons with past climate reconstructions suggest that High Andean grass-dwarf shrublands are more resilient to fire regime changes than forest communities. Also we detected that the replacement of High Andean grass-dwarf shrublands by forests since ca 8000 cal yrs BP which produced a high decrease in plant diversity has never been reverted. Since the last 7000 cal yrs forests communities have been quite stable despite to climate variability except during the Little Ice Age (LIA) where there was a sharp replacement of forest by grasslands. Forest recovery after LIA took a hundred years to recover to values similar to those recorded at 400 cal yrs BP. Modern rates of forest recovery after human induced fires during the early 20s century are much slower than those registered by the proxy record after LIA. The decrease in forest recovery rate may be related to the introduction of cattle and the European hare since European settlement in the area ca 1880s.

The long term perspective warns us about possible vegetation displacements in the future. The continuous reduction of the high Andean communities during the last 12.000 cal yrs alert us about possible local or regional extinctions of different vascular plants adapted to these cold Patagonian environments and its consequences to other insects, mammals or birds that depends on these unique flora.

Network-based metrics of community resilience and dynamics in lake ecosystems using palaeoecological data

David I. Armstrong McKay^{1,2,3}, James G. Dyke^{1,4}, John A. Dearing¹, C. Patrick Doncaster⁵, Rong Wang⁶

¹Geography and Environment, University of Southampton, Southampton, United Kingdom. ²Stockholm Resilience Centre, Stockholm University, Stockholm, Sweden. ³Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ⁴Global Systems Institute, University of Exeter, Exeter, United Kingdom. ⁵Biological Sciences, University of Southampton, Southampton, United Kingdom. ⁶State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

Rather than respond gradually to stressors, ecosystems can suddenly undergo a critical transition to a new regime state after reaching a tipping point, such as a lake shifting from a clear to turbid state as a result of eutrophication. Much effort has been employed in developing robust resilience metrics that could act as early warning signals of impending tipping points by monitoring system metrics for statistically observable changes such as increasing autocorrelation and variance. However, these metric-based techniques have not always been found to be reliable in detecting critical transitions in a wide range of systems. More recently novel methodologies focusing instead on the changing structural composition of an ecosystem, such as compositional disorder and food web stability, have been developed that offer an alternative means of assessing ecosystem stability.

Here we present two novel network-based methodologies for estimating past community stability from palaeoecological abundance data by inferring community structure over time, and their application to diatom abundance data spanning several decades from a selection of Chinese lakes at differing points of eutrophication. We find evidence of increasing diatom community instability during eutrophication in lakes Tai bai, Erhai and Longgan, while there are no consistent long-term signals in the unpolluted Shade Co and Moon lake. These results compare favourably against classical early warning signal and compositional disorder metrics when applied to the same data.

P-2256

Make lake go green- a hybrid agent-based model simulating eutrophication in Lake Erhai, China

Yanjie Zhao, John Dearing, Patrick Doncaster, Peter Langdon
University of Southampton, Southampton, United Kingdom

Abstract

Lake ecosystem is regarded as an ideal experiment field for exploring complexity and system dynamics due to being reasonably self-contained. Eutrophication, notoriously known as an ecological problem induced by nutrient, has been studied a lot due to biological amplification of water deterioration. Numerous empirical studies investigated and reconstructed rich data in limnology and paleolimnology to reveal environmental and ecological changes in system. To understand the cause-and-effect relationship between species and function groups, ecological modelling is a good complement to bridge such a gap, testing hypothesized mechanisms of dynamic change and simulating what scenarios the increased nutrient input results in. Here, we use a novel approach of hybrid modelling Lake Erhai, in southwest China. It is well studied empirically and owns abundant spatial and temporal data sets. Though Erhai lake has not facing large-area algal bloom yet, it was reported to have passed a critical transition to turbid water state in 2000s and there are cyanobacteria bloom near shore in recent years. Besides ecological monitoring and investigation, lake sediment records including diatom were successfully revealed during the past 130 years. Our methodology takes both ABMs' (Agent-Based Models) strength in simulating stochasticity and emergence and SDMs' (System Dynamic Models) advantage in anticipating changes over time in complexity systems. Different from regular setting of agents in ABMs as individual species, we nominate key function groups related to nutrients as agents interacting in specific rules. In phytoplankton, diatom and cyanobacteria have been listed separately for monitoring. Preliminarily, the model named "make lake go green" comprises of two main submodels. The ABMs submodel simulates how biological communities change and the SDMs submodel runs an empirical hypothesis of potential feedback loop network to compare. However, due to the difficulty of whole-lake ecosystem modelling, our scope will zoom out from unstratified water, then gradually combining cooperative partial systems to enhance complexity. Carrying out repetitive experiments, we expect to get validation from empirical evidence and try projecting various scenarios for prediction. To achieve this aim, we will use HPC (High Performance Computer) IRIDIS4 in University of Southampton to run ABMs on Netlogo and R. Results will be produced from hundreds thousands agents and all variables in experiments by modifying different parameters.

Tipping Points?: Rapid Neo-glacial transitions in Greenland

Sarah Woodroffe, Eleanor Maddison, Helen Ranner, Brian Huntley, Antony Long
Durham University, Durham, United Kingdom

Abstract

Possible 'Tipping Point' behaviour has been identified across a spectrum of palaeoclimatic studies, for example, the relatively rapid climatic changes associated with shifts from glacial to interglacial conditions, or short-lived excursions such as the 8200 yr BP cold event. The majority of these changes can be attributed to external forcing mechanisms, such as orbitally-forced changes in insolation, or to internal mechanisms or feedbacks such as pro-glacial lake drainage, changes in ice-sheet extent and sea-level changes.

This study explores a pronounced climatic cooling event. The transition from the generally warmer conditions of the Holocene Thermal Optimum (HTO) to the cooler Neo-glacial is recorded across much of the northern Hemisphere and in a range of proxy records, although, the date for this event at individual localities ranges between 4000 and 6000 yr BP. The signal is particularly clear in Greenland ice-core borehole temperature profiles and ice-rafted debris content of ocean cores from east of Greenland. The underlying mechanism for this climatic transition remains undetermined. Our objective is to investigate the cause(s) for this event by developing new, high temporal resolution palaeoclimatic records from Greenland, using complementary climate proxies, including pollen, Chironomidae and diatoms.

This poster presents new palaeoclimate reconstructions following pollen and chironomid analysis from two lakes close to the ice sheet in the Nuuk fjord area, Southern Greenland. These new palaeoclimate records are based on quantitative temperature models which use enhanced modern training sets of pollen and chironomid data from the Nuuk fjord area (chironomids) and the local area alongside data from elsewhere in the north Atlantic arctic region (pollen). The Neo-glacial transition is identified in the lake cores and its characteristics are discussed within the framework of existing records from the region. These new quantitative reconstructions based on local modern training sets allow a much more accurate understanding of past Greenland climate dynamics than has hitherto been possible.

Holocene trends in phototrophic communities from four lakes in south-western Greenland: the role of ontogeny, climate and climate-catchment interactions

Antonia Law^{1,2}, Suzanne McGowan³, John Anderson²

¹Keele University, Keele, United Kingdom. ²Loughborough University, Loughborough, United Kingdom. ³Nottingham University, Nottingham, United Kingdom

Abstract

Fossil diatom assemblages from lake sediment records across the Arctic have been widely used to reconstruct palaeoenvironmental, palaeoclimate and palaeoecological change. In the low arctic region of south-western Greenland, diatoms have been used alongside chemical and sedimentary proxies to investigate Holocene scale trends in lake development, a process termed ontogeny. These Holocene age lakes demonstrate comparable long-term trends in the nature and pace of lake ontogeny, regardless of climatic setting. However, periods of climate change can cause excursions from the long-term ontogeny trajectory in some lakes; lakes and their catchments filter the impacts of climate change differently depending on their geomorphology, soil and vegetation cover and lake depth. Unlike diatoms, which represent one algal group, sedimentary pigment analysis allows for all components of the phototrophic ecosystem to be integrated and investigated, yet there is an absence of high-resolution, Holocene-scale sedimentary pigment data from Greenland. It remains unknown how different phototrophic groups (e.g., chrysophytes, cryptophytes and cyanobacteria) respond to lake ontogeny and climate change.

Lakes in south-western Greenland provide an opportunity to investigate long-term changes in climate, the lake catchment and ontogeny independent of human influence. We present continuous, Holocene-scale records of phototrophic communities from two paired lake sets from south-western Greenland. In the Kangerlussuaq region, there is a marked shift from a warmer continental climate inland to a wetter, cooler maritime climate at the coast, allowing the effect of climate on phototrophic communities to be investigated. Therefore, using HPLC we investigated sedimentary pigments from two lakes from the coast and two from the inland area to allow comparisons over Holocene timescales. The results demonstrate comparable long-term trends overall biological production as a result of lake ontogeny. However, periods of climate change which can initiate changes in catchment vegetation (e.g., soil and catchment deterioration) lake depth and thermal structure (e.g., arid periods and lake level lowering) can result in rapid regime shifts in autotrophic community composition. Although, not all lakes register regime shifts simultaneously in response to climate change and the associated climate-catchment interactions. These results suggest that phototrophic communities may undergo rapid regime shifts in response to future climate change. Furthermore, phototrophic lake communities experiencing the same climate forcing may demonstrate contrasting responses to climate change.

Applying deep learning convolutional neural networks for improved automated classification of pollen

Katherine Holt¹, Jose Aznarte², Victor Sevillano², Ben Pedersen¹

¹Massey University, Palmerston North, New Zealand. ²Universidad Nacional de Educación a Distancia-UNED, Madrid, Spain

Abstract

Pollen-based vegetation reconstructions underpin much of our understanding of late Quaternary ecological and climate change. Yet pollen analysis is a time-consuming and subjective process. Thus it is no surprise that the automation of pollen counting has increasingly featured within the literature, especially with the rapid enhancements of computing and imaging technology in recent decades. While the results of existing studies can be regarded as promising, they are limited in that they typically deal with a relatively small number of taxa (max 26, mean 8), and accuracy rates vary. While some palynological applications may require a lower level of taxonomic diversity than others, it is arguable that many real world pollen problems, such as those faced in Quaternary vegetation reconstructions, will require higher diversity than that of most of the existing studies. Previous reviews have suggested that the minimum number of taxa for paleoecological applications would be around 40 types.

Here we have applied two types of deep learning convolutional neural networks (AlexNet and DenseNet) to classifying pollen images from 46 different taxa. Our dataset includes several pairs of morphologically similar types which human analysts traditionally have difficulty separating (*Leptospermum scoparium* and *Kunzea ericoides*, *Fuscospora truncata* and *Fuscospora fusca*, *Brachyglottis* and *Olearia*). Images were captured automatically using the Classifynder™ automated palynology system.

The DenseNet and AlexNet CNNs achieved 99% accuracy in classification. 97 - 99% on a 46 class problem is the highest success rate, when weighted for the number of taxa, of any attempt at automated pollen analysis currently documented in the literature. Our next steps are to modify the algorithms to provide a classification confidence measure to help with 'unknown' pollen types and other objects not featured within the training library, and to test the systems on broken and deformed pollen, such as those encountered in Quaternary samples.

Paleoecological Late Holocene tale of varved Lake Kuninkaisenlampi, eastern Finland – Diatoms, natural eutrophy, and erosion intensity changes

Mira Tammelin¹, Yu Fukumoto², Saija Saarni¹

¹University of Turku, Turku, Finland. ²Ritsumeikan University, Kyoto, Japan

Abstract

Varved (i.e. annually laminated) lake sediments allow high temporal resolution studies of short- and long-term environmental change. Several varved lakes have been documented in Finland. Most have clastic-organic laminae and are located on catchments comprising till, bedrock, and fine-grained materials. The clastic laminae typically reflect the intensity of spring floods, but recently a marked difference has been discovered in the climate-catchment interaction of lakes located on fine-grained basal till in central Finland. Lakes in this fine-grained till region are also naturally eutrophic, in contrast to the nutrient-poor lakes in areas with coarse-grained basal till. Fine-grained tills occur sporadically in regions once covered by the Eurasian and Laurentide ice sheets. Their occurrence has been associated with ice sheets overlying sedimentary bedrock. However, the fine-grained till overlying crystalline bedrock in central Finland formed under inactive continental ice between actively flowing ice streams. Its fine fraction includes redeposited interglacial sediments. Despite the important contribution of fine-grained till to the functioning of lakes, studies on such lakes are limited.

We deepen the knowledge on these exceptional lakes by examining the varve-dated diatom assemblage responses of Lake Kuninkaisenlampi to natural and anthropogenic drivers during the Late Holocene. The small and naturally eutrophic Lake Kuninkaisenlampi is located in the fine-grained till area of central Finland and it is connected to a larger drainage system via a narrow channel. Our sample resolution increases from centennial to decadal towards the top of the sediment core. The rate of diatom assemblage change remained stable until the 19th century, when small cyclotelloid and elongate pennate taxa became more abundant, diatom-inferred electrical conductivity (DI-EC) increased, and diatom-inferred total phosphorus (DI-TP) decreased. Similar conditions existed also prior to 2.7 kBP. The first axis of principal component analysis (PCA), i.e. the largest variation in the diatom data, correlated strongly with DI-EC ($r = 0.88$, $p < 0.001$), whereas DI-TP had weaker but statistically significant correlations with the first and second PCA axes ($r = -0.32$, $p = 0.012$ and $r = -0.56$, $p < 0.001$). Both the 2.7 kBP and the 19th century diatom assemblage shifts could be related to changes in erosion intensity, the prior possibly linked with the transition from Subboreal climate to Subatlantic and the latter with intensified land use.

The climate condition and vegetation change by flood during the Late Yayoi period in Wakasa region, central Japan

Junko Kitagawa¹, Koji Seto², Hideaki Kojima³, Kazuyoshi Yamada⁴, Takehito Yoshida^{5,6}

¹Fukui Prefectural Varve Museum, Wakasa-cho, Japan. ²Estuary Research Center, Shimane University, Matsue, Japan. ³Jomon Museum, Wakasa-cho, Japan. ⁴Museum of Natural and Environmental History, Shizuoka, Shizuoka, Japan. ⁵Research Institute for Humanity and Nature, Kyoto, Japan. ⁶University of Tokyo, Tokyo, Japan

Abstract

Five Lakes of Mikata, i.e., Lake Mikata, Lake Suigetsu, Lake Suga, Lake Kugushi and Lake Hiruga are located in the lower stream of Hasu River along the Japan Sea coast of Wakasa region, central Japan. Flood layers formed in the Late Yayoi period (1st century AD to 3rd century AD) are intercalated in the sediments of Lake Suigetsu, Lake Suga and Lake Hiruga in the region. Ego archaeological site in Hasu River basin was hit by a debris flow disaster during the Late Yayoi period. The pottery was dated to be 37 cal BC - 76 cal AD. During the same period, Kurota lowland which is located in the upper stream area of the lakes was a lake judged from the sediment condition. It is said that the Japanese islands were politically unstable and the Chinese history books, Book of Later Han and Record of Three Kingdoms described that many internal disturbances occurred in the Late Yayoi period. It is considered that cold and unstable precipitation during the Late Yayoi period caused the disturbances based on the oxygen stable isotope analysis of Kiso-hinoki cypress and the description in the history book of Silla.

Pollen analysis of the sediment recovered from Lake Hiruga was conducted from the lakes and Kurota lowland to see if the vegetation changes were related to debris flow disasters that can be detected during late Yayoi period. Climate conditions were quantitatively reconstructed by the modern analogue method.

The lake area was covered with a dense *Cryptomeria* and evergreen broad-leaved forest, while, the upper stream area was covered with a *Cryptomeria* and *Alnus* forest from the Yayoi period to the 8th century according to the results of pollen analysis. The annual mean temperature became low from the 1st century AD based on the climate reconstruction. The reconstructed annual precipitation was high throughout the time, but it became higher during the Late Yayoi period. The high precipitation period continued to the 10th century. Several floods occurred during the high precipitation period. The pollen record of Lake Hiruga indicated that floods seemed to destroy the vegetation cover around the lakes. All pollen taxa decreased at one of floods during the Late Yayoi period. Just after the flood, pollen of *Alnus* which grows in wetlands increased. The vegetation was recovered in 50 years. Rice cultivation seemed to become active in the upper stream area around the 1st century AD during the wet period.

This research was supported by the Environment Research and Technology Development Fund (4-1505) of the Ministry of the Environment, Japan and the Research Institute for Humanity and Nature (RIHN), Japan (no. 14200103). The coring of Kurota lowland was conducted by students at Wakasa High School, Obama city, Japan.

The Holocene vegetation dynamics and human influence on the alpine environment in the Julian Alps, Slovenia

Nina Caf¹, Pierre Sabatier², Andrej Šmuc³, William Rapuc², Ulrich von Grafenstein⁴, Fabien Arnaud², Maja Andrič¹
¹ZRC SAZU, Institute of Archaeology, Novi trg 2, 1000 Ljubljana, Slovenia. ²Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, EDYTEM, 73000 Chambéry, France. ³University of Ljubljana, Department of Geology, Aškerčeva ulica 12, 1000 Ljubljana, Slovenia. ⁴LSCE, Université de Versailles Saint-Quentin, Commissariat à l'Énergie Atomique–CNRS, 91198 Gif-sur-Yvette, France

Abstract

The presence of people in the high elevation alpine areas has long been discussed, mostly by trying to understand the main reasons for human occupation of such an extreme habitat. In many regions in the Alps, human settlements have been well documented but in the area of Julian Alps (Slovenia), few evidences have been reported until recent archaeological data. These data indicate that people have been living in the area since the Mesolithic (Cevc & Horvat, 2006). However, the Holocene environment and the human activity (pastoralism, metallurgy) are poorly investigated. In order to recognize vegetational changes and possible human influence throughout the Holocene, microcharcoal and pollen analyses of mountain lake sediments were made. Two lake systems located at different altitudes are 'Jezero na Planini pri jezeru' (1450 m a.s.l.) and 'Jezero v Ledvicah' (1830 m a.s.l.). At lake 'Jezero na Planini pri jezeru', three cores with an entire depth of 237 cm were sampled and cover the last 8000 years and at the 'Jezero v Ledvicah' two cores with a total depth of 212 cm represent the last 5000 years. Pollen results indicate that since c. 4700 cal. BP forest composition was mixed with dominant *Fagus* and *Picea*. Preliminary results also show intensive land use including pastoralism (*Plantago l.* and decline of *Abies*) and agricultural activity (*Cerealia* type, *Secale*, *Cannabis*, *Fagopyrum*), which would indicate continuous human influence on this alpine environment, especially in the Modern period (since the 15th century AD onwards).

P-2263

Multi annual- to decadal NAO and AO spring season signals reflected in leaf morphology in Greenland and Finland.

Fabian Ercan, Astrid Odé, Friederike Wagner-Cremer
Utrecht University, Utrecht, Netherlands

Abstract

Climate change is affecting (sub-)Arctic environments, causing a significant lengthening trend of the vegetation growing season in the Northern Hemisphere. This has great impact on vulnerable polar ecosystems and affects the carbon and hydrological cycle. In NW Europe, winter and spring climate conditions are related the North Atlantic Oscillation (NAO) and the Arctic Oscillation (AO). Past dynamics of these atmospheric circulation systems can be tested on localities at endpoints of the bipolar circulation systems. By using paleobotanical techniques, including the Undulation Index-based growing season length proxy, past growing degree days (GDD) can be reconstructed. The Undulation Index-proxy is obtained by cuticle analysis and reflects the duration and thermal properties of the plants growing period. Applied to leaves from herbarium records from Greenland and fossil leaves from young peats in Finland, we determine growing season dynamics over the past 200 years. The study areas are in the opposite response region of the NAO, and therefore representative for the expression of temperature changes and spring season dynamic trends on annual to decadal scale. Meteorological data are used for calibrating the UI-proxy against modern local GDD, as they capture the growing season duration and thermal intensity. The recorded spring dynamics in the leaf morphology of subarctic *Betula* can subsequently be compared against instrumental records of the atmospheric circulation systems. Constructed proxy records will provide insight in the expression and dynamics of the rapidly changing spring season over NW Europe, as spring dynamics heavily influence overall growing season properties, resulting in important future implications on agriculture and ecology management.

Abstract

The Central Asian forest-steppe ecotones are highly vulnerable to environmental shifts such as drought and overgrazing (Lkhagvadorj et al. 2013). Knowledge about past vegetation and fire responses to environmental change may contribute to a better understanding of future ecosystem dynamics. However, paleo records are scarce in the region.

Our novel high-alpine ice record from Tsambagarav glacier (4130m a.s.l.) in the Mongolian Altai provides unique paleoenvironmental information at the landscape scale with an exceptional temporal resolution and a sound chronology covering the past 5500 years (Herren et al. 2013). We use pollen as proxies for vegetation composition and structure, microscopic charcoal as a proxy for fire activity, and spheroidal carbonaceous particles (SCPs) to infer fossil fuel combustion (Brugger et al. 2018).

We present the first microcharcoal-inferred fire history record from Mongolia which can be directly linked to past vegetation dynamics. Reconstructed mid to late Holocene forests collapsed and fire increased, likely in response to climate change. Our results underscore the vulnerability of relict forest ecosystems in the Mongolian Altai and imply that in these steppic areas, moisture is more important than temperature for tree growth. We conclude that Central Asian forest ecosystems including the Russian Altai are highly vulnerable and may collapse rapidly in the future, if global warming will be associated to moisture declines as anticipated by regional climate models.

Abstract

The aim of this study was to compare forest and fire history recorded in small mires that developed within landslide depressions in Western Carpathians. The analysed sites are located in the Beskid Makowski (lower mountain forest zone) and Beskid Wyspowy Mountains (foothill forest zone). The profiles retrieved from both sites were densely dated using ¹⁴C AMS method and subjected to pollen, charcoal and plant macrofossil analyses. The profile from the Beskid Makowski Mountains dates back to ca. 11,200 cal. BP when *Pinus sylvestris*, with an admixture of *Betula*, *Picea abies*, *Populus*, *Pinus cembra*, and *Larix decidua*, were the main constituents of the woodlands. About 11,090 cal. BP *Ulmus* advanced rapidly (>10 % of pollen) contributing to the withdrawal of *L. decidua* and *P. cembra*. During the period of ca. 11,230–10,710 cal. BP high fire activity was identified. About 10,280 cal. BP *P. abies*, afterwards ca. 10,030 cal. BP *Corylus avellana*, and ca. 9930 cal. BP *Tilia* started to expand, which contributed to the retreat of the *Pinus–Betula* woodlands. About 4400–4000 cal. BP *A. alba* spread restricting *C. avellana* and *Tilia*, and gradually *P. abies*. About 2700 cal. BP *Fagus sylvatica*, being earlier an admixture in *Abies–Picea* forests, became more frequent, whereas ca. 2020 cal. BP it reached an optimum. The topmost layer, covering the last ca. 400 years represents increased human activity and vast deforestations. The profile from the Beskid Wyspowy Mountains reached at the bottom ca. 9500 cal. BP. *C. avellana* dominated in the site vicinity until ca. 8540 cal. BP which was related to high fire activity, contrary to patterns revealed by the site from the Beskid Makowski Mountains. This was also a period of gradual spread of *P. abies* which dominated in the local forest from ca. 8520 to 3120 cal. BP. From ca. 4920 cal. BP *A. alba* and *F. sylvatica* became probably regular but scattered component in local forests. About 3120 cal. BP *A. alba* started to dominate (up to ca. 20 cal. BP) simultaneously to the spread of *P. sylvestris* and to a lesser degree of *F. sylvatica*. It probably contributed to *P. abies* withdrawal. The beginning of *A. alba* domination was connected with a rapid increase in fire activity (ca. 3320–3030 cal. BP) as well as a gradual human-induced decline of this species and of *F. sylvatica* (since ca. 740 cal. BP). Both sites, even if situated relatively close to each other, revealed different patterns in terms of timing of major forest changes and fire activity with its impact on vegetation changes.

Scientific work financed from the budget sources for science activity in 2016–2019, project number 0342/IP1/2016/74.

Abstract

Small peatlands are sensitive archives recording local to global environmental and climate changes. The aim of the research is to reconstruct vegetation, water table and fire activity changes in relation to human impact and climate changes. We selected 118 cm of the peat profile and contiguous 1-cm subsamples were selected for: pollen, non-pollen palynomorph (NPP), plant macrofossil, testate amoebae (TA), microcharcoal (0.01-0.1 mm), macrocharcoal (>0.1 mm) and geochemical analyses. The absolute chronology is based upon a Bayesian age-depth model comprising 18 ¹⁴C AMS dates and ²¹⁰Pb dates. The analysed section of the profile spans 1800 calibrated years with a hiatus between ca. AD 1300–1890. Hydrology of the peatland was very unstable through time, reconstructed testate amoeba-based water table depth revealed a decreasing trend up to the present times. The results revealed the domination of a *Pinus sylvestris*-*Betula-Quercus* forest in the peatland vicinity during the entire studied period. Distinct agricultural activity and strong deforestation before ca. AD 370 were related to the occupation during the Roman Period of the Wielbark Culture communities. From ca. AD 400 hornbeam (*Carpinus betulus*) started to spread along with the significant weakening of human activity during the Migration Period and it reached an optimum (pollen >10 %) during the period of ca. AD 630–1060. Around AD 670 *Tilia cordata* started to occur regularly which might indicate the establishment of forest type similar to the modern *Tilio cordatae-Carpinetum betuli* association. Our results showed that a period of ca. 300 years after the decline of agricultural activity is necessary for the establishment of this forest type. Simultaneously *Fagus sylvatica* became more regular, but as a scattered forest component. The stage of *C. betulus* optimum in the forest was characterised by many quasi-regular increases in fire activity as reflected by the microscopic charcoal data. The occurrence of a local peat fire, which is indicated by high concentrations of macrocharcoal (probably during the 19th century AD) contributed to the loss of the peat layer spanning the period of ca. AD 1300–1890. The reliable chronology of the profile combined with the palaeoecological analyses of the contiguous samples give a unique opportunity to investigate the long-term ecology of naturally regenerated forests. This research was funded by National Science Centre (Poland), grant 2015/17/B/ST10/01656 and the funds of National Programme for the Development of Humanities (Project: NPH012; PI: Piotr Guzowski).

Vegetation changes during the last 4 millennia in west tropical Africa

Anne-Marie Lézine, Kévin Lemonnier
LOCEAN/CNRS, Paris, France

Abstract

Compared to the large-amplitude changes in vegetation that characterized the tropical regions during the last glacial-interglacial transition, the last millennia appear to have been relatively "stable". At the end of the Holocene Humid Period (HHP), all the forests which widely expanded throughout the tropics dramatically decreased and the environment switches to its modern aspect (e.g., Vincens et al., 1999; Hély and Lézine, 2014). However, increased lines of evidence show that the 3 to 5 millennia that followed the end of the HHP have also recorded noticeable environmental changes (Nash et al., 2016).

In this study we analyse how ecosystem vulnerability in response to climate hazards has developed in the past at both large and small time scales. We investigate changes in vegetation during the last 4 millennia in two sectors of West tropical Africa: the gallery forests of Senegal (Mboro and St Louis) and the montane forests of Cameroon (Bambili). New, high resolution pollen analyses are used to discuss the following questions: (1) did the dramatic switch from forest to grassland communities which occurred at the end of the HHP result from a crossed threshold or from a longer process characterized by successive disappearance of forest tree species? (2) what was the timing and amplitude of the environmental changes which punctuated the last millennia? A focus is put on the last millennium and the key environmental and/or anthropogenic factors at play.

Decadal environmental change in the Marrakech High Atlas: Impacts of snow melt on alpine ecology during the last 500 years

Benjamin Bell, William Fletcher, Philip Hughes
The University of Manchester, Manchester, United Kingdom

Abstract

In arid and semi-arid mountainous regions, the role of meltwater is especially important for agricultural activities, human development and the wider economy. In Morocco, fluctuations in snow and ice in the Atlas Mountains directly impacts on the fluvial regimes of rivers throughout Morocco. Therefore, past environmental changes, driven by changes in winter snowfall, may have influenced human development over time. Currently, very little is known about the state of the cryosphere in North Africa during the Holocene.

Here, we present a new high-resolution (12 year) pollen and non-pollen palynomorph (NPP) record for the last 500 years from a spring-fed alpine marsh at Oukaimeden, located in the Marrakech High Atlas, Morocco. The site is set within a largely open but dynamic landscape influenced by several forcing factors which affect the alpine ecology (including snow melt). Arboreal pollen is largely absent, while non-arboreal pollen reveals shifts between wet and dry conditions, inferred to be driven by changes in winter snowfall and subsequent spring snowmelt. Wet periods have high Cyperaceae pollen abundance and corresponding increases in NPPs indicative of wet environments. Conversely, drier periods see low abundance of these taxa, while Poaceae abundances are high. Basal radiocarbon ages indicate that the marsh formed near the time of the onset of the northern hemisphere Little Ice Age (LIA). Recurrent (multi-decadal to centennial) wet intervals appear to correlate with reduced drought stress in Moroccan tree rings, increased humidity as indicated in Middle Atlas speleothems, and phases of glacier advance in European mountains. There is evidence of pastoral exploitation of the marsh throughout the record highlighting the importance of such alpine wetlands for mountain societies and the wider regional economy.

Our working hypothesis is that intervals of high snowfall during the LIA (and possibly other Holocene cooling episodes) allowed permanent snowpack and glacier development in the High Atlas. The cryosphere expansion contributed to sustained year-round wetter conditions in the alpine valleys, promoting wetland development and increased productivity of alpine pastures. An enhanced pastoral economy ensued which underpinned societal development, urbanisation and trade in southern Morocco.

A severe drought homogenizes the diatom composition of two shallow lakes in southwest China

Anna-Marie Klamt, Kui Hu, Linpei Huang, Guangjie Chen
Yunnan Normal University, Kunming, China

Abstract

In the context of global warming, extreme droughts have occurred more frequently and this is projected to continue in the future in many parts of the world. However, their ecological consequences on shallow lakes are not well studied. Here we compare the succession of diatom assemblages of two medium-sized shallow lakes in southwest China during the past ~70 years and under the impact of an extreme drought event between 2009 and 2013. Before the drought, Lake Yuxian was characterized by a stable diatom composition which was dominated by *Fragilaria* sensu lato (e.g., *F. construens/pinnata* complex) and *Achnanthes minutissima*. In contrast, the diatom composition of Lake Chahei was increasingly affected by eutrophication from the 1970s as inferred by enrichment of sedimentary $\delta^{15}\text{N}$ values. The pioneer species *Achnanthes minutissima* increased at the expense of *Epithemia sorex*. In both lakes, the most striking change occurred with the recent drought event when species of the genera *Nitzschia* and *Navicula* and *Surirella angusta* (NNS group) became abruptly dominant. This is also reflected in a strong decrease in the Jaccard dissimilarity index, indicating increased homogeneity in the previously distinct diatom compositions of the two lakes. The increased abundance of the NNS group was preceded by a peak in the percentage of silt in both study sites, suggesting more turbid conditions in the remaining lake water during the drought event. Species of the NNS group are characterized by motility, which allows them to actively seek out optimal habitats and makes them well adapted to conditions that prevail in shallow lakes during severe droughts. For the study region, several drought events are documented since ~1950. However, the diatom composition at both study sites displayed no or a relatively muted response, suggesting that a threshold level of hydrological fluctuation may exist beyond which the resilience of diatom communities is significantly reduced. Hence, this study finds that diatom species of the NNS group can serve as paleo proxies for the reconstruction of severe drought events (with a large magnitude of hydrological fluctuation) in shallow lakes.

⁵Archaeological Department of Canton Thurgau, Frauenfeld, Switzerland

Abstract

Palynological and plant macrofossil analyses performed on a 82 cm long stratigraphy from the small Alpine peatland „Blackenalp-Oberes Moor“ (Attinghausen, Canton Uri, Switzerland, 1820 m a.s.l.) allowed detailed insights into the local flora, vegetation and landscape development since the late 16th century on a ca. 20 year-resolution. At that altitude, a treeless open pastoral landscape prevailed during the Little Ice Age, whereas fruit trees such as chestnut (*Castanea sativa*) and walnut (*Juglans regia*) were planted in the lowlands. From ca. AD 1650–1900, the nearby valleys of Engelberg in the West and the Reusstal in the East were also used for the cultivation of hemp (*Cannabis*) and for the agricultural production of cereals (incl. rye – *Secale cereale*). Since AD 1900, a continuous record of *Ambrosia* pollen gives evidence for the regional immigration and expansion of this neophyte. Pollen from corn (*Zea mays*) around AD 1930 hints at the introduction of this crop for fodder purposes. These pollen evidences do well correlate with written sources on the intentional and non-intentional introduction of above-mentioned plants.

Vegetation responses to abrupt climatic shifts during the Last Glacial-Interglacial Transition: evidence from a north-south transect across the British Isles

Ashley M Abrook¹, Ian P. Matthews¹, Alice M. Milner¹, Ian Candy¹, Adrian P. Palmer¹, David J. Maas², Dirk Sachse²
¹Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom. ²Helmholtz-Centre Potsdam, GFZ German Research Centre for Geosciences, Section 4.6 Geomorphology, Organic Surface Geochemistry Laboratory, Potsdam, Germany

Abstract

The Last Glacial-Interglacial Transition (LGIT; 16-8 ka BP) in northern Europe is a well-characterised period of abrupt climatic change where millennial-scale oscillations in climate led to large-scale reorganisation of ecosystems. Imprinted upon these longer-term episodes are a series of centennial-scale climatic oscillations which are far less well understood. These short-lived events appear to be spatially and temporally complex across northern Europe and frequently have either not been identified or are shown to have limited impact. Furthermore, many sequences have not been studied for proxies that provide evidence of a palaeoclimatic driver and vegetative response, or they are not resolved in sufficient detail. Consequently, landscape responses to these abrupt events are largely unknown and phase relationships cannot be adequately constrained.

We present research from a number of sites spanning a latitudinal and climatic gradient across the British Isles, from northern and central Scotland, north-east England and south Wales. The sites contain high-resolution palaeoclimatic reconstructions, including oxygen isotopic data ($\delta^{18}\text{O}$), chironomid-inferred summer temperature reconstructions (C-IT) and biomarker compound-specific isotope data ($\delta\text{D}_{\text{wax}}$) as a palaeohydrological proxy. These data occur alongside high-resolution palynological and charcoal records and have been chronologically constrained through radiocarbon and/or tephrochronology. In general, the sequences demonstrate vegetation responses to abrupt climatic change across millennial and centennial climatic transitions during the LGIT. However, the characteristics and dynamics of vegetation responses vary between individual sites and across time-periods. For example, during the Lateglacial Interstadial, following climatic deteriorations, upland locations demonstrate wholesale landscape change with concomitant increases in herbaceous taxa with ecologies of landscape disturbance; whereas, lowland sites show an 'opening' of the landscape under similar climatic stress. In contrast, during the early Holocene vegetation change at the centennial-scale appears muted.

The collection of data presented here also allows for an understanding of the phasing between climate and landscape response within the sequences. Early Interstadial and early Holocene vegetation changes appear not to exhibit a significant lag with climatic shifts. This is in contrast with the greater lag in vegetation response observed during the later Interstadial. The data suggest that the magnitude of the climatic event, non-linearity in vegetation response and stages of vegetation development are important controls over the phasing between climatic drivers and vegetation responses during the LGIT. These effects may be further mediated by the role of fire across each of the sites.

Neolithic forest use and dynamics around Lake Mondsee, Austria, revealed by palynological analyses at decadal resolution

Benjamin Dietre¹, Christoph Daxer¹, Marie-Claire Ries¹, Brigitte Hechenblaickner¹, Werner Kofler¹, Juh-Jaan Steven Huang¹, Kerstin Kowarik², Michael Strasser¹, Timothy Taylor², Jean Nicolas Haas¹

¹University of Innsbruck, Innsbruck, Austria. ²University of Vienna, Vienna, Austria

Abstract

Our comprehension of past ecosystem changes lies on palaeoecological studies. The vegetation is a major component and one of the main descriptors for an ecosystem. Palynological analyses can reliably reconstruct past vegetations. However, they are time consuming, and high resolution is rarely achieved. We achieved such a resolution with contiguous sampling for the Neolithic Period of well-dated sediment cores from Lake Mondsee, Austria. Our continuous record of 166 1-cm thick sediment samples runs from 4600 to 1950 BC, covering the archaeologically defined, so-called *Mondsee Culture*. Each sample contained the pollen signal of 2 to a maximum of 35 years of the surrounding vegetation (median 14 years). Sequences of higher pollen amounts of *Corylus avellana*, *Betula sect. alba*, *Fraxinus excelsior*, and *Fagus sylvatica* were regularly found along the record. Assuming that they derive from secondary vegetation succession, we questioned possible triggers for these successions. Three origins are plausible: stochastic, climatic, or anthropogenic. To address this question, we compared the palynological signal of these forest cycles with possible erosion and flooding events provided by μ -XRF analyses, with climatic data, and with archaeological evidence. Finally, we compare the forest vegetation dynamics with fire events through the micro-charcoal signal, using cross-correlations. These comparisons suggest that the *Mondsee Culture* populations may have practised a particular forest management, using fire to open the landscape, and that their practises were the main (if not the only) driver of vegetation change in the area, leading to secondary forest successions during periods of lower anthropogenic and livestock pressure.

Abstract

Cultural sediment layers of the short-lived Neolithic lake village of Mooswinkel (Upper Austria) radiocarbon dated to 3542 ± 153 BC were analysed in an interdisciplinary study between palaeoethnobotanists, palynologists, wood-anatomists, sedimentologists, radiocarbon specialists and archaeologists within the International D.A.CH-Programme „Beyond Lake Villages“ (2015–2019). This study was performed on a 1.15 m long sediment core with a diameter of 9 cm extracted 2 meters underwater in the southwestern part of the former village area, and comprised Neolithic cultural layers 50 cm thick. The high-resolution sedimentological, XRF-scanning (μ -XRF), palynological, and palaeoethnobotanical analyses revealed that these cultural layers were quickly deposited at the littoral north-eastern edge of Lake Mondsee in a humid, non-inundated state, attesting therefore an at least 2 meters lower lake level during Neolithic Times than today. It also revealed a huge amount of plant macrofossil remains such as from strawberry (*Fragaria vesca*), blackberry (*Rubus fruticosus*), raspberry (*Rubus idaeus*), pomaceous fruit trees (*Malus/Pyrus*), hazel (*Corylus avellana*), flax (*Linum usitatissimum*), and cereal chaff (such as from *Triticum monococcum*) within the cultural layers, all witnessing Neolithic fruit collection and crop production practices. However, whole cereal grains were not found, implying eventually the presence of a Neolithic refuse heap in this near-lake, southwestern part of the former pile-dwelling village. The determination of several wood and charcoal remains to species level added massively to the palynological reconstruction of the tree and shrub vegetation in and around the site, and the according use by Neolithic societies. Pollen finds of mistletoe (*Viscum album*) and ivy (*Hedera helix*) do hint at the use of these species as winter fodder for livestock, and pollen of boneset (*Symphytum*) might be the result of the palaeoethnobotanical use of this taxon for medical purposes. High elemental copper values within the organic cultural layers might have been the result of local copper smelting and production within the prehistorical settlement. In addition, some bones, silex radiolarite, gem (epidot), slag, ceramic, coleopteran, and twined fiber remains give detailed insights into prehistoric live of these Central European Neolithic societies belonging to the so-called Mondsee-Culture.

P-2274

Centennial and millennial-scale dynamics in *Araucaria-Nothofagus* forests in the southern Andes

Michael-Shawn Fletcher¹, Bianca Dickson¹, Patricio Moreno²

¹University of Melbourne, Carlton, Australia. ²University of Chile, Santiago, Chile

Abstract

We aim to assess the relative roles of long-term role of climatic change, fire and volcanic disturbance on the dynamics of *Araucaria-Nothofagus* forests of south central Chile. We developed a new 8500 year (8.5 kyr) pollen, charcoal and LOI dataset from Lago Cilantro, Chile (38°51'36.71"S, 71°17'14.17"W). The new dataset was compared to proxies of regional climatic change and Superposed Epoch Analysis was employed to test the relationship between tephra depositions and pollen composition. Millennial-scale trends are dominated by a shift from *Araucaria* to *Nothofagus* dominance in concert with increasing regional precipitation and decreasing local-scale fire activity between ca. 8.5-5.5 ka, with a reversal of this trend after ca. 4 ka in concert with a reduction in regional precipitation. Centennial-scale increases in *Araucaria* are associated with a reduction in the fire-return-interval. Tephra >2 cm thickness are associated with short-term (<100 year) compositional shifts in the pollen spectra, while a single large (255 cm) tephra at ca. 3 kyr is associated with a substantial reduction in *Nothofagus* and no change in *Araucaria*. Our data indicates that climate and climate mediated fire activity are the dominant drivers of millennial-scale *Araucaria-Nothofagus* dynamics at our study site. A shortening of the fire-return-interval is associated with an increase in the importance of *Araucaria*, supporting the notion that recurrent fires are required to allow this tree species to compete with *Nothofagus*. Tephra drive a short-term, compositional response in this system that appears to be overwhelmed by climate and fire at longer-timescales. *Araucariaceae* survive and potentially take advantage of very thick tephra deposits relative to *Nothofagus*, likely due to the physiological traits of thick bark and tall canopy (>15 m).

The interstadial/stadial type changes during the Late Saalian and three abrupt intra-Eemian climatic events - the Boćki site, E Poland

Mirosława Kupryjanowicz, Magdalena Fiłoc
University of Białystok, Białystok, Poland

Abstract

About 100 samples of palaeolake sediments from the profile coring at the Boćki site, E Poland, were examined by pollen analysis. On the basis of obtained results, we determined that the studied sequence span the closing phase of the Warta Stage of Odranian Glaciation (Late Saalian), and Eemian Interglacial. The studied profile turned out to be unique, because it contains the pollen record of almost all abrupt climate-vegetation events registered already earlier for this part of the Upper Pleistocene in Central Europe and other regions of the world, including: (i) the interstadial/stadial type changes at the end of Late Saalian, (ii) climatically induced intra-Eemian break in sediment accumulation (hiatus) that was covered the end of hornbeam phase (E5) and the whole spruce phase (E6) and (iii) temporary cooling in the middle part of the pine phase (E7) of the last interglacial that was resulted in the decrease in forested areas and the increase in open plant communities of a cold step type. Additionally, in the investigated profile there is also a record of the sedimentation gap during the oak phase (E3). Similar event has recently been recognized in several other profiles from E and NE Poland.

A 27 ka paleoenvironmental lake sediment record from Taro Co, Tibetan Plateau: implications for the interplay between monsoon and Westerlies

Junbo Wang^{1,2}, Qingfeng Ma¹, Lei Huang¹, Jianting Ju¹, Yun Guo³, Xiao Lin⁴, Yameng Li⁵, Liping Zhu^{1,2}

¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Tibetan Plateau Earth Sciences, Beijing, China. ³State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, China. ⁴Faculty of Earth Sciences, China University of Geosciences, Wuhan, China. ⁵Institute of Geology and Paleontology, Linyi University, Linyi, China

Abstract

The interaction of the Indian Ocean Summer Monsoon (IOSM) and the Westerlies is a crucial scientific issue to understand how they impact the climate on the Tibetan Plateau (TP), especially in the geological times. Here we present a lake sediment record retrieved from Taro Co covering the last 27 ka to elucidate how the IOSM and the Westerlies interact.

Taro Co (486 km², D_{max} : 132m, 4565 m a.s.l., currently closed), located on the central TP, is a fresh lake with the major supply from glaciers. Two parallel piston cores as well as several gravity cores were retrieved from the deepest parts. These cores were correlated based on high resolution XRF scanning and a continuous 1069 cm-long core was finally integrated. Chronology was determined by ²¹⁰Pb, ¹³⁷Cs and AMS ¹⁴C measurements. Multidiscipline analyses including grain size, total organic carbon (TOC), total nitrogen, diatom, pollen and n-alkanes were accomplished to reconstruct paleoenvironmental changes.

The lake level of Taro Co was low since 27 cal ka BP indicated by very coarse materials and diatom assemblages. The terrestrial water input decreased continuously reflected by such elements as Si, Ti, Fe, K. It is likely that there was a sedimentation gap between 961-954cm, corresponding to 23.4 to 18.6 cal ka BP probably demonstrated Taro Co was very shallow at that period. The first prominent abrupt change of most proxies was observed at 14.7 cal ka BP showing a great lake deepening which likely indicated an enhancement of IOSM. There were several spells with abrupt changes of cold/warm stages before the Holocene and the Younger Dryas event occurred at 11.8 cal ka BP. During the Holocene, carbonate dissolution was identified at 9.76 to 3.44 cal ka BP which indicated a high moisture availability hence high lake level even the lake became an open system.

P-2403

Differential response of vegetation in Hulun Lake region at Northeast China to extreme cold events of the last deglaciation

Shengrui Zhang¹, Jule Xiao², Qinghai Xu¹, Ruilin Wen², Jiawei Fan², Yun Huang²

¹College of Resources and Environment, Hebei Key Laboratory of Environmental Change and Ecological Construction, Hebei Normal University, Shijiazhuang, China. ²Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The response of vegetation to extreme cold events during the last deglaciation is important for assessing the impact of possible extreme climatic events on terrestrial ecosystems under future global warming scenarios. Here, we present a detailed record of the development of regional vegetation in the northern margin of Asian summer monsoon during the last deglaciation (16,500–11,000 cal yr BP) based on a radiocarbon-dated high-resolution pollen record from Hulun Lake, northeast China. The results show that the regional vegetation changed from subalpine meadow-desert steppe to mixed coniferous and deciduous forest-typical steppe during the last deglaciation. However, its responses to the Heinrich event 1 (H1) and the Younger Dryas event (YD) were significantly different: during the H1 event, scattered sparse forest was present in the surrounding mountains, while within the lake catchment the vegetation cover was poor and was dominated by desert steppe. In contrast, during the YD event, deciduous forest developed and the proportion of coniferous forest increased in the mountains, the lake catchment was occupied by typical steppe. We suggest that changes in Northern Hemisphere summer insolation and land surface conditions (ice sheets and sea level) caused temperature and monsoonal precipitation variations that contributed to the contrasting vegetation response during the two cold events. We conclude that under future global warming scenarios, extreme climatic events may cause a deterioration of the ecological environment of the Hulun Lake region, resulting in increased coniferous forest and decreased total forest cover in the surrounding mountains, and a reduction in typical steppe in the lake catchment.

P-2404

Climate evolution since 9.4 ka in Keluke Lake, northeastern Qaidam Basin, China

Gao Song, Hailei Wang

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China

Abstract

Core sediments from Keluke Lake in transitional zone between arid central Asia and monsoon Asia, provide insights into the advance-retreat history of the summer monsoon and the Westerlies. Sediment grain size and $\delta^{13}\text{C}$ of authigenic carbonate reveal paleoclimatic evolution since 9.4 ka: a dry-cold climate in the early Holocene, a wet-cold climate in the early stage of mid-Holocene, a relatively dry-warm climate in the late stage of mid-Holocene and, a moderately wet and frequently oscillating climate after 2.5 ka. Keluke Lake area was mainly controlled by the Westerlies from 9.4 to 5.8 ka, and was dominated by the East Asia monsoon during 5.8-2.5 ka. While in the late Holocene, this area was re-controlled by the Westerlies since 2.5 ka. The boundary line between the Westerlies controlled arid central Asia and monsoon Asia varied during the Holocene. When the Westerlies strengthened and the East Asian summer monsoon weakened, the boundary line may be pushed southeastward, and vice versa. Generally, the climate in this area showed a wet-cold and dry-warm variation. In arid northwestern China, the effective moisture mainly depends on the degree of evaporation. High evaporation in a warm climate leads to a low effective moisture and, consequently a dry-warm climate.

P-2405

A 1000-year record of centennial-scale cyclic vegetation change from Maar Lake Sanjiaolongwan in northeastern China

Jiaoyang Zhang, Jie Li, Yao Yan, Jingjing Li, Xiaoqiao Wan
China University of Geosciences, Beijing, Beijing, China

Abstract

We present a high-resolution 1000-year pollen record of vegetation change from Sanjiaolongwan Maar Lake (SJML) in northeastern China. An age model was established using analyses of ^{210}Pb , ^{137}Cs and AMS ^{14}C . Our aims were to examine possible relationships between regional changes in vegetation and climate and fluctuations in solar activity. The pollen assemblages indicate that during the last millennium the vegetation of the study area was temperate coniferous and deciduous broadleaved mixed forest. Although *Pinus* is the most abundant pollen type, various lines of evidence suggest that it is not especially temperature-sensitive. However, from an analysis of changes in pollen assemblages over the past 1000 years and a comparison with pollen records from other lakes in the region, we conclude that *Quercus* frequencies can be used as a relatively sensitive temperature index for the study area. Several notable cold periods, with lower *Quercus* frequencies, occurred at approximately 1200 AD, 1410 AD, 1580 AD, 1770 AD and 1870 AD. These century-scale cold periods basically correspond to major minima in solar activity, leading us to conclude that variations in solar activity may have been an important driver of climate and vegetation change in the study area during the last millennium.

P-2406

Postglacial fire history and interactions with vegetation and climate in southwestern China based on charcoal and pollen records

Xiayun Xiao¹, Simon G. Haberle², Ji Shen¹, Bin Xue¹, Mark Burrows², Sumin Wang¹

¹State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China. ²Department of Archaeology and Natural History, College of Asia and the Pacific, Australian National University, Canberra, Australia

Abstract

A high-resolution, continuous 18.5 kyr (1 kyr=1000 cal yr BP) macroscopic charcoal record from Qinghai Lake in southwestern Yunnan Province, China, reveals postglacial fire frequency and variability history. The results show that three periods with high-frequency and high-severity fires occurred during the periods 18.5–15.0, 13.0–11.5, and 4.3–0.8 ka, respectively. This record was compared with major pollen taxa and pollen diversity indices from the same core, and tentatively related to the regional climate proxy records with the aim to separate climate- from human-induced fire activity, and discuss vegetation–fire–climate interactions. The results suggest that fire was mainly controlled by climate before 4.3 ka and by the combined actions of climate and humans after 4.3 ka. Before 4.3 ka, high fire activity corresponded to cold and dry climatic conditions, while warm and humid climatic conditions brought infrequent and weak fires. Fire was an important disturbance factor and played an important role in forest dynamics around the study area. Vegetation responses to fire after 4.3 ka are not consistent with those before 4.3 ka, suggesting that human influence on vegetation and fire regimes may have become more prevalent after 4.3 ka. The comparisons between fire activity and vegetation reveal that evergreen oaks are flammable plants and fire-tolerant taxa. *Alnus* is a fire-adapted taxon and a nonflammable plant, but density of *Alnus* forest is a key factor to decide its fire resistance. The forests dominated by *Lithocarpus/Castanopsis* and/or tropical trees and shrubs are not easy to ignite, but *Lithocarpus/Castanopsis* and tropical trees and shrubs are fire-sensitive taxa. Fire appears to be unfavourable to plant diversity in the study area.

Special features of the Eemian pollen succession from the Struga site (Garwolin plain, Central Poland)

Aleksandra Bober¹, Magdalena Kończak¹, Marcin Żarski²

¹Faculty of Earth Sciences and Spatial Management, Maria Curie-Skłodowska University, Lublin, Poland. ²/ Polish Geological Institute - National Research Institute, Warszawa, Poland

Abstract

The study reports high resolution pollen analyses of the palaeolake sediment samples at G-120 Struga site in the Garwolin Plain (Central Poland). The pollen succession covers Late Saalian (MIS-6) and fully developed Eemian (MIS-5e) interglacial and has been divided in detail into regional zones and subzones according to Kupryjanowicz et al. (2018). The Late Saalian section contains sub-zones reflecting the alternating dominance of steppe-tundra and boreal forest communities. The analysed Eemian sequence is an uncommon succession described as a variant with early appearance and high culmination of *Tilia* (Granoszewski 2003). In these terms, the succession of the Struga site resembles those of sites of Eemian interglacial known from the vicinity of Warsaw: Błonie, Warszawa-Żoliborz and Warszawa-Wola. In the E5 *Carpinus* regional pollen zone, the individual *Fagus* grains are noticeable. It may suggest the presence of beech trees associated with excellent climatic conditions. The Struga site is one of several recently discovered fossil sites of the Eemian lakes in the Garwolin Plain, constituting the southern fragment of the extensive Eemian lakeland in the Polish Lowlands. Their pollen sequences differ in terms of thickness of deposits representing the same regional zones in spite of the fact that the palaeolakes are situated close to each other.

This research was financially supported by the research project (number 2017/27/B/ST10/01905) financed by the National Science Centre (Poland) and the funds from the Faculty of Earth Sciences and Spatial Management UMCS in Lublin (Poland) (BS-M-12-011-18-C-01).

Abstract

Lakes are an important component of global ecosystems. Although the biodiversity of lake primary productivity plays a very important role in the lake ecosystem, little is known about how the biodiversity of lakes in tropical regions responded to climate change on the millennial timescales that are the most relevant for predicting future changes. In this study, we analyzed millennial-scale biodiversity changes during the last deglacial at Huguangyan Maar lake (HML), in tropical-subtropical South China. We used diatom records to reveal biodiversity changes, since diatoms are an important component of the primary productivity in lakes and are well-preserved in the sediments. Diatom biodiversity changed synchronously with millennial-scale climate change during the last deglacial at HML. Species diversity decreased rapidly at the end of abrupt cold events with the weakening of the East Asian Winter Monsoon (EAWM) decreased. These events include Heinrich 1 (H1) and the Younger Dryas (YD). The significant relationship between diatom diversity and the short-term changes in the EAWM may have been mediated via factors such as the role of water column stratification in affecting diatom suspension and nutrient availability. Our results suggest the possible occurrence of abrupt lake ecosystem responses to future human-induced climate change.

Asynchronous 500-year cyclic summer monsoonal rainfall change between north and south of East Asia associated with low latitude climate changes

Deke Xu¹, Houyuan Lu¹, Guoqiang Chu¹, Naiqin Wu¹, Fengjiang Li¹, Luo Wang¹, Jing Wu¹, Caiming Shen²

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²Yunnan Normal University, Kunming, China

Abstract

The summer monsoon plays a dominant role in the precipitation of East Asian Monsoon Region (EAMR), yet a long-standing unclarity exists concerning the spatial and temporal process and dynamics of precipitation in this region on centennial time scale. A decadal-resolution pollen record obtained from annually-laminated Maar Lake in Northeast China provided unambiguous evidence for vegetation and summer monsoon variability in EAMR. The Pollen record reflects ~500-year quasi-periodic vegetation and warm-humid/cold-dry changes in the north of EAMR throughout the past 9300 years. The speleothem record from previous studies also shows a ~500-year cyclic rainfall change in the south of EAMR during the Holocene. The humid (dry) phases in the north of EAMR nearly correspond to dry (humid) phases in the south of EAMR. Thus, the ~500-year periodic anti-phased precipitation change between the north and the south of EAMR are discovered for the first time during the Holocene. During the ~500-year periodic monsoonal change, "North Drought South Flood" condition prevails in El Niño-liked phase, whereas "South Drought North Flood" stage occurs in La Niña-liked (or normal) phase. Asynchronous ~500-year cyclic monsoonal climate change between the north and south of EAMR may be influenced mainly by El Niño-Southern Oscillation (ENSO), linked to the low-latitude oceanic and atmospheric process. These findings are particularly valuable in providing strong long-term evidence for our understanding of the climate mechanism in global monsoon regions, and may shed light on forecasting of future monsoonal rainfall changes.

P-2410

A mid-Holocene dry event (~7.0 ka BP) recorded by pollen data from the Mu Us Sandy Land, China

Sun Aizhi¹, Wu Huining²

¹College of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, China. ²Bailie School of Petroleum Engineering, Lanzhou City University, Lanzhou, China

Abstract

High resolution pollen record from Qigai Nuur, which lies between the steppe-dominated margin of the Loess Plateau to the southeast and the Tengger Desert to the northwest, showed that there was an obvious dry event (7.4-6.4 ka BP) lasting about 1000 years under the warm and humid mid-Holocene. The most remarkable feature of pollen record is considerable increases in *Chenopodiaceae* and *Ephedra* pollen percentages. This dry event was consistent with the pollen record from Diaojiaohaizi lake at a distance about 200 km. The event also has been recorded in the Chinese Loess Plateau, the western desert region of China, the Qinghai-Tibet Plateau and so on. There are two possible mechanisms leading to this event: one is drought caused by the decrease of precipitation caused by the recession of summer monsoon, the other is drought caused by the decrease of effective precipitation and the increase of evaporation caused by high temperature climate. This work need further study.

Figure. Comparison of reconstructed mean annual temperature (MAT) and mean annual precipitation (MAP) with other proxy data including OM (%) and pollen concentration (grains/g). Two pollen ratios are also presented for comparison and they are Br/Co (Br: Broadleaved tree pollen percentage, Co: Coniferous tree pollen percentage) and (E+N)/A (E=*Ephedra* pollen percentage, N=*Nitraria* pollen percentage, A=*Artemisia* pollen percentage). The dark-shaded strips marks the Holocene cool and dry stages (i.e., Pollen Zones 1, 3 and 5) and the light-shaded strips mark the mid-Holocene cool and dry epochs. The dash lines mark the trends of MAT and MAP changes.

P-2411

The seasonal characteristics of Younger Dryas event inferred from the lacustrine records in the Great Khingan Mountain range, Northeast China

Jing Wu, Qiang Liu, Luo Wang, Guoqiang Chu, Jiaqi Liu
Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The Great Khingan Mountain range, Northeast China, is located on the northern limit of modern East Asian Summer Monsoon (EASM) and the most active region of the East Asian Winter Monsoon (EAWM), thus highly sensitive to the variability of the East Asian Monsoon (EAM) from glacial to interglacial modes. The vegetation and climate change of this region should response to the Younger Dryas (YD) event, nevertheless, the seasonal characteristics of YD event in this region is still ambiguous. Here, we present high-resolution records covering the late glacial and the early Holocene from two closed crater lakes (Lake Moon and Lake Sifangshan) based on pollen, stomata, total organic carbon (TOC) and total nitrogen (TN), to reconstruct vegetation history and climate change during the glacial-interglacial transition and thus register the evolution of the EAM during the YD event. The results of pollen and stomata analysis indicate that the vegetation history of the Great Khingan Mountain range has remained forest steppe dominated by *Betula* and *Artemisia* from the late glacial to the early Holocene, and an expansion of the conifers dominated by *Larix* and the shrink of broadleaves and herbs from 12.8 to 11.8 ka BP. On the other hand, the values of TOC and TN do not have obvious change from 12.8 to 11.8 ka BP, which shows that the productivity of the lakes and coverage of land plants do not deteriorate during the YD event. All this results do not agree with the description of the YD event as simple climate deterioration, but the seasonal characteristics as a mild summer and extremely cold winter temperature caused by the enhancement of the EAWM in Northeast China. The seasonal characteristics and long duration of the YD event might provide the conditions for the pre-domestication of crops and the origin of the agriculture.

P-2412

Study on fluviolacustrine cyclic stratigraphy and its environmental significance in the Weihe Basin

Wang Ting, Sun Youbin

institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China

Abstract

The Weihe Basin is a mid-sized basin formed in Central China, which located at the margin of the Asian monsoon region, therefore sensitive to changes in monsoon precipitation. Long fluviolacustrine sediments are developed in the Weihe Basin. On the basis of a series of records from a fluvial sediment(HX core) in Huxian, Xi'an, we discuss the environmental significances of different proxies and attempt to discover more details about glaciation. Paleomagnetic results reveal that the Brunhes/Matuyama(B/M) boundary is in 177m, According that the 320-m HX sequence accumulated after 1.3 Ma. The lightness(L*) shows a dominant 100-kyr glacial-interglacial cycles, the gamma-ray(GR) and susceptibility exhibit combined 100, 41, and 23-kyr cycles, whereas the apparent resistivity(ρ_s) displays clear precession oscillations over last 1.3 Ma. These proxies reflect different climate characteristics and may reveal varied responses of astronomical and ice forcing.

Vegetation and climate history in the arid inland area during the H1: multi-proxy date of the Balikun Lake

Yongtao Zhao^{1,2}, Chengbang An²

¹Key Laboratory of Desert and Desertification, Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, Lanzhou, China. ²Key Laboratory of Western China's Environmental Systems (Ministry of Education), College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China

Abstract

Reconstructing the vegetation and climate in the arid inland areas during the Heinrich 1 (H1) event is beneficial for us understanding the relationship between arid ecosystem and abrupt climate change. We use multi-proxy analyses (e.g., lithology, grain size, LOI, XRF-Ti, pollen) of a sediment core obtained from Balikun Lake, eastern Tianshan Mts., to elucidate variations in sedimentation, vegetation and climate during the postglacial, with emphasis on the H1 event. The results show that: 1) the H1 deposition was dominated by sandy silt or silty sand, along with the high value of XRF-Ti, both indicated a high frequency of dust storm around the Balikun lake, which in turn brought more coarse material to the lake. Grain-size distribution of the H1 samples showed a similar mode to the modern aeolian dust collected from Balikun region. 2) the regional vegetation around Balikun Lake during the H1 was mainly dominated by desert and/or desert-steppe, with low vegetation cover reflected by the low pollen concentration, suggested a degraded environment, also the watershed bio-productivity showed a relatively low value. 3) a synchronous cold-dry climate prevailed over the mid-latitude inland areas of the Eurasia during the H1, and it caused a catastrophic drought condition along these areas with an (a) increase in aeolian input, shrink in lake area, and degradation of vegetation. The general pattern of widespread aridity in the arid inland areas during the H1 was generally caused by decreased evaporated water vapor along the westerlies linked to the low temperature, together with limited meltwater contributions of the mountain glaciers.

P-2414

Diatom recorded climate change in the Altai Mountains over the last 15 cal. kyr BP

Sun Mingjie¹, Huang Xiaozhong¹, Fontana Luciane²

¹College of Earth and Environmental Sciences, MOE Key Laboratory of Western China's Environmental Systems, Lanzhou University, Lanzhou, China. ²Departamento de Geoquímica, Universidade Federal Fluminense, Rio de Janeiro, Brazil

Abstract

Lake Kanas (48°11'-49°11'N, 86°23'-88°05'E; 1370 m a.s.l) is a large deep lake located in the southern Altai Mountains, fed by rainfall and melt water from Kanas Glacier in the high mountains. Regional climate is determined by the westerlies in summer and influenced by the Asian anticyclone in winter. In its sedimentary core, there is a high content of well-preserved diatom with rich species. Here presents the results of diatom analysis of the last 15 cal. kyr BP based on AMS ¹⁴C dates of terrestrial plant materials, combined with environmental proxies such as grain size, biogenic silica, to reconstruct the regional abrupt climate changes and palaeoecological evolution of diatoms. The diatom assemblages in Kanas are dominated by various species since Holocene, four stratigraphic diatom zones could be distinguished. Before 11.5 cal. kyr BP, very few diatoms could be counted. From 11.5 to 7.8 cal. kyr BP, benthic species *Staurosirella pinnata* was the most abundant, which indicated that lake water was more transparent in the early Holocene. During this period, larger grain size indicated a higher in erosion processes on the near slopes, and relatively high alkalinity was in accordance with high Chrysophycean percentage, which might be connected with lower vegetation cover on the nearby slopes. From 7.8 to 3.5 cal. kyr BP, more planktonic diatom taxa appeared and increased in abundance together with benthic species *Karayevia suchlandtii*, indicating that the lake became more productive as diatom concentration increased, coincided with high content of biogenic silica, which might indicate warm summer and more nutrients input. Since 3.5 cal. kyr BP, the planktonic species *Pantocsekiella gordonensis* is largely dominated with smallest grain size, indicating more glacial rock flour deposits from Kanas Glacier in a colder climate.

Extant Ostracoda and their importance in Quaternary hydrological changes in Lake Nam Co, Tibetan Plateau, China

Paula Gabriela Echeverria Galindo¹, Peter Frenzel², Wengang Kang¹, Nicole Börner¹, Anja Schwarz¹, Jinlei Kai³, Liping Zhu³, Antje Schwalb¹

¹Institut für Geosysteme und Bioindikation Institute of Geosystems and Bioindication, Technische Universität Braunschweig, Braunschweig, Germany. ²Institute of Earth Sciences, Friedrich Schiller University of Jena, Jena, Germany. ³Global Change and Quaternary Environment, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Abstract

Quaternary ostracod records from the Tibetan Plateau (TP) China show dramatic changes taking place during the Pleistocene and Holocene, including the occupation of large basins by freshwater lakes and their subsequent salinization and desiccation. Nam Co (30°30' - 30°56' N, 90°16' - 90°03' E) is the highest (4718 m a.s.l) and second largest (1962 km²) saline (1.3 ‰) lake system on the southeastern part of the TP. Its closed-basin and its maximum depth (> 100 m) allow a good sediment record for detecting past hydrological changes based on ostracods remains. Because ecological information is still poorly known, we determine the ecological preferences of extant ostracods from Lake Nam Co, in order to provide a reliable basis for the interpretation of Quaternary ostracod assemblages from sedimentary sequences. A total of ninety water and sediment samples were collected in 2018 from the lake and nearby rivers and lagoons. Modern sediment samples were taken to determine ostracode species composition and relative abundances from different depths using an Ekman grab and a hand net (125- μ m mesh) for littoral zone and rivers (0.5 – 1 m). Water samples were collected for chemical analysis (cations, anions, and isotopes [$d^{18}O$ and $d^{13}C$]); and physical variables (temperature, dissolved oxygen, conductivity and pH) were measured *in situ*. Characteristics such as proximity to glacier meltwater input, presence of slopes and macrophytes, anthropogenic influence, etc. were taken into account. Preliminary results based on taxonomic and quantitative analyses along with limnological information of the extant ostracod fauna identified distinct ostracod associations as a function of conductivity and water depth. Ostracod associations are related to: (1) rivers, characterized by low conductivity (300 μ S cm⁻¹); (2) Nam Co Lake, characterized by high conductivity (1800 μ S cm⁻¹); and (3) lagoons or ephemeral lacustrine environments, generally characterized by higher conductivity (<2000 μ S cm⁻¹). Results suggest that quantitative-ecological significance of shell morphological variations such as nodding or shell size must be emphasized, including more samples from higher conductivity sites to establish accurate conductivity inferences. In addition, our approach serves as a model for future paleoecological studies that employ other aquatic bioindicators in Nam Co, such as testate amoebae, cladocerans, and chironomids.

Holocene abrupt climate change: the view from Crudale Meadow, Orkney Mainland.

Joanna Tindall^{1,2}, Jonathan Holmes¹, Ian Candy², Simon Blockley², Rhys Timms², Melanie Leng³, Ian Matthews², Adrian Palmer²

¹University College London, London, United Kingdom. ²Royal Holloway, University of London, Egham, United Kingdom. ³British Geological Survey, Nottingham, United Kingdom

Abstract

Utilising oxygen isotope ratios as tracers of past climate change is a well-established technique because of the range of materials (e.g. bulk carbonates, diatom silica etc.) that can be analysed and the sensitivity of isotopic composition to changes in temperature and precipitation, among other factors. This work uses the oxygen isotope composition of calcite from ostracod shells. These data will be used to reconstruct palaeotemperature and palaeoprecipitation of abrupt climatic events during the early-mid Holocene. The aim is to understand the driving mechanisms of palaeoclimatic change and the environmental and potential archaeological responses associated with them.

Crudale Meadow, SW Orkney Mainland, Scotland, has been identified as an ideal site to develop an ostracod derived oxygen-isotope record. Current sites demonstrating early Holocene oxygen-isotope records produce a SW to NE transect and includes sites from W. Ireland¹, NW England² and extend into Scandinavia³. Crudale Meadow will contribute an additional site on this transect. Whilst there is an existing high-resolution bulk carbonate oxygen isotopic record for Crudale Meadow⁴, the skeletal chronology limits its usefulness for comparing with regional trends.

Here, a new multi-centennial scale oxygen isotopic record from ostracod shells covering the early-mid Holocene from Crudale Meadow is presented. The isotopic data from Crudale Meadow are produced from winter calcifying *Candona* species; these have proven an ideal choice due to their abundance, good preservation and presence throughout the sequence, and well characterised vital offset⁵. Moreover, because they are known winter calcifiers, the impact of isotopic enrichment due to lake water evaporation in the summer months is reduced. This work also provides additional chronological constraint by presenting a tephrostratigraphy for the Holocene Crudale Meadow sequence, anchored by the Saksunarvatn visible tephra layer at the base of the studied sequence section which is dated to 10,210 ± 70 cal. years BP⁶.

Overall this research contributes both an additional site to the existing SW-NE transect across NW Europe, and a northernmost British record. It further allows us the potential to reconstruct atmospheric circulation changes by compiling isotopic data from multiple NW European sites during the early to mid-Holocene and comparing these with outputs from an isotope-enabled General Circulation Model, allowing for research into driving mechanisms. This is important for furthering understanding regarding the relationship between palaeoclimatic change and proxy $\delta^{18}\text{O}$ data.

The Dark Age Cold Period recorded in lake sediments in the Netherlands.

Marjolein Gouw-Bouman¹, Nelleke van Asch², Stefan Engels³, Wim Hoek¹

¹Utrecht University, Utrecht, Netherlands. ²ADC Archeoprojecten, Amersfoort, Netherlands. ³Birkbeck University of London, London, United Kingdom

Abstract

Here we present the first chironomid-inferred summer-temperature reconstruction for the late Subatlantic in the central Netherlands. A core segment from lake Uddelermeer covering the period 2500 cal. yr. BP to 400 cal. yr. BP was analysed on a high-resolution for organic content, pollen, spores and NPPs, and chironomid head capsules. In the temperature record, we could identify the presence of a Roman Warm Period, the Dark Age Cold Period and the Medieval Warm Period. The reconstructed temperature drop from the Roman Warm Period to the Dark Age Cold Period is 1.5 °C. These warm and cold periods have been identified in a range of proxy records throughout NW Europe indicating a regional climate trend. In this record the Dark Age Cold Period seems contemporaneous with a reforestation phase. This reforestation phase is recognized in numerous palynological records throughout the Netherlands and is commonly linked to a drop in population density following the decline of the Roman Empire. Additionally, this period appears to be characterized by large scale landscape changes in the Netherlands. The timing of all these changes might suggest that climate developments had an (in)direct influence on landscape developments and cultural trends.

Sedimentary Records from Lakes Reconstructing Late Quaternary Paleoclimate Changes in Mongolia

Alexander Orkhonselenge¹, Goro Komatsu², Tuyagerel Davaagatan³, Munkhjargal Uuganzaya¹

¹Laboratory of Geochemistry & Geomorphology, National University of Mongolia, Ulaanbaatar, Mongolia.

²International Research School of Planetary Sciences, Università d'Annunzio, Pescara, Italy. ³Division of Physical Geography, Institute of Geography, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia

Abstract

This study reconstructs the Late Quaternary paleoclimatic history of Mongolia based on multi-proxy sedimentary records from lakes in Mongolia. The high-proxy data show that in the Late Pleistocene, the cold and dry and cold and wet climates dominated in western and northern Mongolia, respectively. In the Holocene, paleoclimates in Mongolia differ from region to region depending on each landscape driven by local atmospheric circulations. In the early Holocene the warm and wet climates prevailed in western, central and southern Mongolia, while the cold and wet and cold and dry climates existed in Lake Darkhad and Lake Khuvsgul basins, and the valley between Khuvsgul and Khentii Mountain Ranges in northern Mongolia, respectively. In the middle Holocene, the warm and dry climates prevailed in northern (Lake Khuvsgul basin), western (Lake Khoton, Lake Achit and Lake Uvs basins), central and southern Mongolia, whereas the warm and wet climates dominated in western (the Depression of Great Lakes) and northern (Lake Darkhad basin and the valley between Khuvsgul and Khentii Mountain Ranges) Mongolia. In the late Holocene, the warm and wet climates prevailed in western, central and southern Mongolia, whereas the cool and dry and cool and wet climates differ in the Lake Darkhad basin and the valley between Khuvsgul and Khentii Mountain Ranges, and Lake Khuvsgul basin in northern Mongolia, respectively. A few high-proxy series of acceptable quality reflecting Holocene climates review with relatively precise dates from the lake sediments. Therefore, more precise investigations with detail dates from the lakes throughout Mongolia are needed to review the Late Quaternary paleoclimatic history in Mongolia and Central Asia.

P-2420

Late Glacial and Holocene vegetation and climate change in Western Sayan mountains derived from peat-lake sediments of mire Buibinskoye

Tatiana Blyakharchuk

Institute of Monitoring of Climatic and Ecological Systems of Siberian Branch of Russian Academy of Science (IMCES SB RAS), 634055 Tomsk, Russia. , Tomsk, Russian Federation

Abstract

Buibinskoye mire is located in central part of the Western Sayan Mountains in Ergaki Nature Reserve. This present day moss mire originated from lake and most of its 600 cm deposits are composed by lake sediments - gyttja. Sedge-moss peat forms only upper 130 cm of sediments. In common, peat and lake's sediments cover without interruption Late Glacial and Holocene time. Five radiocarbon dates were obtained by AMS method for this sediment section. Spores-pollen diagram reflects changes of the three main types of vegetation which dominated the study area from the Late Glacial to modern time. The beginning of the lake sedimentation started in the cryo-arid landscapes of the Younger Dryas covered by unique complex vegetation of forest-tundra-steppe. About 11000 cal. yr BP this type of vegetation was quickly replaced by mountain forests dominated by fir (*Abies sibirica*) and Siberian pine (*Pinus sibirica*). Pine forests with birch spread on foothills of the Western Sayan Mountains. During next stage of vegetation, which started about 5000 cal. yr BP domination in mountain forests passed from fir to Siberian pine. This type of vegetation cover is characteristic also for modern mountain forests of the Western Sayan. With the reduction of the role of fir in mountain forests the belt of subalpine shrubs began to expand like during Late Glacial time. Quantitative palaeoclimatic reconstructions based on palaeopollen data with use of transfer function evidence about cryo-arid climate in Late Glacial till 11000 cal. yr BP, humid moderate cool climate in Middle Holocene and humid and cool climate - in late Holocene after 5000 cal yr BP.

This research was performed with support of grant RFBR № 17-55-52020/MHT_a, and by budget thema of IMCES SB RAS

Ancient algae and crater chemistry: A 5,000-year record of environmental change from an Ethiopian crater lake

David Grady¹, Asfawossen Asrat², Sarah Davies¹, Henry Lamb¹, Frank Schäbitz³

¹Aberystwyth University, Aberystwyth, United Kingdom. ²Addis Ababa University, Addis Ababa, Ethiopia. ³University of Cologne, Köln, Germany

Abstract

Babogaya is a small (~500 m diameter), 60 m-deep maar lake, part of the Bishoftu Crater Lakes (BCLs) system, 50 km south of Addis Ababa, Ethiopia. Environmental conditions at the BCLs promote a seasonal cycle of lake mixing (dry season; November-February) and stratification (wet seasons). This cycle stimulates varying levels of nutrient circulation leading to the deposition of light-coloured, aragonite-rich lamina in the dry season, alternating with darker, more organic layers deposited in the wet season. Consequently, the sediments of this lake facilitate the high-resolution analyses of past climatic changes in a region sensitive to fluctuations in both Pacific and Atlantic moisture sources.

Diatom analysis of ~13 m of partially-laminated core, combined with bulk (C/N and $\delta^{13}\text{C}$) and XRF-derived sediment geochemistry, are used to infer past environmental changes in the area. A chronological framework from the radiocarbon dating of micro-charcoal fragments reveals a high sedimentation rate, with a basal date of ~5,500 cal BP.

Laminated sections of the core (500–3,200 cal BP, and ~4,000–5,500 cal BP) are characterised by organic rich, aragonitic sediments, dominated by small, planktonic *Nitzschia lancetulla*, with high abundances of Fragilaroid species characteristic of shallower (but still fresh) waters, (predominantly *Pseudostaurosira brevistriata* and *Staurosirella pinnata*), towards the base of the core. However, between 3,200 and ~4,000 cal BP the core is characterised by organic-poor, clastic sediment bounded at the base by a *Gastropod* shell layer, underlain by further laminated sediments. Lithogenic element (Ti and Fe) content through this clastic section is comparatively high, with decreased organic matter and biogenic silica (Si/Ti), interpreted as a period of low productivity in dry conditions. The record from Lake Babogaya illustrates a complex environmental history, including evidence for intense, abrupt Holocene aridity and potential desiccation, despite its depth.

Szafer Institute of Botany, Polish Academy of Sciences, Kraków, Poland. ⁴Polish Geological Institute - National Research Institute, Marine Geology Branch, Gdańsk, Poland. ⁵Department of Structural Geology and Geological Mapping, University of Wrocław, Wrocław, Poland

Abstract

A very peculiar profile with two palaeolakes divided by peat layer was discovered in the surroundings of Gorzów Wielkopolski, NW Poland. Sediments of the lower reservoir beared almost complete and well-preserved skeleton of rhinoceros *Stephanorhinus kirchbergensis* (Jäger, 1839). Above the skeleton, also a single bone of a fallow deer *Dama dama* (Linnaeus, 1758) was found. Some other faunal remains, lake fish and snails were also abundant in the profile. The analysis of pollen and plant macro-remains show, that during the deposition of lacustrine sediments, there were several changes in climate and environment. Research done so far, together with the obtained OSL and ¹⁴C dates, point out that this is a profile unique in Central Europe, covering the upper part of Saalian glaciation (MIS 6) and Eemian interglacial (MIS 5e, in the lower lake). The upper lake formed in the last glaciation, after Hengelo and Denekamp interstadials (MIS 3). The reservoirs are overlain by LGM sediments, and those are covered with Holocene sediments. The palaeobotanical research proves that the rhino skeleton comes from the optimal phase of Eemian interglacial with warm hornbeam forests. Also presence of a fallow deer confirms the warm climate. The lake was broad and diversified in its depth. The geochemical and palaeobotanical survey enabled to reconstruct several phases of the Gorzów Wielkopolski lakes' development in accordance to environmental changes in Upper Pleistocene and recreate the living conditions of *S. kirchbergensis*. It inhabited forests and scrublands, feeding mostly on the branches of birch, hazel and alder. This skeleton represents an adult specimen in the age exceeding 30 years. Except some minor pathologies bound with its age, there is a single bite mark on its pelvis. It was probably bitten when the carcass was floating in the water.

Controlling processes of diatom assemblages and their distribution in Lake Nam Co, Tibetan Plateau

Wengang Kang¹, Anja Schwarz¹, Patrick Rioual², Paula Echeverria Galindo¹, Nicole Börner¹, Jinlei Kai³, Junbo Wang³, Liping Zhu³, Antje Schwalb¹

¹Institution of Geosystems and Bioindication, Braunschweig, Germany. ²Geology and Geophysics Institute, Chinese Academy of Science, Beijing, China. ³Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Abstract

In arid and semi-arid regions with high variability of precipitation and evaporation, such as the Tibetan Plateau (TP), lakes react more sensitive to climate change and hydrological variations. Diatoms from Nam Co, the second largest (~1920 km²) saline lake (1.3 %) on the Tibetan Plateau are used as indicators for variations in hydrological balance and lake water quality including lake level, salinity and trophic state. Preliminary results from Nam Co sediments show climate-induced shifts in diatom communities during the late Holocene (Kasper et al., 2013), however, the autecology of modern diatom flora and their relationship with environmental conditions still remains unclear. Furthermore, high spatial heterogeneity of such a large lake should be considered because this can change sedimentary transportation processes, alter water physical and chemical parameters, and influence diatom community structure, diversity as well as distribution patterns. In order to characterize the ecology of living diatoms and to provide a reliable basis for paleoenvironmental interpretation from lake sedimentary sequences, twenty water samples and seventy sediment samples were collected in 2018 with a phytoplankton net (mesh size: 20 µm) and an Ekman grab from different water depths in the lake, incoming streams and nearby ponds. The diatom species composition and their planktonic: benthic (P:B) ratios were calculated and spatial distribution patterns were mapped. Other habitat properties such as macrophyte cover and anthropogenic influence were taken into consideration to better understand autecology of diatom species. Furthermore, we measured water physical parameters (temperature, dissolved oxygen, conductivity and pH) and water chemical variables (anions, cations, δ¹⁸O and δ¹³C isotopes) as well as grain size and loss on ignition for surface sediments. Redundancy analysis (RDA) was conducted to help identify the main drivers of diatom succession and to quantify their relationships with environmental conditions. Our results suggest that Nam Co is still an oligotrophic lake, and diatoms display high spatial heterogeneity, which could represent a response to the climate-induced changes of water conductivity and hydrological processes. Overall, this study will enhance the development of regional diatom datasets and understanding of diatom autecology, which can be used to interpret diatom-based reconstructions of environmental change on the Tibetan Plateau.

High-resolution hydroclimatic reconstructions through the Last Glacial-Interglacial Transition from the Vale of Pickering, Northeast England

Paul Lincoln, Ian Matthews, Adrian Palmer, Simon Blockley
Royal Holloway, University of London, Egham, United Kingdom

Abstract

The Last Glacial to Interglacial Transition (LGIT; 18-8 ka BP) was a climatically dynamic period characterised by abrupt changes in temperature and precipitation regimes across the European continent. Recent hydroclimatic research has demonstrated that spatially heterogeneous and diachronous hydrological shifts occurred across the European mid-latitudes, associated with abrupt temperature changes through the LGIT. This is particularly evident from hydroclimatic (lake-level) records through abrupt climatic events in the Early Holocene (e.g. the 8.2 ka event) which are bifurcated, with mid-European latitudes becoming more arid (with lower lake-levels), and lower and higher latitudes becoming more humid (with higher lake-levels) in response to cooling. Whilst shifts in temperatures (namely TMax/Mean July temperature estimates) are relatively well established through similar abrupt climatic events in the preceding Lateglacial Interstadial (i.e. c. 14.7-13 ka BP), hydrological shifts associated with these events are poorly understood, particularly in Northern Europe. This is pertinent as hydrological parameters are a primary control on the growth and decay of ice masses, the expansion and distribution of flora and fauna, and the mode and intensity of fluvial systems. Temporal and spatial changes in hydrology is therefore an important variable to reconstruct, in order to explain and quantify palaeoenvironmental/ palaeogeomorphic variability to abrupt climatic events.

This presentation will summarise work undertaken in the Vale of Pickering (VoP) in NE England (54.22 °N, 0.65 °W), aimed at reconstructing changes in hydroclimate through the LGIT via the multiproxy analyses (sedimentology, plant macrofossils, carbonate stable isotopes) of high-resolution palaeolake records, constrained by precise radiocarbon-based chronologies. Lake-level fluctuations in the VoP occurred in close association with threshold shifts across abrupt climate change boundaries, typically lowering in response to cooling. These fluctuations occurred at similar times (although in some cases were anti-phased) to hydrological changes in other European record. This presentation will summarise by discussing the implications of these findings, most notably the need for more high-resolution mid to high latitude hydroclimatic records, covering intervals of abrupt climatic change prior to the present interglacial.

Climatic variations in Central Brazil during the Mid-Holocene recorded in lacustrine sediments from Lagoa Feia- GO

Elder Yokoyama¹, Luciana Prado¹, Jeremie Garnier¹, Marie-Pierre Ledru², Suzan Rodrigues¹, Paula Bianchini¹
¹Universidade de Brasilia, Brasilia, Brazil. ²Institut de Recherche pour le Développement, Montpellier, France

Abstract

Climatic changes and their socio-environmental impacts are an issue of constant debate. Besides the instrumental data collected over the last 150 years, the climate variation before the instrumental period have been studied by sedimentary records, such as lakes, rivers, speleothemes, among others. The study of these records is part of paleoclimatological research through paleoenvironmental proxies to infer about climates of the past (e.g. pollen assemblages, stable isotope analysis, and environmental magnetism). In recent years, several paleoclimatic studies have identified lacustrine environments as important records of climatic and environmental changes because they integrate atmospheric and environmental variations. In this framework, paleoclimatic studies in lakes in the South American region are modest when compared to other parts of the world. An example of this gap in paleoclimatic studies is Central Brazil area. Central Brazil's predominant biome is the Cerrado (Brazilian savanna) and this is an important region to the water resources dynamics. This environmental data gap impairs the validation of global numerical simulations and, consequently, the improvement of future climate projections representing a limiting factor in climate change analysis and a challenge for the Brazilian and the international scientific community. The Federal District (FD, included in Central Brazil area) presents many small lakes located in several river basins affected by different contexts of land use evolution. Climate of the FD is driven by the South American Monsoon System, that establishes well-marked dry and wet seasons. Therefore, this study aims to contribute to the understanding of the South American climate during the Mid-Holocene in Central Brazil by investigating lake records in the FD and surroundings. Here, we will discuss the results for the Lagoa Feia, one of surrounding FD lake. These results comprise environmental magnetism data (e.g., magnetic susceptibility, MRN, ARM and S-ratio) and geochemical data (major and minor elements), obtained from a holocenic 6-m-length core collect in the Lagoa Feia. Mid-Holocene climate variations recorded in this core will be discussed.

P-2426

Distribution features of organic matter in sediments of small lakes of tundra and taiga in Western Siberia (Russia)

Natalia Larina¹, Sergei Larin², Daniil Nakov¹, Aleksandr Ustimenko¹

¹Tyumen State University, Tyumen, Russian Federation. ²Cryosphere Earth Institute SD RAS, Tyumen, Russian Federation

Abstract

Bottom sediments are one of the few sources of information about the genesis and lakes dynamics for a long time. Bottom sediments indirectly reflect the climate change of their territories. The layer-by-layer study of their chemical composition with a high resolution is of particular interest. Special interest is a layer-by-layer study of the chemical composition of bottom sediments with a high resolution. Columns of bottom sediments from 5 small lakes located in different climatic zones of Western Siberia were selected for study. The columns were divided into layers in 1 cm increments. The content of total carbon (TC), total nitrogen (TNb), as well as the organic and inorganic form of their being was determined in each layer. It should be noted that organic substances are unevenly distributed in depth and accumulate mainly in the upper 10-25 cm of bottom sediments. The total carbon content in the tundra lakes is insignificant and makes up less than 1% of the mass of bottom sediments. The total carbon content increases markedly to 5-25% in taiga lakes. The definition of water-soluble TCW showed that its average content varies in the opposite direction (see table), despite the increase in total carbon content.

Table. The content of total (TC,%) and water-soluble (TCW, mg / kg) carbon in the bottom sediment columns of tundra and taiga lakes in Western Siberia

Area	Tundra	Taiga		
Lake	Langotibeyto	Gol'tsovoye Lokhtokurt Rangetur		
	Total carbon (TC,%)			
Average	0,34	0,31	2,39	8,28
Median	0,30	0,15	2,72	0,35
Minimum	0,11	0,03	0,54	0,23
Maximum	0,94	1,19	5,77	26,04
	Water soluble organic matter (TC _w , mg/kg)			
Average	815	324	239	185
Median	805	299	222	173
Minimum	534	6	149	122
Maximum	1192	1102	385	338

Layer-by-layer analysis shows that determining the average content of organic matter (and other indicators) is not very informative and does not reflect its distribution over the column profile. The spectra of the most enriched sediment layers were taken to clarify the differences in the distribution of organic matter in the sediment profile. Potentiometric titration of isolated humic and fulvic acids was also carried out.

Thus, a comprehensive layer-by-layer study of bottom sediments allows one to assess its content in bottom sediments, as well as to establish possible causes of changes in its content and establish its relationship with changes in climatic and environmental conditions during the period of their formation.

ACKNOWLEDGEMENT

The work was carried out with the financial support of the Russian Foundation for basic research (Contract No. №18-44-860010) and the government of the Khanty-Mansiysk Autonomous Okrug–Yugra.

Abstract

Eemian Interglacial (MIS 5e) represents an important analogue for the current Holocene period and provides crucial knowledge into the paleoclimatology and paleoecology of interglacial environments developed without human impact. Outcrop Beckentin site is located in the SW of the federal state of Mecklenburg-Vorpommern (NE Germany). The study site lies outside the Weichselian zone of glaciation, approximately 25 km, which marks the southernmost ice marginal position reached by the Scandinavian Ice Sheet (SIS) during the Last Glacial Maximum. The Beckentin sequence of lake sediments provided rich plant micro- and macroremains along with cladoceran fauna, which permitted a palaeoenvironmental reconstruction between MIS 6 and MIS 4.

The Beckentin pollen sequence begins in the Late Saalian Glaciation (MIS6) when the landscape was dominated by Poaceae and Chenopodiaceae and was almost treeless. The beginning of the Eemian Interglacial shows a presence of pioneer forests with *Pinus* and *Betula* and followed by *Pinus* with *Quercus* and a raised participation of *Tilia* and *Corylus*. Next phase was characterized by an expansion of mixed deciduous forest with a dominance of *Corylus*. Also, riparian forests with *Alnus*, *Salix*, *Ulmus*, *Fraxinus*, *Taxus baccata* and *Humulus lupulus* developed. *Tilia* was increasingly important in the local forest communities. During the Eemian climatic optimum an expansion of *Carpinus* and *Picea* was observed, accompanied by *Ilex aquifolium*, *Buxus sempervirens*, and *Abies*. Deterioration of climatic conditions at the end of this interglacial led to a predominance of *Pinus-Betula* forests. The sedimentation in the palaeoreservoir ended in the Early Vistulian (MIS 4), when the steppe-tundra communities and especially heathlands created the landscape. The oligotrophy is confirmed by the numerous spores of *Isöetes lacustris* and peat bog with *Sphagnum*.

The results of palynological analyses were supported by plant macrofossil data, including fruits, seeds and wood remains that corroborate the palynological sequence. The most outstanding is a presence of thermophilous taxa typical of the Eemian climatic optimum such as *Brasenia* sp., *Dulichium arundinaceum*, *Najas minor*. Also, an occurrence of megaspores of *Salvinia natans* was of a special importance as it grows in warm climate.

The subfossil cladoceran fauna in Beckentin profile is represented almost only by the Chydoridae family (16 species), which lives in shallow water associated with water plants. The most abundant were remains of *Alona affinis* species. Only one marked species – *Bosmina longirostris*, originated from open water zone. Climatic and hydrological changes in the Eemian Interglacial from the Early to the Late Eemian resulted in improved living conditions of zooplankton, which was reflected in the increase in number of individuals and species diversity.

Stable isotope records of pollen fossils in Lake Suigetsu, Japan, during the Last Glacial-Interglacial Transition

Keitaro Yamada¹, Takayuki Omori², Takeshi Nakagawa¹, Ikuko Kitaba¹

¹Research Centre for Palaeoclimatology, Research Organization of Science and Technology, Ritsumeikan University, 1-1-1, Noji-Higashi, Kusatsu, Shiga, Japan. ²Laboratory of Radiocarbon Dating, The University Museum, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo, Japan

Abstract

Interactions of atmospheric, marine, terrestrial, and cryospheric realms are important factors in considering climate change mechanism (Lowe et al., 2008). Temporal difference between these realms is one of the keys to clarify cause/effect of palaeoclimate changes. Pollen analysis traditionally used as a one of the important methods to provide terrestrial proxy but involves a question that vegetation responses with lags to climate changes. Stable isotopic analysis is one of the solutions to this issue. Pollen is composed of sporopollenin and potentially provides isotopic signals which has applications within palaeoclimatology (Loader and Hemming, 2004). In this study, we therefore established a new method for concentrating pollen fossils using cell sorter and reconstructed a new proxy data of pollen stable isotopes using varved sediments obtained from Lake Suigetsu, Japan.

Lake Suigetsu (35°35'N, 135°53'E, 0 m a.s.l.), Fukui prefecture, central Japan, is one of the Mikata Five lakes, which measures 3 km east-west by 3 km north-south and the maximum water depth of ca. 34 m. Lake Suigetsu preserves annually laminated sediments over the last ca. 70 kyr with a significant number of event layers. Two long cores (SG93, SG06) have previously been recovered from the centre of the lake and an exceptionally precise age model has been established for the cores through a combination of over 800 radiocarbon (¹⁴C) dates and high precision varve counting (Staff et al., 2011; Marshall et al., 2012; Schlolaut et al., 2012; Bronk Ramsey et al., 2012).

In this study, we used well-dated SG06 cores and extracted pollen fossils using cell sorter. Cell sorter is able to separate specified particles using electrostatic deflection relying on differences in size, shape, and fluorescence. Pollen fossils can be sorted using cell sorter because sporopollenin constituting pollen fossils is naturally auto-fluorescent (Tennant et al., 2013). After pre-treatments with acid, alkali, and heavy media, pollen-enriched suspension was introduced into cell sorter to make high-purity pollen pellets. In this study, we collected half a million pollens per sample. After drying and weighting, $\delta^{18}\text{O}$ and δD of the pollen pellets were determined using High Temperature Conversion Elemental Analyzer (TC/EA, Thermo Scientific).

Purity of pollen in the concentrated pellets were >98%. The pellets contained multiple pollen species, and their composition slightly varied depending on the age. Pollen $\delta^{18}\text{O}$ fluctuates in synchronism with that of NGRIP but deviated after 11 ka. The fluctuation is more similar to that of Hulu. As a result, pollen isotopic changes include at least valuable global signal and has a potential as quantitative indicator of not only past terrestrial palaeoclimatological changes but also vegetation response. This research is still under development and requires more data points in order to discuss interaction between terrestrial and other regions.

Abstract

The Younger Dryas chronozone is the last and coldest abrupt climatic change that took place at the end of the late Pleistocene producing a significant environmental disruption in America Europe and Asia. These changes include diversity and abundance of vegetation, and are often associated with a large amount of charcoal recorded in several paleoenvironmental records and coincide with high mortality of large vertebrates. This abrupt YDB (Younger Dryas Boundary) change has been always associated with major drainage of Lake Agassiz producing a major change in southern overturning driving freshwater draining into the western Arctic Ocean. The mechanism of this overturning is not well understood. Several authors suggest that there was a comet affecting the atmosphere that occurred at around the YD Boundary as observed in a widespread anomaly in 50 YDB sites in all latitudes. This anomaly is found in lacustrine, fluvial, glacial and aeolian systems that date to around 12,800 y BP. The YDB layer has been proposed as a widespread correlation datum in America (North, and South), Europe and Asia. In order to investigate in Mexico sites potentially affected by the Younger Dryas event, we collected sediment samples from four ancient lakes in central Mexico (Chapala, Cuitzeo, Acambay, Chalco lake) and two rivers in the south Mexico (Oaxaca and Chiapas). All contain distinctive characteristics as determined by sedimentological, geochemical, micropaleontological and paleopedological analyses. The retrieved and dated lake and fluvial sediments encompass the Pleistocene-Holocene transition and provide good materials for studying the YD transition. The detailed stratigraphical analyses in the buried YDB layer intervals show anomalous values for bulk chemistry, pollen, stable isotopes, diatoms, nanodiamond polytypes, TOC, charcoal, soot, and platinum. All show higher concentrations than average background values associated with numerous quenched Fe spherules. These are morphologically and geochemically identical to quench-textured YDB spherules found elsewhere.

The nanodiamonds in the Mexican samples show the skeletal iron crystallization typical of rapid quenching, with about 96% iron oxide. Ternary diagrams make it clear that the spherules are not cosmic, volcanic, or anthropogenic in origin. In some river systems in Oaxaca Mexico, the quaternary landscape displays widespread evidence of outburst floods that produce extensive lag deposits. These sedimentological characteristics may indicate a sudden flood event that buried Late Pleistocene vertebrate remains. In Chiapas State, river sediments show clear fluvial traction deposits, with large channels, associated with lag deposits which incorporated Late Pleistocene vertebrate fossils.

All the anomalous changes found could be associated with a large extraterrestrial object, possibly a comet that produced abundant debris. The evidence suggest that the impact event causes a sudden influx of water into the atmosphere inducing abundant rainfall that may have caused a major shift in precipitation and fluvial patterns across the Northern hemisphere.

Timing of Quaternary glaciations in eastern Turkey, inferred from ^{36}Cl cosmogenic dating

Serdar Yeşilyurt¹, Uğur Doğan², Susan Ivy-Ochs³, Christof Vockenhuber³, Naki Akçar¹

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland. ²Department of Geography, Ankara University, Ankara, Turkey. ³Laboratory of Ion Beam Physics, ETH Zurich, Zurich, Switzerland

Abstract

Two mountain belts in Turkey, which are extending parallel to the coast in the north and south, give rise to moist air masses to leave precipitation substantially in the coasts. For this reason, the central Turkey receives lower precipitation than coastal regions, and thus continental climate prevails. This contradiction causes the coastal and inland equilibrium line altitudes (ELA) be different. To find out how this difference was in the past and how it changed in time, we focused, in this study, on significant geomorphological evidence of past glaciations in the eastern Turkish mountains. We investigated Quaternary geology and glacial geomorphology in the Kavuşşahap Mountains (3634 m above sea level, asl), Mount Bingöl (3193 m asl), Munzur Mountains (3462 m asl) and Tahtalı Mountains (2967 m asl) in detail and reconstructed the glacial chronology with surface exposure dating. In the field, we prepared detailed geomorphological maps for glacial landforms in the field and collected surface samples from glacially transported boulders on the moraines for cosmogenic ^{36}Cl analysis.

Our results indicated that these mountains have experienced several glacial advances. Palaeoglaciers reached their maximum positions in Tahtalı Mountains prior to the MIS-4 (Marine Isotope Stage 4); in Munzur Mountains during the MIS-3 and at Mount Bingöl during MIS-2. For instance, we reconstructed Late Pleistocene glacial chronology of four advances in the Narlıca valley system in the Kavuşşahap Mountains. The oldest and most extensive glacier advance occurred at ca. 48 ka (ka: thousands years) during the MIS-3. During this advance, the equilibrium line altitude (ELA) was 1150 m lower than today and mean temperature was ca. 10 °C colder than today. The second advance was ca. 32 ka prior to the global Last Glacial Maximum (LGM; 22.1 ± 4.3 ka). Third advance was occurred ca. 21 ka during the global LGM. In the Narlıca valley system, last advance of glaciers occurred ca. 16 ka during the Lateglacial period.

The deglacial history of the Donegal ice dome

Chris Millar¹, Paul Dunlop¹, Sara Benetti¹, Peter Wilson¹, Peter Clark²

¹Ulster University, Coleraine, United Kingdom. ²Oregon State University, Corvallis, OR, USA

Abstract

Accurately reconstructing the history of paleo-ice sheets is critical for understanding climate and ice sheet dynamics which is important if we are to better understand the future trajectory of the Greenland and Antarctic Ice Sheets in a warming world. Ice sheets have long life cycles and the best way of understanding their response to climate change is to investigate the geological record of paleo-ice sheets which provides a record of former ice sheet behaviour through full glacial cycles. The former British-Irish Ice Sheet (BIIS) is known to have been sensitive to climatic signals from the North Atlantic making it a good proxy for examining these long-term climate/ice sheet relationships. During the Last Glacial Maximum in Ireland (~27 ka), the BIIS covered all of Ireland, extended to the continental shelf edge and then retreated to a coastal position as an ice dome by ~21ka in the North. After ~18 ka it is thought to have retreated into the Donegal Mountains and down-wasted to lower altitudes during its final stages. However, to date the full retreat pattern has not been mapped and new dates are required to fully age constrain the final deglaciation in this region. This PhD project addresses these issues through geomorphological mapping and dating using Schmidt Hammer Exposure Dating (SHED), a technique which has been shown to accurately constrain the timing of BIIS deglaciation in granite lithologies (Fig 1). This will be achieved by: 1) The identification and mapping of deglacial geomorphological features using high-resolution aerial imagery. 2) Dating of these features to reconstruct the deglacial chronology of the Donegal Ice Dome. 3) Using both datasets to develop an age-constrained conceptual model of the final deglacial chronology of the Donegal Ice Dome constraining down-wasting and retreat. This poster presents results from 30 sites that have been dated using SHED across the Derryveigh Mountains in northwest Donegal (Fig. 2) providing deglacial ages ranging from 19.58 ka to 11.85 ka. This research will further our understanding on the pattern and timing of deglaciation of this significant ice source and provides a framework investigating the drivers glacial change in this region.

Reconstruction of climate from the high altitude glacial lakes of the Ladakh range, Trans Himalaya, India.

Priyanka Joshi, Binita Phartiyal, Anjum Farooqui
Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

The glaciers of the Ladakh Range are retreating and depleting over time and as this is taking place, a new landscape with lakes commonly behind the newly exposed moraines are being observed all along the ridge line. Hence a detailed multi-proxy study (mineral magnetism, textural analysis, loss on ignition, pollens, algae and testate amoebae) from the sediment archive of these glacial lakes was undertaken to decipher the climatic fluctuations during the Holocene as these lakes directly recharged by melt-water from glaciers and melt snow provide complete record of past climatic variability due to a continuous sedimentation. The region is located in a junction zone of Indian Summer Monsoon (ISM) and Westerly wind influence, which makes it an ideal region for studying the regional response on global climatic changes. The Ladakh range is a prominent range trending NW-SE for ~350 km (length) and varying from ~50 km in the west and pinching towards the eastern side to 20 km (width) and tectonically active placed between the Indus Suture Zone in the south and the Karakoram Thrust in the north making its position all the more vital to study the climate-tectonic interaction as well. Two types of lakes are exposed, one with peak primary productivity comprising of the pro-glacial lakes which occupy the higher elevations and the other ones positioned in lower altitudes are seen as remnant/palaeolakes scattered over the abandoned moraines. The pro-glacial lakes of the Chang La- Tangtse basin were examined on the basis of the preserved biota, which includes pollen, algal and testate-amoebae concentration. The relative percentage of the palynomorphs recorded constitute Pollens (13%), Bryophytic spores (0.9%), Algae (25.3%), Algal cysts (7.6%), Fungal spores (5.6%), Testate amoeba (46.7%), Insect wing (0.3%) and Sponge spicule (0.3%). High percentage of testate amoebae indicates oligotrophic ecosystem with sufficient dissolved oxygen and optimum pH levels, whereas enhanced algal growth suggests prolong summer season and sufficient nutrient supply. About 12 species of testate amoebae have been recorded from the lake, out of which *Centropyxis pontigulasiformis* has been observed for the first time from the Indian subcontinent. From a biological perspective an understanding of climate in the high altitude regions is especially important because even slight shifts in climate can affect the biota of the region. In the other study a palaeolake section bracketed between 1737 to 6529 cal yrs BP, the multi-proxy results indicate a cold and harsh condition prevailing between 6529-6039 cal yrs BP with glacial advancement and a shift to slightly better conditions from 6039 cal yrs BP and three spells of abrupt monsoon phases (ISM) are recorded. Five cycles of cold and warm episodes are evidenced from ~5000-1700 cal yrs BP with peak aridity between 3099-2826 cal yrs BP.

P-2433

Dating the last British–Irish Ice Sheet from basin-fill sediments in the Vale of York, UK

Della Murton, Simon Crowhurst
University of Cambridge, Cambridge, United Kingdom

Abstract

We report an age model for the Devensian (Weichselian) glacial Stage (marine isotope stages (MIS) 4–2) from basin-fill sediments in the Vale of York, and use it to constrain the advance and retreat of ice lobes of the British–Irish Ice Sheet (BIIS) in this region during this time. Our age model is based on optically stimulated luminescence (OSL) dating, and relative palaeointensity (RPI) measurements calibrated to a RPI record from deep-sea sediments in the northeast Atlantic Ocean. Four near-continuous cores drilled to bedrock indicate the basin-fill sediments comprise alternating units of reddish brown to dark greyish brown laminated to faintly stratified silty clay, and dark greyish brown silt interbedded with yellowish brown silty sand. To assess climatic variability recorded in them we quantified colour variations using the CIELAB colour space and compared a^* reflectance—a measure of sediment redness—with the GICC05 NGRIP $d^{18}O$ chronology. We draw two conclusions from our sedimentological and chronological data. (1) Basin sedimentation began at c. 40.25 ka (MIS 3) and ceased at c. 16.10 ka (MIS 2). This timing corroborates ice-rafted debris records of the BIIS from the northeast Atlantic Ocean, but is inconsistent with the most recent palaeoenvironmental reconstructions derived from OSL dating of glaciogenic sands in our study region. (2) Our a^* reflectance records identify millennial-scale variations during MIS 3 that we attribute principally to periglacial weathering and transport of frost-susceptible reddish brown Permo–Triassic bedrock underlying the Vale of York.

Quantifying long-term processes of moraine evolution: Implications for terrestrial cosmogenic nuclide dating and moraine age interpretations

Matt Tomkins¹, Jason Dortch², Raimon Pallàs³, Philip Hughes¹, Jonny Huck¹, James Allard¹, Andrew Stimson¹

¹University of Manchester, Manchester, United Kingdom. ²Kentucky Geological Survey, Lexington, USA. ³Universitat de Barcelona, Barcelona, Spain

Abstract

The Quaternary glacial record is a valuable resource, which underpins palaeoclimate reconstructions and chronicles links between terrestrial ice masses and climatic variability. In turn, this information provides context for modern climate change and the widespread global pattern of glacier mass loss. However, determining causal links between palaeoclimate and periods of glacier advance/retreat is predicated on the development of robust chronological frameworks. The widespread application of terrestrial cosmogenic nuclide (TCN) dating on glacial moraines has transformed our understanding of past glacial cycles but considerable challenges remain: in particular the degree to which moraine ages accurately record the timing of deglaciation. Processes of moraine stabilisation and nuclide inheritance can result in erroneously 'young' and 'old' TCN ages respectively, introducing considerable complexity to moraine age interpretations. The most significant barrier to isolating biased ages is the cost of TCN dating, which often precludes a large number of samples ($n \geq 30$) and prevents statistically robust identification of outliers. As a result, the best resource-limited strategy is to perform a careful geomorphological assessment prior to sample selection. However, current sampling approaches, which prioritise moraine crest boulders and derive landform ages from the mean of few TCN ages (typically $n \leq 6$), appear to be at odds with models of moraine evolution (which predict the greatest ground lowering at the crest) and guidance on interpreting moraine datasets as minimum limiting ages. In this project, we investigate four moraines in the Pyrenees mountains of France and Spain, deposited at ~ 27 , ~ 23 , ~ 12 and ~ 3 ka, in order to assess the suitability of current TCN sampling approaches. Through intensive Schmidt Hammer (SH) sampling (n boulders = 505), we show that the spatial distribution of "good" and "bad" boulders is complex and does not conform to existing crest or slope models. For some moraines, the distribution is effectively random and the probability of selecting "good" ages is not significantly improved by sampling on moraine crests, ice-proximal or -distal slopes. Exhumation is a significant post-depositional process for the large lateral LGM moraines deposited in the Aranser (*IQR* 7.8 ka, *Skew* -1.02, *Exhumed* 52%) and Gave de Pau catchments (*IQR* 3.6 ka, *Skew* -1.47, *Exhumed* 36%). While exhumation is generally less significant for post-LGM cirque moraines in the Noguera Riborgçana catchment, topography can control the distribution of TCN ages through post-depositional avalanching and incorporation of pre-existing deposits. Importantly, these data indicate that spatial criteria alone cannot be used to isolate exhumed boulders, and that current sampling approaches are indistinguishable from random boulder selection. As such, the abandonment of a crest-only strategy widens the population of suitable boulders for TCN dating; in turn producing more consistent datasets, better moraine age interpretations and more robust links to palaeoclimate drivers.

P-2435

Impact of glacial isostatic adjustment on surface-exposure dating

Richard Selwyn Jones, Pippa Whitehouse, Mike Bentley, David Small, April Dalton
Durham University, Durham, United Kingdom

Abstract

Calculating cosmogenic-nuclide surface-exposure ages is critically dependent on a knowledge of the altitude of the sample site. Changes in altitude have occurred through time as a result of glacial isostatic adjustment (GIA), potentially altering local nuclide production rates and, therefore, surface-exposure ages. Here we assess the impact of GIA on surface-exposure dating by calculating global time-dependent production rates since the Last Glacial Maximum (LGM) using surface elevations that were corrected and uncorrected for GIA. We find that the magnitude of the GIA effect is spatially and temporally variable. Nuclide production could be reduced by up to 50% in the interior of large ice masses (in North America, Scandinavia and West Antarctica) at times of maximum glacial isostatic depression. Although smaller, the effect is still significant at ice sheet margins, where nuclide production is reduced by >5% and potentially >10%, making exposure ages older in those areas. Away from the ice sheet margins, land surfaces may have been isostatically elevated during the LGM, which can increase nuclide production by >5% and, therefore, make exposure ages younger. Areas that were more recently exposed or that are distal to large ice masses will generally be less affected. Importantly, we find that the effect at the primary ^{10}Be production calibration sites is <1%. Applying a GIA correction to surface-exposure data may help resolve mismatches between some chronologies, but not necessarily in all regions, implying that additional factors may need to be considered. Past atmospheric changes could amplify or reduce the impact of GIA on nuclide production, and the combined effects should be fully accounted for in the future. These time-dependent influences on surface-exposure dating have potentially large implications for interpreting chronologies and for using the data to constrain ice sheet models.

P-2436

The significance of local topo-climatic factors for cirque glacier formation during the Younger Dryas in the Wicklow Mountains, Ireland

Lauren Knight^{1,2}, Clare Boston¹, Harold Lovell¹, Nicholas Pepin¹

¹University of Portsmouth, Portsmouth, United Kingdom. ²University of Worcester, Worcester, United Kingdom

Abstract

The Wicklow Mountains are a key area for understanding glaciation extent in the east of Ireland during the Younger Dryas (YD; 12.9 – 11.6 ka BP). Due to its location between the mountains of western Ireland and mainland Britain, the region offers an important insight into the understanding of both local and regional palaeoclimate. Similar work has recently been undertaken in the Mourne Mountains and Snowdonia, increasing understanding of restricted upland glaciation during the YD. Traditionally, the Wicklow Mountains have been considered marginal for YD glaciation, characterised by small cirque glaciers in limited upland locations. Yet, the only thorough investigation of YD glacier extent is at the Irish type-site, Lough Nahanagan, where a series of moraines within the cirque lake have been radiocarbon dated to 11.5 ka BP. Here, we present the first detailed examination of YD glaciation extent and style in the Wicklow Mountains. The limits of six viable YD glaciers are identified using a combination of geomorphological mapping, morphostratigraphy, and radiation and snowblow modelling. A total glacierised area of 2.33 km² is reconstructed, with an average glacier area of 0.39 km². Reconstructed ELAs (AABR 1.9 ± 0.81) range from 467 ± 9 to 739 ± 8 m, with a regional average of 621 ± 9 m. We demonstrate that not all cirques in the Wicklow Mountains were occupied during the YD. Geomorphological evidence supportive of YD glaciation is absent in all cirques with southern and south-eastern aspects. Radiation modelling shows that these sites received the highest levels of solar insolation, up to 7000 Wh/m². In contrast, all proposed YD sites identified through the use of morphostratigraphy received lower levels of solar insolation (up to 5000 Wh/m²) than surrounding areas, due to a combination of topographic shading and aspect. A glacier-derived sea-level equivalent precipitation range of 1648 ± 569 to 2476 ± 273 mm^{a-1} implies wetter conditions than at present in the Wicklow Mountains. We suggest that calculated precipitation estimates actually reflect the influence of topographically enhanced snow accumulation. Snowblow modelling suggests that glacier mass balance was augmented by the redistribution of snow by wind, lowering glacier ELAs from 'true' climatic ELAs. Both snowblow and enhanced topographic shading were key factors in YD glacier initiation and survival in the region. Our research adds to the growing evidence for cirque glaciation in upland areas of Ireland and Britain during the YD and provides important insights into the importance of topo-climatic factors.

Alpine glacier fluctuations and paleoclimate reconstruction: post-LGM glacial history of Aosta Valley (Italian Alps)

Elena Serra^{1,2}, Natacha Gribenski^{1,2}, Pierre G. Valla^{3,1,2}, Julien Carcaillet³, Romain Delunel¹

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland. ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ³Institute of Earth Sciences, CNRS-University Grenoble Alpes, Grenoble, France

Abstract

Past-ice extent and thickness fluctuations can be used as quantitative paleoclimate proxies since glacier mass-balance is sensitive to both temperature and precipitation changes (Kerschner and Ivy-Ochs, 2008). Paleo-glacier reconstructions in the Alps, together with speleothem records and other proxies (Heiri et al., 2014), suggest that a shift in Alpine atmospheric circulation took place during the Last Glacial Maximum (LGM), at or just before the onset of Alpine glaciers retreat. A major change occurred from south-westerly moisture advection from the Mediterranean to northerly moisture advection from the Atlantic, due to the northward migration of the North Atlantic storm track (Florineth and Schlüchter, 2000). However, both the exact timing of this shift and the resulting change in precipitation and associated alpine glacier responses remain elusive (Luetscher et al., 2015; Monegato et al., 2017).

This study aims to improve our understanding of the paleoglacial and paleoclimate conditions in the Western Alps since the LGM. We here focus on the Dora Baltea valley and its tributaries (Aosta Valley, Italy). Few chronological constraints are available for the post-LGM glacial history of Aosta Valley, mainly related to the Ivrea Amphitheatre and the Mont Blanc massif (Gianotti et al., 2008; Wirsig et al., 2016). However, differences in glacier responses between tributary valleys may be expected, because of distinct local geomorphological and climatological conditions between the glacial catchments. The main glacial subsystems of Aosta Valley are indeed related to prominent Alpine massifs (Mont Blanc, Grand Paradiso and Monte Rosa) that are fed by different moisture sources.

Following a detailed geomorphological mapping of glacial landforms and deposits in Aosta Valley, moraine boulders and glacially-polished bedrock along formerly-glaciated valleys were sampled for *in situ* ¹⁰Be surface exposure dating. We specifically targeted the Mont Blanc and Monte Rosa glacial subsystems, in order to obtain a high-resolution reconstruction of post-LGM glacier retreat. Morphometric and especially hypsometric analyses were conducted on the different drainage subsystems to investigate the possible influence of local factors (e.g. topography, aspect, glacier geometry...) on potential variability in post-LGM glacier fluctuations, before isolating a climatic signal from our paleoglacial reconstructions. To further study the sensitivity of glacier systems to climate forcing in Aosta Valley, geomorphological evidence and geochronology data will be included in ice-dynamics numerical simulations (iSOSIA model, Egholm et al., 2012).

Integrating near surface geophysical and sedimentological techniques to assess proglacial sediment properties at Midtdalsbreen, southern Norway.

Hannah Watts¹, Benedict Reinardy¹, Peter Jansson¹, Adam Booth², William Murphy²

¹Stockholm University, Stockholm, Sweden. ²University of Leeds, Leeds, United Kingdom

Abstract

The impact of sediment availability and mechanical properties on moraine production and preservation is currently poorly understood, particularly at small mountain glaciers where responses to climate change are rapid. To maximize the potential of moraines as proxies for former glacier geometries and palaeoclimate indicators, a thorough understanding of the controls on landform genesis and subsequent evolution is required. Traditionally, moraines have been studied using glacial geological techniques such as sedimentary logging. While this provides valuable, in situ information, there are numerous limitations, namely poor availability and spatial extent of exposures. Geophysical methods, such as ground penetrating radar (GPR) and seismic reflection and refraction, offer a means to undertake non-destructive subsurface exploration of sedimentary sequences. However, the full potential of these methods has yet to be exploited in the proglacial environment.

This study is combining near surface geophysical and sedimentological techniques to image the proglacial sediments and detect buried glacier ice across the foreland of Midtdalsbreen, an outlet glacier of the Hardangerjøkulen icefield, southern Norway. Initial processing of trial seismic refraction data, using 48 geophones at 1 m spacing along the 2001 terminal moraine at Midtdalsbreen suggests a refracting interface at 0.5 m - 0.8 m depth between layers with seismic velocities of ca. 1200 ms⁻¹ - 1600 ms⁻¹ and ca. 2800 ms⁻¹ - 3500 ms⁻¹. There are four possible interpretations of these values: coarse material with abundant air filled voids underlain by (1) permafrost (2) ice core (3) frozen, water saturated sediments or (4) compacted, consolidated sediments. Each of these scenarios has significant implications for interpreting past glacier dynamics, landscape geomorphology and preservation potential and the associated palaeoclimate. Therefore, it is important that further geophysical surveys and sedimentary logging are carried out to provide a robust interpretation of the foreland composition at Midtdalsbreen.

To overcome the inherent limitations of each geophysical technique, namely the non-uniqueness of interpretations, multiple methods are being deployed. Seismic reflection and refraction and GPR surveys are being applied across the glacier foreland to image the depth to the bedrock and reveal the internal structure and sediment properties of moraines, including whether they are ice cored. Sedimentary logging and laboratory-based geotechnical analysis of sediment samples from across the foreland will be carried out to provide empirical data, enabling robust interpretations of the geophysical datasets.

Through integration of these techniques this study looks to provide more extensive knowledge of the proglacial sediments and sedimentary structures present within the foreland of Midtdalsbreen. This will improve our understanding of the controls on moraine morphology and preservation, in turn, leading to an advanced understanding of past ice dynamics and the associated palaeoenvironments at Midtdalsbreen and the future stability of the Hardangerjøkulen icefield.

Comparison of equilibrium line altitudes calculated from glacier topography versus directly measured equilibrium line altitudes for glaciers in Scandinavia

Rachel Oien¹, Matteo Spagnolo¹, Brice Rea¹, Iestyn Barr², Robert G. Bingham³

¹University of Aberdeen, Aberdeen, United Kingdom. ²Manchester Metropolitan University, Manchester, United Kingdom. ³University of Edinburgh, Edinburgh, United Kingdom

Abstract

Palaeo-glaciers are increasingly being used to infer palaeo-climate conditions. They are typically reconstructed using numerical (recommended) or cartographic methods to generate a 3D surface from which the glacier equilibrium line altitude (ELA) is calculated. At the ELA climate is linked, by empirical relationships, to summer temperature and annual precipitation. Here, we present a validation of the Area-Altitude Balance Ratio (AABR) and Accumulation-Area Ratio (AAR) methods typically used to estimate palaeo-glacier ELAs. We utilise an existing ArcGIS toolbox to extract the ELA of 11 extant glaciers based on DEMs of their surface area. These measurements are then compared to direct ELA measurements of the same glaciers. The extant glacier ELAs were calculated using the Area-Altitude Balance Ratio (AABR) and Accumulation-Area Ratio (AAR) methods, using AABR and AAR value of 1.5 ± 0.4 and 0.58. This approach implicitly assumes that the glacier is in equilibrium with climate so in order to compare like-with-like we calculated the zero net mass balance for the 11 glaciers. The annual specific net balance was plotted against the ELA, as measured by the Norwegian Water Resources and Energy Directorate (NVE). The zero net balance ELAs are correlated to the AABR/AAR calculated ELAs, with an $R^2 = 0.996$ and 0.992 . The minimum difference between the measured and calculated ELAs is 6m and the average is 26m. These results indicate the validity of the AABR approach to estimate the ELA, for extant and palaeo-glaciers. This work is being further validated against other glaciers worldwide, for which a zero net balance can be calculated and a DEM of the glacier surface is available.

New luminescence dating from glaci-fluvial and glacial-lacustrine deposits from South-Central and South-eastern Pyrenees (Noguera Ribagorzana, Noguera Pallaresa, Valira & Segre)

Valenti Turu^{1,2}, Jose-Luis Peña-Monne³, Pedro-Proença Cunha⁴, Jan-Pieter Buylaert^{5,6}, Andrew Murray⁶

¹Marcel Chevalier Earth Science Foundation, Andorra la Vella, Andorra. ²Departament de dinàmica de la terra i l'oceà, Facultat en Ciències de la Terra, Barcelona, Spain. ³Departamento de Geografía y Ordenación del Territorio, Facultad de Filosofía y Letras, Zaragoza, Spain. ⁴MARE - Marine and Environmental Sciences Centre, Department of Earth Sciences, Coimbra, Portugal. ⁵Centre for Nuclear Technologies, Technical University of Denmark, Risø, Denmark. ⁶Nordic Laboratory for Luminescence Dating, Aarhus University, Risø, Denmark

Abstract

New OSL dating from the Southern slope of the Pyrenees are present in this work. Such a datations update the most relevant glacial phases identified by previous authors. From our data two glacial cycles are clearly dated, the penultimate and the last glacial cycle. The last glacial cycle can be divided in four major phases:

1. An early glacier extension at MIS5c
2. Glacial readvance at MIS4, when the Last Maximum Ice Extent (LMIE) occur in most of the Pyrenean range
3. Glacial fluctuations during MIS3 and MIS2
4. Deglaciation phase starting at the MIS2 end.

We focus our results in three questions:

- What is new from the penultimate glacial cycle
- Did the LMIE coincides with an early Würmian stage?
- Were the Last Global Maximum (LGM) and the LMIE coincide.

A MIS6 glacial cycle is asserted at both extremes of the Southern Pyrenees (this work and García-Ruiz *et al.*, 2013), however our datings improve its knowledge in the Valira valleys, were we found a two fold sedimentary sequences starting at MIS6 (**Figure 1**).

Figure 1: NNW-SSE section from the Segudet kame and glaciolacustrine complex in Andorra (SE-Pyrenees). Gr: Imbricated gravels (kame). Fl: Laminated fines (Glaciolacustrine). Gs: Stratified gravels (colluvium). Dmc: Massive diamicton rich in boulders (Würmian supraglacial till).

The Würmian cooling start close to 90 ka (MIS5c), being synchronous in both Pyrenean slopes, at least in its Eastern side (French Cerdagne and at La Margineda in Andorra, this work, the French Niaux cave, Pallàs *et al.*, 2006). From La Margineda (980 m a.s.l.), this first glacial advance is behind the LMIE (< 845 m a.s.l.). This also happen in the South-Central Pyrenees (Noguera Ribagorzana, Cinca-Cinqueta, Ara, Gallego and Aragon; Sancho *et al.*, 2018), however at the Easternmost side of the Southern-Pyrenees not. This is the case of Puigcerdà (Cerdagne), were the LMIE from the Carol glacier coincides twice in MIS4 and in MIS2. However an early Würmian glacial front behind this LMIE position might be expected since we got a MIS5c glaci-fluvial deposits at LMIE position (**Figure 2**).

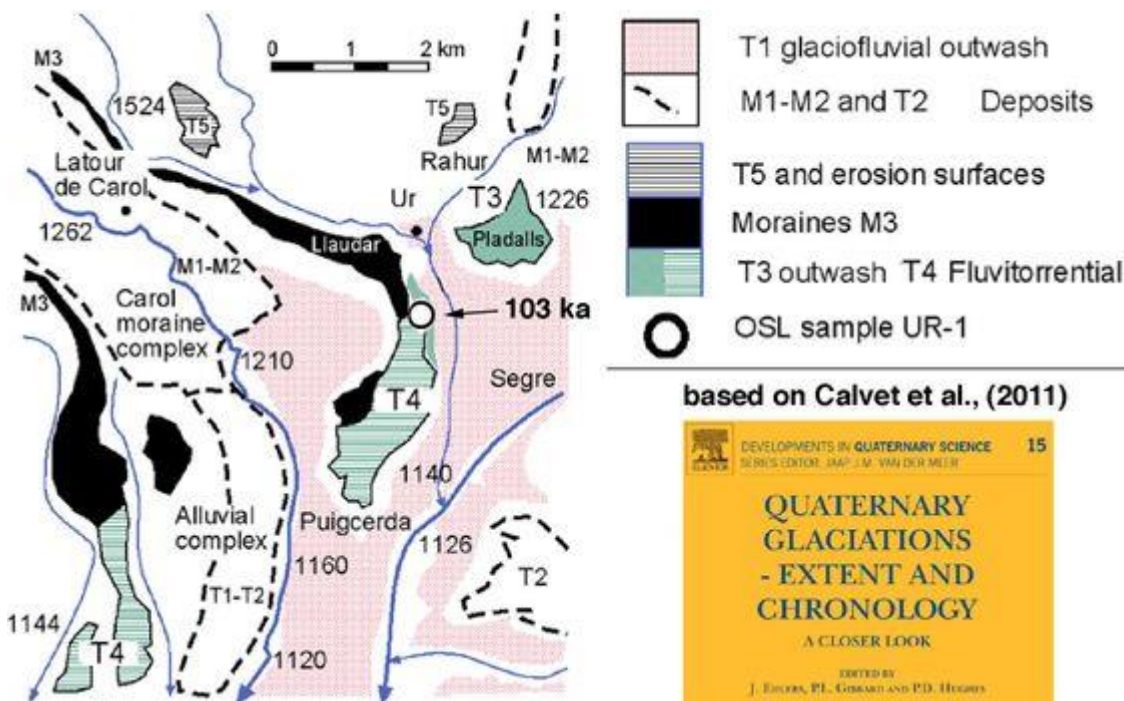

Figure 2: Geomorphological sketch at Puigcerdà. Previous authors dated Moraine M2 as from MIS4 and moraine M1 as from MIS2 (LGM). Outwash T3 early Würm (this work).

The idea of an LMIE-like for the LGM phase (Pallàs *et al.*, 2006) still remains in the literature, however updated data denies this, almost at the southern slope of the Pyrenees. However this glacial feature seems occur only at the Easternmost Pyrenees (Carol valley) but further work is still needed.

Timing of the local Last Glacial Maximum and deglaciation on Pico de Orizaba and Cofre de Perote volcanoes (Mexico)

Jesús Alcalá-Reygosa¹, Lorenzo Vázquez-Selem², Irene Schimmelpfennig³, ASTER Team³

¹Facultad de Filosofía y Letras, Universidad Nacional Autónoma de México, Ciudad Universitaria, 04510, Ciudad de México, Mexico. ²Instituto de Geografía, Universidad Nacional Autónoma de México, 04510, Ciudad de México, Mexico. ³Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, Aix-en-Provence, France

Abstract

Glaciers are highly sensitive indicators of global modern and past climate change especially in the tropical region (Kaser and Osmaston, 2002). In Mexico, the glacial history has been studied extensively, but the chronology of the local Last Glacial Maximum and deglaciation remain poorly constrained in some mountains such as Pico de Orizaba and Cofre de Perote stratovolcanoes. Both stratovolcanoes are located in the eastern part of the Pliocene-Quaternary Transmexican Volcanic Belt, ~100 km to the west of the Gulf of Mexico.

In situ-produced cosmogenic ³⁶Cl ages of moraines and glacially polished bedrocks from Iztaccíhuatl volcano, which present the most accurate dated glacial record in central Mexico, suggest that the local Last Glacial Maximum took place between 20 and 14 ka whereas the deglaciation began ~ 14 ka ago (Vázquez Selem and Lachniet, 2017). Based on the well-constrained glacial chronology of Iztaccíhuatl volcano, we expect to obtain a similar chronology of the local Last Glacial Maximum and deglaciation on Pico de Orizaba and Cofre de Perote volcanoes. To verify this hypothesis we also used ³⁶Cl cosmic ray exposure (CRE) dating to determine the age of moraines and glacially polished bedrocks from both stratovolcanoes.

The ³⁶Cl CRE ages of a moraine of the local Last Glacial Maximum from Pico de Orizaba range from 20.9 ± 2.3 ka to 16.7 ± 2.8 ka. Regarding the deglaciation, two glacially polished bedrocks yielded the following ³⁶Cl CRE ages: 13.6 ± 2.8 ka and 11.0 ± 1.7 ka. Cofre de Perote presents similar ³⁶Cl CRE ages: 20.4 ± 1.1 to 13.2 ± 1.0 ka from three moraines (n=6 samples) of the local Last Glacial Maximum; and 14.1 ± 1.0 ka to 11.4 ± 0.6 ka from glacially polished bedrock (n=4). Overall, these ³⁶Cl CRE ages reveal a similar glacier behavior between the central and the eastern part of Mexico during the local Last Glacial Maximum and the beginning of deglaciation. Moreover, it must be noted that the local Last Glacial Maximum coincides with the global Last Glacial Maximum and the onset of the deglaciation could correspond with the Bolling-Allerod. However, these connections must be confirmed through more dating efforts due to the high uncertainties that present the ³⁶Cl CRE ages.

Quaternary South glacial advancement in the Andes at ~ 37° S and the discussion about paleoglacial meaning

Delia Rodríguez-Oroz¹, Yoal Díaz Reyes², Matias Barrera González²

¹Universidad del Desarrollo, Santiago, Chile. ²Universidad Andrés Bello, Concepción, Chile

Abstract

In Chile between 30°S - 40°S little is known about the Last Glacial Maximum (LGM) because of the gap in studies about palaeoenvironmental changes. Few studies in Laguna del Maule (~ 36° S) and el Yeso (~ 33° S) showed that LGM glacier advances in this area of the Andes have not been neither synchronic nor equal and have presented lags related to weather conditions. Moreover, the geomorphological registers are no continuous due to the activity of volcanos during Quaternary in the area and landslide events.

The present work shows results of a geomorphological study focused on determining the maximum glacier advancement in the Diguillín valley at ~ 37° S. The valley presents typical characteristics of U-shaped valleys and glacial evidences such as moraines, erratic rocks and outwash deposits. The geomorphological cartography of the valley shows that the action of glaciers had a great importance in the formation of relief in the area.

The moraines studied along the Diguillín valley are dissected by recent alluvial channels and covered by alluvial fans showing different degrees of preservation and extension. These morphologies are the result of glacial retreat since the Pleistocene. Related to glacial body descendent erratic rocks deposits has been observed at 697 m.s.n.m suggesting the existence of glacier development formed by the Diguillín and its tributaries, which would have reached a level below 700 m.s.n.m. The fluvioglacial deposits constitute the most western glacial deposits in the hydrographic basin of the Diguillín River. These results imply that the maximum local advance of the glaciers during the Last Glaciation reached levels of 630 m.s.n.m. over the west side of the mountain range.

Through the identification of glacial deposits this study shows the first evidence of Quaternary glacial advancement below 900 m.s.n.m between 30°S - 40°S in Chile and contributes to the knowledge of the geomorphological and paleoclimatic evolution glacier advancement of the late Quaternary South Andes. To determine the glacial chronology events, it is necessary to complemented this study with ages of exposure through cosmogenic methods. That will provide absolute age control on the palaeoenvironmental history and the differentiation between global Last Glacial Maximum (LGM) (21 ka BP) and to the Younger Dryas/Antarctic Cold Reversal (10 ka BP) event will be possible.

The rapid deglaciation of the La Vega gorge (Sierra de Gredos, Spain) following the Last Glacial Maximum

Jesús Alcalá-Reygosa¹, David Palacios², Néstor Campos², Nuria De Andrés², Irene Schimmelpfennig³, Laetitia Léanni³, Jorge Sanjurjo⁴, ASTER Team³

¹Facultad de Filosofía y Letras, Universidad Nacional Autónoma de México, Ciudad Universitaria, 04510, Ciudad de México, Mexico. ²Departamento de Geografía, Universidad Complutense de Madrid, Madrid, Spain. ³Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, Aix-en-Provence, France. ⁴Departamento de Física y Ciencias de la Tierra, Universidad de A Coruña, A Coruña, Spain

Abstract

The highest Iberian mountains have been intensely affected by Quaternary glaciations. One of them is the Central Range in Spain where local maximum glacial advances have been dated between ~ 33 ka and ~ 21 ka using cosmic ray exposure dating. However, the deglaciation following the Last Global Maximum has been poorly constrained. The existing evidence in other Iberian mountains such as the Central Pyrenees show a massive and rapid pattern of glacier retreat. A similar glacier behaviour has been also reported in the large ice sheets of the Northern Hemisphere and the Alps where by ~ 18 ka the Rhine Valley had lost 80% of its ice mass.

To confirm that a massive deglaciation took place in other Iberian Mountains following the Last Glacial Maximum, we dated moraines, glacially polished bedrock surfaces and lacustrine and aluvial deposits from La Vega gorge located in the northern slope of the Sierra de Gredos. These ages were obtained using ^{10}Be cosmic ray exposure (CRE), Optically Stimulated Luminescence (OSL) and radiocarbon dating.

The results derived from ^{10}Be CRE dating indicate the deposition of the mayor moraines in La Vega gorge took place between $\sim 25 - 19$ ka in agreement with the Last Glacial Maximum. Furthermore, ^{10}Be CRE dating from glacially polished bedrock surfaces, located upvalley from the dated moraines, suggest that the glacier retreat began ~ 19 ka ago, interrupted by minor advances, and the valley was ice-free shortly after ~ 17 ka. This rapid glacier retreat is confirmed with OSL and radiocarbon dating of lacustrine and aluvial sediments in basins closed by the mayor moraines located at the bottom of the valley, indicating that the depositional process began ~ 18 ka ago and the filling lasted until ~ 4 ka ago.

Therefore, the new ages obtained in La Vega gorge suggest that a rapid and massive deglaciation occurred after the Last Glacial Maximum in the Iberian Central Range. This drastic retreat agrees with the data reported in Central Pyrenees, the Alps and the large ice sheets of the Northern Hemisphere.

Reconstruction of the deglacial chronology based on geomorphological survey and surface exposure dating on Soya Coast, East Antarctica

Moto Kawamata¹, Yusuke Suganuma^{2,1}, Koichiro Doi^{2,1}, Takanobu Sawagaki³, Akihisa Hattori¹

¹SOKENDAI, Tokyo, Japan. ²NIPR, Tokyo, Japan. ³Hosei University, Tokyo, Japan

Abstract

A better reconstruction of past deglaciation history in East Antarctica since the Last Glacial Maximum (LGM) is important in order to constrain ice sheet and glacial-isostatic adjustment models and to anticipate their contribution to global sea-level rise. Geomorphological studies and surface exposure dating (SED) will provide direct evidence of the timing and potential magnitude of ice retreat on coastal oases and nunatak regions in East Antarctica. Recent studies have reported ice sheet retreat ages based on SED at the Skarvsnes, southern part of Soya Coast, East Antarctica. However, deglacial history remains unclear, because a limited number of surface exposure ages were reported by a previous study, and the results were not interpreted based on field-based geomorphological data.

This study reconstructs a detailed deglacial history since the LGM of the East Antarctic Ice Sheet based on geomorphological field survey at the Skarvsnes ice-free area on the Soya Coast, Dronning Maud Land. Thus, it is revealed that the basement rocks higher than 250 m asl were more weathered than those below ca. 250 m asl. The extensively weathered basement rocks at the highest peak (ca. 400 m asl) at the Skarvsnes are quite similar to those of the other ice-free areas of the northern part of Soya Coast, where have been estimated as had been remained ice-free throughout the LGM based on some previous results of ¹⁴C dating of fossil shells in the marine sediments. Therefore, the differences of weathering features are interpreted to be indicating the upper limit of the ice surface elevation during LGM in this area. Judging from the multiple directions of glacial striae, the ice sheet covering the area had retreated while changing the flow direction under the influence of the basement topography after LGM.

Several surface exposure ages were obtained from different altitude and distance from the current ice margin. These ages are consistent with the above geomorphological interpretation, suggesting that the ice sheet retreating history as follows; the ice was extended out of 5 km from the current ice margin at 13.7 ka; then it retreated almost to the current ice margin at about 9 ka. Finally, the deglaciation in this region was generally completed by the early Holocene.

Dating the last British-Irish Ice Sheet using luminescence dating of glacial cobbles

XianJiao Ou^{1,2}, Helen Roberts¹, Geoff Duller¹, Richard Chiverrell³

¹Aberystwyth University, Aberystwyth, United Kingdom. ²Jiaying University, Meizhou, China. ³Liverpool University, Liverpool, United Kingdom

Abstract

Understanding the response of glaciers to past climate change is vital to help predict the response to modern drivers, and future climate change. An accurate chronology is key to interpreting the glacial deposits and landforms which may serve as excellent archives of the extent and timing of previous glaciations. However, dating glacial deposits is notoriously difficult. Optically stimulated luminescence (OSL) dating of unconsolidated, sand-sized sediment grains, is one of the few techniques capable of providing a chronology for glacial sediments. One of the key issues for this technique is the potential for incomplete resetting ('bleaching') of the previous OSL signal prior to deposition. If unresolved, this incomplete bleaching of the signal used for dating the sediment grains will cause overestimation of the true depositional age. Small aliquot and single grain methods have been applied to date glacial sediments, using statistical models to identify the well-bleached grains and hence to assess the depositional age of the sediments. However, the choice of the statistical model employed, and estimation of key parameters within the model, are somewhat subjective.

An alternative approach is luminescence dating of large clasts (e.g. Sohbaty et al., 2012), where cobbles can be examined instead of unconsolidated sediment grains. Dating involves drilling into the surface of the cobble, and making measurements of the OSL signal as a function of depth; this provides an unambiguous assessment of the degree to which the OSL signal was bleached on deposition prior to subsequent burial, and hence also gives a clear indication of the likely reliability of the ages generated. This approach has been successfully applied to glaciofluvial cobbles from a known-age sandur on the Isle of Man (Jenkins et al., 2018). This presentation applies this method to a range of other sites.

Glaciofluvial cobbles were collected at sites along a transect from the British Midlands to northwest England, along the line of retreat of a land-terminating lobe of the last British-Irish Sea Ice Sheet. The results from these cobbles have been integrated with ages from the BRITICE-CHRONO project, obtained using cosmogenic radionuclides (CRN) and OSL dating of unconsolidated glacially-derived sediments. Bayesian analysis is used to assess the consistency of this data set and to integrate the geomorphological and chronological data.

¹⁰Be exposure dating on moraines in the Sayan Mountains, Siberia

Patricia Rauh¹, Lea Schweri², Ezequiel Garcia Morabito², Silke Merchel³, Georg Rugel³, Roland Zech¹

¹Friedrich-Schiller-University, Jena, Germany. ²University of Bern, Bern, Switzerland. ³Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany

Abstract

Mountain glaciers are very sensitive to (past) climate changes. Paleoglaciation of the Tibetan Plateau and the Himalaya received plenty of attention for the reconstruction of past climate and environmental conditions, whereas few studies have been conducted so far in the adjacent Altai and Sayan Mountains in Siberia, although they promise a complex history.

The investigated Sayan Mountains in the Russian Altai indicate extensive glacial activity during the Pleistocene and a shifting of the local Last Glacial Maximum (LGM). Rich glacial residues in terms of moraine ridges and erratic boulders in the region provide excellent opportunities to establish a detailed age chronology using *in-situ* cosmogenic ¹⁰Be surface exposure dating and derive information about paleoclimatic conditions.

We present 28 ¹⁰Be surface exposure ages from the Ergaki Range and Tuva Uplands in the western Sayan Mountains. Distinct lateral moraines document the extents of former glaciation during a last glacial maximum. Several recessional moraines in the Ergaki Range additionally record stand stills or readvances during the last glacial termination.

The prominent lateral moraine in the Ergaki Range yields three exposure ages of ~19 ka, indicating a MIS 2 glaciation. The maximum advances correlate with the end of the global LGM. Concluding, glaciers in the Ergaki Range existed continuously during the late Pleistocene only varying in their extent. The well-clustered ages of the Ergaki Range provide a robust deglaciation chronology. The readvances/ stand stills consistently date to ~18 ka (three boulders), ~17.5 ka (two boulders), ~17 ka (three boulders), and ~16 ka (two boulders), with a deglaciation starting after 16 ka. The valley is not elevated enough to record younger, less extensive glaciation, e.g. during the Younger Dryas and the Holocene. Exposure ages from the Tuva Uplands are more difficult to interpret: The lateral moraine documenting the most extensive glaciation yields two exposure ages of ~22 ka. The immediately adjacent inner lateral moraine has two slightly younger and stratigraphically consistent ages of ~21 ka, yet two more boulders from that moraine are ~27 and 43 ka. At this point, we suspect these older boulders to have inheritance, but we cannot confidently exclude a much older deposition age for both moraines. Planned are analyzes of other cosmogenic nuclides, such as ²⁶Al and/or *in situ* ¹⁴C, which might help to more robustly identify inheritance and complex exposure histories.

Late Pleistocene Cosmogenic ^{36}Cl Glacial Geochronology and *PISM* Ice Flow Model of the Central Taurus Range, Turkey

Oğuzhan Köse¹, Mehmet Akif Sarıkaya¹, Attila Çiner¹, Cengiz Yıldırım¹, Adem Candaş², Klaus M. Wilcken³
¹Eurasia Institute of Earth Sciences, Istanbul Technical University, İstanbul, Turkey. ²Mechanical Engineering Department, Istanbul Technical University, İstanbul, Turkey. ³Nuclear Science and Technology Organization (ANSTO), Lucas Heights, Australia

Abstract

The glacial geochronology of the Taurus Mountain Range is well-studied thanks to several works that use quantitative methods. Here, we report the timing of deglaciations in the central part of the Taurus Range, in the Mount Karanfil and Aladağlar during the Late Pleistocene. In the light of terrestrial cosmogenic nuclide ^{36}Cl surface exposure ages and glacial geomorphology, we use the Parallel Ice Sheet Model (PISM) to model Last Glacial Maximum (LGM-20 ka) cycle in central Taurus Range. Aladağlar Massif, covers an area of 800 km², composed mainly of Mesozoic carbonate rocks and shows the evidence of Late Pleistocene glaciations. We carefully carried out glacial geomorphological map of Aladağlar and Karanfil mountains and collected moraine boulder samples for cosmogenic ^{36}Cl surface exposure dating. We collected 21 samples from Karanfil Mountains and 39 from Aladağlar to assess the timing of paleoglaciations. The ages obtained from W-NW-facing Körmenlik Valley indicate a deglaciation starting from ca. 35.000 years (35 ka) in Aladağlar which give substantial evidence regarding ice accumulation before the global LGM. Moraines of ca. 20 ka in age are observed in higher altitudes in Aladağlar and Mount Karanfil. Late Glacial (ca. 15 ka) moraine ages are also well established from Maden Valley. We also present preliminary field observations as 13 samples are still in progress from Eastern Valleys of Aladağlar. The results from the NW-facing valleys in Mount Karanfil indicate deglaciation starting during local Last Glacial Maximum (LGM), ca. 19 ka. Late Glacial (ca. 15 ka) moraine ages are also well established in Mount Karanfil. Additionally, a rock glacier at ca. 2500 m was dated to early Holocene (ca. 11 ka) indicating periglacial conditions in this mountain. The moraine and rock glacier ages are first dates obtained from this part of the Taurus Range, which is compatible with the glacial chronology of southern Turkey and surrounding regions. In order to obtain glacial conditions of the past, we used simulations of nine conditions, in Mount Karanfil, with open-source PISM, which necessitates 9°C decrease in air temperatures and 25% more precipitation compared to today's conditions. This work was supported by TÜBİTAK 116Y155 project.

Abstract

The Tatra Mountains witnessed the strongest Pleistocene glaciation amongst all massifs of the Carpathians. The Tatras are also the northernmost mountains with typical alpine relief in Central Europe, in the Alpine and Carpatho-Balkan realm. The key position of the Tatra Mountains on the border of Poland and Slovakia provides a link between the northern cold and southern warm parts of Europe. The Tatra Mountains are currently not glacierized neither were they during the Little Ice Age. There are also no active rockglaciers. Although, the highest parts of these mountains contain a rich archive of well-developed glacial landforms as well as relict rockglaciers. These facts open up a discussion about the development and retreat of glaciers in the area. The youngest glacier advances left sequences of moraines, which indicate that the style of glaciation was marginalised and predominantly controlled by local climate and topography. Boulder-rich, well-preserved landforms, with no developed soil cover are very suitable for surface exposure dating. The ¹⁰Be isotope as well as GIS analysis were used to determine the extent and age of the latest deglaciation phases in these mountains. For each glacier, we reconstructed ice surfaces and calculated the local ELA and rockglacier initiation altitude. Dated landforms are mostly located not further than 500 m from cirque backwalls. In case of such small glaciers, which are strongly influenced by topo-climatic factors, estimation of the ELA using traditional methods is unreliable and gives underestimated results. Those small paleoglaciers and rockglaciers, most probably persisted slightly below the regional ELA in the highest parts of the High Tatra Mountains in the end of last glaciation. The exposure dating of glacial boulders and bedrock together with morphostratigraphy confirmed that the last phases of glacial activity took place within the Lateglacial, during the Younger Dryas cold period, around 12.5 ka. The results indicate lack of activity of glaciers and rockglaciers within the entire Holocene.

P-2449

Heinrich1 and Dryas glacier stages in High Asia and their implication for a reassessment of TCN ages in the Himalaya

Nils Schroeder

Geographisches Institut, Georg August Universität, Göttingen, Germany

Abstract

Heinrich 1 and Dryas events constitute global signals for which we also find evidence in different climate proxies in China and on the Tibetan Plateau. In the present study, we identified all Heinrich 1/Dryas events among the available ^{10}Be ages of glacial deposits of the Himalayan-Tibetan orogen. Taken together, we identified 51 localities with outstanding clustering in the TCN-dating results. The corresponding Δ ELA depressions of $\sim 1000\text{--}300$ m are within the range of what is commonly ascribed to the LGM. These localities are clearly distinguishable from the surrounding area as younger glacial stages. By contrast, the stages older than Heinrich 1 cannot be ascribed to any single time frame. We assume that the high inheritance rates of the older, polyglacial till sheets are the result of a glaciation of the Tibetan Plateau under cold-based conditions similar to the polar regions as it is still a permafrost area and suggest that this explains why even the more extensive Heinrich 2 event is not detectable as a distinct signal in the available TCN data. The formerly glaciated regions of the Arctic and Antarctica yield sound evidence of the phenomenon of limited ice sheet erosion and complex exposure histories due to cold-based ice. If this body of evidence is taken seriously, the complicated patterns of TCN ages of glacial deposits in High Asia becomes less of a mystery and is offered an explanation. All of the evidence that is available to us today suggests that the Himalayan-Tibetan orogen did not merely undergo the Late Glacial Heinrich 1/Dryas events but also, indeed, Heinrich 2 and the LGM. The latter (H2, LGM) occurred as an inland glaciation with an extensive network of outlet glaciers. In order to make glacial deposits with high inheritance rates accessible to absolute datings, future research should not only rely on ^{10}Be and ^{26}Al data, but also on the determination of *in situ* cosmogenic ^{14}C nuclides. This latter dating technique is already successfully applied in the formerly glaciated Arctic regions.

Constraining the LGM in the Drau-Glacier Area by Single-Grain-Feldspar Luminescence Dating - Implications for reconstructing Ice Dynamics in the European Alps

Christopher Lüthgens¹, Jürgen Reitner²

¹University of Natural Resources and Life Sciences (BOKU), Vienna, Institute of Applied Geology, Vienna, Austria.

²Geological Survey of Austria, Sedimentary Geology, Vienna, Austria

Abstract

The area of the former Drau glacier system is located in the south-eastern sector of the Alps, and is characterized by extensive sedimentary archives of the last glacial cycle. These can be traced from LGM terminal moraines and proglacial outwash cones to areas close to modern glaciers. This offers the opportunity to constrain glacial chronology and dynamics of the LGM (last glacial maximum), and close the gap in knowledge between the northern and southern flanks of the Alps.

Previous efforts in establishing and improving glacial stratigraphy in the Alps have predominantly been focused on the northern flank of the Alps and its foreland (e.g. Preusser, 2004). However, recent progress in constraining the timing of the LGM was achieved on the southern flank (e.g. Monegato et al., 2007). Despite the progress, even for the short time span of the LGM, our understanding of e.g. climatic gradients across the Alps and their implications for the LGM ice dynamics of the Alpine ice sheet as a function of paleoclimatic forcing factors is still limited due to sparse data especially in the inner alpine areas.

The focus of this study lies on constraining the chronology of proglacial aggradation at the onset and during the climax of the LGM and during Termination I. Recent studies applying optically stimulated luminescence dating techniques to glaciofluvial sediments in the European Alpine foreland (e.g. Rades et al. 2018) highlighted the obstacles, but also the chances in deciphering the chronology of processes during the Late Pleistocene period by using numerical dating methods. We present luminescence ages from the tongue basin of the Drau glacier and its forefield, based on single-grain measurements of potassium-rich feldspar, using a post infrared infrared (pIRIR) luminescence SAR (single aliquot regenerative) dose protocol at stimulation temperatures of 50°C (IR50) and 225°C (pIRIR225). Despite methodological challenges, these ages may allow constraining the timing of advance and retreat of the Drau Glacier. In addition, these new results emphasise the urgent need for a synoptic review of available numerical age data from the last glacial cycle of the European Alps and their process-specific (re)interpretation, in order to provide a more robust framework for the reconstruction of over-regional ice dynamics in the context of paleoclimatic change.

Glacier evolution in the Alps during the early and mid-Holocene – new results from Tschierva and Pasterze glaciers

Kurt Nicolussi¹, Ruth Drescher-Schneider², Andreas Kellerer-Pirklbauer³, Melaine Le Roy⁴, Christian Schlüchter⁵
¹Institute of Geography, University of Innsbruck, Innsbruck, Austria. ²Institute of Plant Science, University of Graz, Graz, Austria. ³Institute of Geography and Regional Science, University of Graz, Graz, Austria. ⁴EDYTEM, Université Savoie Mont Blanc, Le Bourget du Lac, France. ⁵Institute of Geological Sciences, University of Bern, Bern, Switzerland

Abstract

Current climate change strongly affects the glaciers in the Alps causing partly fast recession and collapses of glacier termini or even entire glacier tongues. This is a consequence of a strong temperature increase in the Alps that approximately doubles the global warming rates during the last decades. The ongoing recession indicates that extent and length of Alpine glaciers are not in equilibrium with current climate conditions. However, as these glaciers have shrunk, some of them have unveiled displaced and in-situ tree remains as well as other organic material and sediment profiles near their termini. Radiocarbon dates of organic material as well as calendar dates of tree remains established on the base of the Eastern Alpine Chronology prove that most of these finds date back to the early and mid-Holocene, allowing new insights in past glacier variability and evolution. Here we report new results from two Alpine glaciers. At the Tschierva glacier, Switzerland, the tree-ring series established for dozens of tree remains prove three multi-centennial to millennial long retreat phases around 4.0, 7.0 and 9.8 ka. These retreat phases were followed by advances of the Tschierva glacier beyond today's extent. At the glacier Pasterze, Austria, a c. 2.5 m long sediment profile with alternating organic and clastic layers was discovered at a site that got free of ice in 2010. Radiocarbon dates show that sedimentation took place between ca. 7.1 and 3.9 ka. Detrital tree remains sampled in the surroundings of this sediment date mainly into the same time period. A comparison of the results of both glaciers suggests a different sensitivity to past climate variability caused by varieties in size and topography.

Ages and transport history of moraine boulders from rock surface luminescence profiles

Eike F. Rades^{1,2}, Reza Sohbati², Christopher Lüthgens³, Helena Alexanderson⁴, Mayank Jain², Andrew S. Murray¹

¹Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Roskilde, Denmark.

²Center for Nuclear Technologies, Technical University of Denmark, Roskilde, Denmark. ³Institute of Applied Geology, University of Natural Resources and Life Sciences, Vienna, Austria. ⁴Department of Geology, Lund University, Lund, Sweden

Abstract

Moraine deposits are the key to untangling former ice sheet movements. Unfortunately, it is often difficult, sometimes even impossible to date these deposits by currently available methods (e.g. cosmogenic nuclide (CN) or radiocarbon dating) because of problems with inheritance, post-depositional shielding and/or lack of suitable (organic) material. Rock surface luminescence burial dating has the potential to provide not only ages for glacial moraines, but in addition information about past deposition and transport events in the history of individual boulders.

Here, we present rock surface burial ages and rock surface luminescence profiles from moraine boulders to illustrate the potential of the method when applied to previously undateable deposits and to broaden our understanding of glacial transport. In contrast to associative dating methods (e.g. radiocarbon), in rock surface dating all samples are indisputably linked to the event of interest, and samples are generally readily available. The main differences compared to the more common CN dating of moraines lie in the criteria used to select boulders and clasts for analysis. In CN dating, one looks for clasts that have not been exposed at the surface before final emplacement. In rock surface dating using luminescence, one wants exactly the opposite – i.e. significant exposure to daylight before final deposition inside the moraine. Most post-depositional movement within the moraine deposit is irrelevant, as long as the surface of interest remains buried.

A major advantage of rock surface luminescence burial dating compared to conventional luminescence dating using sand-sized or smaller grains arises because boulders are large enough to internally record the degree of bleaching prior to burial. Thus, clasts that have been sufficiently bleached prior to burial can be unambiguously identified from the shape of the luminescence-depth profile close to the rock surface. This is a major factor in ensuring that the age derived from the surface layer is reliable. Of course, only a fraction of the large clasts in a moraine will have received enough daylight exposure to be sufficiently bleached, , nonetheless, we find that 11 out of 19 boulders so far were usable of which 8 boulders showed a bleaching front at a depth of more than 5 mm. However, even inadequately bleached surfaces provide process information as they record histories of surface erosion and/or deposition and subsequent transport without daylight exposure. One of the main challenges in the application of the method remains the efficient identification of suitably light-exposed clasts prior to sampling.

Timing of Lateglacial moraines in the Northern and Western parts of the Ecrins massif (French Alps)

Philippe Schoeneich¹, Philip Deline², Julien Carcaillet³, Irene Schimmelpfennig⁴, Xavier Bodin², Philippe Choler⁵, Melaine Le Roy²

¹Université Grenoble Alpes, PACTE, Grenoble, France. ²Université Grenoble Alpes, Université Savoie Mont Blanc, CNRS, EDYTEM, Chambéry, France. ³Université Grenoble Alpes, ISTerre, CNRS, Grenoble, France. ⁴Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, Aix-en-Provence, France. ⁵Univ. Grenoble Alpes, CNRS, SAJF, Grenoble, France

Abstract

The Ecrins massif, in the French Alps, is very suitable for TCN dating, due to its quartz-rich rocks (mainly granite and gneiss). Nevertheless, only very few data are available so far on the Lateglacial glacier retreat, mainly because of the sparsity of well-preserved Lateglacial moraine sequences.

For the present study, four moraine sequences were dated by means of ¹⁰Be TCN dating on erratic boulders. Three are collected in the Northern area of the massif, around the Combeynot massif : i) a sequence of four frontal moraines along the Vallon du Fontenil, ii) a set of three latero-frontal moraines from the morainic complex of the Plan de l'Alpe, located just outside of those already dated by Chenet et al. (2016), iii) one frontal moraine of the Arsine glacier, and iv) three subparallel lateral moraines and one frontal moraine at Font Turbat in the Western area of the massif.

The methods include a detailed geomorphological mapping of the whole area, a morphostratigraphical approach into stadials and positions, the reconstruction of the glacier topography for each considered position, and ELA calculations based on the AAR method with a standard AAR of 0.67, in order to ensure comparison with other data from the central and eastern Alps. For each selected landform, at least three suitable boulders were sampled for TCN analysis (collaboration for analysis with the ASTER team, Aix-Marseille). A total of 31 boulders and 4 erosion surfaces, corresponding to 12 positions, was dated.

After removal of a few obvious outliers, resulting from complex exposure histories, results show that all dated moraines fall into the Greenland Stadial 1 (GS-1) cold event and can be attributed to the Egesen stadial of the Alpine Lateglacial morphostratigraphy. The results are fully consistent with the existing data on the massif (Chenet et al. 2016; Hofmann et al. this congress). They confirm:

i) that the Egesen stadial is the only well preserved Lateglacial stadial in the massif. The absence of preserved older moraines is due to the very steep trough topography which may have prevented deposition, and to thick scree and torrential accumulations which may have entirely covered glacial deposits.

ii) the large extent of the Egesen stadial in some valleys. This can be explained by the high altitude of the upper catchment, inducing a large increase of accumulation area even for moderate ELA lowering.

iii) the multiphase character of the Egesen stadial. At Plan de l'Alpe, up to 10 successive frontal positions cluster into two distinct groups of moraines, with a significant thickness and length difference. However, the overlap of dating uncertainties does not allow to distinguish two sub-stadials. At Fontenil and Font Turbat, consistent chronological sequences are obtained.

Chronology of Laurentide Ice Sheet (Huron-Erie Lobe) fluctuations during the Last Glacial Maximum, Indiana, USA

Henry Loope^{1,2}, Thomas Lowell³, Brandon Curry^{4,5}, Jose Luis Antinao^{1,2}

¹Indiana Geological and Water Survey, Bloomington, USA. ²Indiana University, Bloomington, USA. ³University of Cincinnati, Cincinnati, USA. ⁴Illinois State Geological Survey, Champaign, USA. ⁵University of Illinois, Champaign, USA

Abstract

The chronology of Laurentide Ice Sheet (LIS) advance to and retreat from its maximum Oxygen Isotope Stage (OIS) 2 limit in central North America is important because it allows evaluation of the driving mechanisms of ice sheet growth and decay and provides a terrestrial chronology that can be compared to the marine record and other paleoclimate proxies. New radiocarbon dating from outcrop and cores in central Indiana, USA, has refined the timing of LIS Huron-Erie Lobe OIS 2 advance to and retreat from the maximum limit. These new ages, combined with previously published radiocarbon ages from the southern Great Lakes region (Illinois, Indiana, and Ohio) within or below OIS 2 till, indicate LIS advances ca. 25.8, 23.7, and 21.5 k cal yr BP. In Indiana and Ohio, these three advances terminated within ca. 25 km of each other, with the 23.7 k cal yr BP advance typically representing the maximum limit across the southern Great Lakes region. The advances were separated by two significant episodes of ice retreat of >50 km, documented by the preservation of organics, terrestrial gastropods, and glacial lake sediments between tills. These millennial-scale fluctuations of the LIS during the Last Glacial Maximum (LGM) [ca. 26 to 21 k cal yr BP] do not correlate with known climatic forcings and point to yet unknown dynamic controls on ice margin position. An additional record of LIS advance is recorded in the timing of outwash aggradation and associated slackwater sedimentation in the West Fork White River valley and tributaries in central Indiana. Eight radiocarbon ages from a core 10 km beyond the OIS 2 limit indicate slackwater sedimentation began ca. 27 k cal yr BP and continued until ca. 20.5 k cal yr BP, representing the timing of ice sheet advance into and out of the paleo-White River drainage basin. Ice sheet advance and retreat rates average ca. 40 m/yr during the LGM, when ice was within ca. 50 km of the OIS 2 maximum. Retreat rates increased slightly to ca. 50 m/yr after 21.5 k cal yr BP, as ice retreated ca. 110 km from central Indiana to the Union City Moraine (19.3 k cal yr BP) in northeastern Indiana. Needed future work involves investigation of the role of subglacial conditions (frozen vs thawed) on ice margin fluctuations.

⁴Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, IRD, IFSTTAR, ISTerre, Grenoble, France

Abstract

Due to the sensitivity of mountain glacier dynamics to climate change, reconstruction of Holocene glacier chronologies allows us to better understand the evolution of the natural climate system during the current interglacial. However, records of glacier variations spanning from the Early Holocene to the Little Ice Age (LIA) and based on direct dating of glacial deposits remain scarce. The forefield of Arsine glacier, located in the Ecrins Massif of the Western Alps (France; 45°N), is characterized by the existence of abundant glacio-geomorphologic markers bearing witness of numerous past glacier extents of different size. Cosmogenic ^{10}Be dating of the most distal moraines in the study area provides evidence for multiple glacier extensions during the Early Holocene, while dating several of the crests on the proximal massive vegetation-free moraine complex yields ages of ~ 3 ka and a few hundred years. These glacier extensions are thus in accordance with the Neoglacial and the LIA, respectively. No moraines are preserved from between ~ 10 ka to ~ 3 ka ago. These results are in very good agreement with Holocene-spanning ^{10}Be moraine records in the Swiss Western and Central Alps, suggesting that glacier fluctuations during the Holocene were regionally synchronous at least on millennial timescales.

The glacio-geomorphic peculiarity at the study site of Arsine glacier consists in the existence of a 1-km-wide and 0.5-km-long rockglacier-like deposit mostly composed of big sub-concentric blocky lobes and stratigraphically located between the Early Holocene moraines and the Neoglacial/LIA moraine complex. It could testify to a major glacier extent that must have occurred sometime between ~ 10 ka and 3 ka ago, but at present further age constraints are missing. ^{10}Be dating of boulders from this deposit are currently ongoing to complement the chronology of Arsine glacier's behaviour during the Holocene and to put the origin of the peculiar deposit in the context of the Holocene climate evolution.

Debris-flow cobbles as chronometers of mountain glaciation

Alastair Cunningham^{1,2}, Andrew Murray¹, Roger Kurbanov³, Darisa Khashevskaya⁴, Reza Sohbaty²

¹Department of Geoscience, Aarhus University, Roskilde, Denmark. ²Center for Nuclear Technologies, Technical University of Denmark, Roskilde, Denmark. ³Russian Academy of Sciences, Institute of Geography, Staromonetny pereulok 29, Moscow, Russian Federation. ⁴Moscow State University, Leninsky Gory, 119991, Moscow, Russian Federation

Abstract

Optically stimulated luminescence (OSL) methods are widely applied for dating Quaternary sediments, and typically utilise the sand or silt-sized grains in clastic sediment as natural radiation dosimeters. The luminescence signal is reset by daylight, so the methods aim to date the last time that grains were exposed to daylight before burial. Daylight may also penetrate rock faces, and recent progress in measurement procedures has allowed OSL dating to be applied to buried cobbles and boulders. This has expanded the range of Quaternary sediments that can feasibly be dated using OSL methods, to potentially include moraine and debris-flow material. Such sediments are difficult to date at present, so an accurate method of doing so would greatly help in reconstructing glacial history and sediment transport in mountainous regions.

Debris flows and other mass movements are usually difficult to date by standard OSL, because resetting of sand grains during transport is unlikely. Cobbles and boulders, however, have a high probability of being exposed on hillslopes and stream beds for prolonged periods, so may have their luminescence signals reset prior to transport. Furthermore, a record of the bleaching history of a clast can be read by measuring the OSL signal with depth, and this provides an internal check on the degree of bleaching.

Here we investigate the debris-flow sediments of the upper Baksan valley in the Caucasus Mountains. The valley contained a major glacier during Pleistocene glaciations, and has evidence of smaller, presumably Holocene glacier advances. The area has steep topography sculpted by ice, prone to debris-flows and avalanches, and many destructive debris flows observed in the last few years. The numerous debris fans in the valley must post-date the last valley glaciation. Dating of these debris fans serves a double purpose: first, to help understand the recurrence intervals and causes of the debris flows; second, to place a chronology on glacier retreat in the Caucasus

Abstract

Only few chronological constraints on Late Glacial and early Holocene glacier fluctuations in the western part of the European Alps (French Alps) have been published. To provide additional chronological benchmarks on glacier variability in the French Alps, moraines of two palaeoglaciers in the southern Écrins massif were mapped and dated. Based on their relative positions in the field, the moraines were correlated and assigned to pre-Little Ice Age (LIA) glacier positions to establish a morphostratigraphy. Thirty-nine ^{10}Be exposure ages from boulders on selected moraines were obtained to establish a chronology of glacier fluctuations. For suitable comparison with previous studies, 44 ^{10}Be exposure ages from moraines at key sites in the Alps were recalculated according to recent ^{10}Be production parameters. As a third step, the equilibrium line altitude (ELA) depression relative to the LIA during moraine deposition was reconstructed to enable local stratigraphical correlations, whereby an accumulation area ratio of 0.67 was assumed throughout, as done elsewhere in the Alps.

Regarding the first palaeoglacier, ten pre-LIA positions were identified. According to a ^{10}Be boulder exposure age from its third outermost mapped moraine, this landform may have stabilised at ca. 17 ka b2k when three confluent glaciers reached the moraine. The ELA of the first palaeoglacier was then depressed by about 220 m with respect to the LIA, whereas the ELA of two tributary glaciers must have been lowered by 490-590 m. The moraine was likely shaped or re-occupied by the first palaeoglacier at around 13 ka b2k when the ELA was about 230 m lower than during the LIA. At least six periods of stable ice margins associated with ELA depressions between 230 and 170 m occurred thereafter. The moraines of the innermost pre-LIA position of the first palaeoglacier stabilised at ca. 12 ka b2k.

Regarding the second palaeoglacier, two distinct groups of four pre-LIA moraines were identified. Their formation was associated with ELA depressions between 130 and 190 m with respect to the LIA. Hence, the moraines can be linked to the same period of glacier variability as the moraines of the first palaeoglacier. This is supported by three ^{10}Be exposure ages from one moraine of the second palaeoglacier indicating moraine stabilisation at ca. 12 ka b2k.

The ^{10}Be exposure ages are in agreement with exposure ages obtained from other moraines in the Alps that stabilised during the regional Egesen stadial as well as with data from other types of palaeoclimatic archives. This suggests a common climatic forcing of the glacier variations. Local factors, such as topography, likely explain the exposure age variability. Overall, this study contributes a significant refinement of the chronology of glacier fluctuations in the French Alps.

Ice cap behaviour in the Zackenberg region, East Greenland

Timothy Lane¹, Vincent Jomelli², Vincent Rinterknecht², Fatima Mokadem², Kathryn Adamson³, Mélody Biette²

¹School of Natural Sciences and Psychology, Liverpool John Moores University, Liverpool, United Kingdom.

²Université Paris 1 Panthéon-Sorbonne, CNRS-LGP, Paris, France. ³School of Science and the Environment, Manchester Metropolitan University, Manchester, United Kingdom

Abstract

Ice caps and independent glaciers at the periphery of the Greenland Ice Sheet (GIS) cover over 89,000 km². Their small size means that they respond sensitively to climate change, and can provide important insights into Arctic environmental change and GIS margin dynamics. Understanding the Quaternary behaviour of peripheral ice masses is therefore key for predicting the response of Arctic glaciers and the GIS to future climate change. However, detailed reconstructions from Greenland are limited, and many studies focus on south and west Greenland. Here we reconstruct the fluctuations of A.P. Olsen and Clavering Ø ice caps in Zackenberg, High Arctic East Greenland (74°N) using geomorphological mapping of glacial landforms and surface exposure ages (¹⁰Be) of moraine boulders and glacially scoured bedrock surfaces.

Our new geomorphological mapping and regional chronology indicate that during the Last Glacial Maximum (LGM) it is very likely that the ice caps became confluent with the Greenland Ice Sheet. Trimlines suggest that the highest peaks in the region remained ice free throughout the LGM. Following the LGM, the GIS and A.P. Olsen and Clavering Ø ice caps decoupled. A Younger Dryas readvance (c. 11.7 ka) of A.P. Olsen is marked by clear moraines in Zackenberg valley, and is followed by retreat throughout the Holocene. Extensive areas of hummocky moraine suggest ice marginal stagnation during this retreat phase.

These results provide vital information constraining ice cap behaviour from the Greenlandic High Arctic, a region with very few long-term glacier reconstructions. In comparison to previous regional reconstructions, based on trimline extrapolation, our results demonstrate an earlier deglaciation, and suggest that ice caps in this region responded in phase with climate during deglaciation.

Pleistocene glaciers reconstruction on the northern valleys of Făgăraș Massif (Romania) from Last Glacial Maximum to Younger Dryas

Maria Daniela Putici (Pascal)^{1,2}, Alfred Ionuț Vespremeanu - Stroe¹, Mihaela Enăchescu², Cătălin Stan - Sion², Alexandru Petre², Regis Braucher³, Răzvan Popescu¹, Alina Toma¹, Tiberiu Sava²

¹University of Bucharest, Faculty of Geography, Bucharest, Romania. ²Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering (IFIN-HH), Măgurele, Romania. ³Centre Europeen de Recherche et d'Enseignement des Geosciences de l'Environnement, Aix en provence, France

Abstract

Following a long period of major discrepancies in knowledge about glaciation ages between the Carpathians and other European mountain ranges, the Romanian Carpathians finally benefitted in the last decade from several studies presenting numerous absolute age datings of the glacial deposits that improved considerably the knowledge on the last glaciations chronology. Despite the fact that Făgăraș Massif is the highest massif from Southern Carpathians (and of the Romania) and the richest in terms of glacial features with deep glacial valleys and large cirques it remained the least studied and dated in relation with the Pleistocene glaciations.

The concentration, rate of production and rate of decay of terrestrial cosmogenic nuclides (TCN) can be used to determine the exposure ages for a variety of landforms and geomorphological processes associated with deglaciation. Due to the high quartz content of the crystalline schist rocks which are dominant in Făgăraș the exposure ages were determined via ¹⁰Be. Samples were chemically processed and for the first time dated within a Romanian institution, respectively at Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering (IFIN-HH), Măgurele – Romania (RoAMS Laboratory - Tandem Accelerators Department and Applied Nuclear Physics Department). The new obtained exposure ages (¹⁰Be) were compared to the measurements performed at the CEREGE laboratory (France) and the differences were negligible. Based on the measurements carried out on samples taken at different altitudes, using erratic blocks and large blocks of moraines, absolute ages were obtained for 5 valleys with northern exposure (Doamnei, Bâlea, Arpașul Mare, Sâmbăta and Urlea Valleys), which indicate similarities (Younger Dryas advance recorded in most of valleys) in the manifestation of cold phases of glacier advancement, as well as some differences dictated by inherited morphological features of the respective valleys.

Recent data on Pleistocene glaciation history of central part of the North Caucasus

Daria Khaschevskaya¹, Alastair Cunningham^{2,3}, Andrew Murray^{2,3}, Redzhep Kurbanov⁴, Mikhail Ivanov¹

¹Moscow State University, Moscow, Russian Federation. ²Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Roskilde, Denmark. ³Center for Nuclear Technologies, Technical University of Denmark, Risø, Roskilde, Denmark. ⁴Russian Academy of Sciences, Institute of , Moscow, Russian Federation

Abstract

It is well-known that Central Caucasus region had large glacier systems in the past, that affected the climate of the entire region significantly. Modern landscape of Elbrus highlands is a typical alpine zone with frequent avalanches, debris flows, rockfalls and etc. Geomorphological processes are taking place very intensively and in many places, and because of them it is particularly difficult to study glacial history here.

There were numerous attempts to reconstruct distribution of Pleistocene glaciers. Most of the previous investigations stated, that the Caucasus Mountains have experienced at least three periods of glaciation. Also, there are plenty of unexplored evidences of glacial fluctuations in the valleys. However, paleoclimate reconstructions of the area are fragmentary and incomplete. Moreover, the origin of some particularly large landforms, such as Tubele hill in the Baksan valley, still remains unknown.

Since the dating by standard OSL is difficult in mountain areas, we used rock-surface dating, which allows us to establish the burial date of mostly rock material, since large cobbles are more likely to be exposed to daylight. In the Baksan valley (Central Caucasus), we have investigated cobbles from fans of various genesis. Due to received data, we got the rate of accumulation and ages of different mudflows and avalanches activation phases. These data also can be seen as a good indicator for paleoclimate chronology.

Here we offer recent data on the Pleistocene glaciations stages in the central part of the North Caucasus. The OSL dating of several fans sheds light on the Pleistocene Central Caucasus history.

P-2461

Late Quaternary Glacial history in the Kali Ganga Valley, Tethyan Himalaya, Uttarakhand, India.

Dr. Pinkey Bisht¹, Ashish Rawat², Y.P Sundriyal²

¹Wadia Institute of Himalayan Geology, Dehradun, India. ²HNB Garhwal University, Srinagar, India

Abstract

The Himalaya region has preserved the evidences of various glacial advances. These evidences shows that the glaciers have fluctuated many times throughout the late Quaternary period. Yet, there is a debate whether the glacial advance in the Himalaya occurred as a response to low temperature or it is a result of increased monsoon brought by Indian summer monsoon. We have tried to examine this issue, by observing multiple sets of lateral moraine preserved in four different tributary valley of the Kali Ganga valley, Tethyan Himalaya, India. The glacial chronostratigraphy and history of this region is defined for the first time using Optical Stimulated Luminescence dating. The study also reported the oldest preserved moraine in the valley, which is corresponds to Marine Isotopic Stage-3 (31-56 ka), witnessed by the Optical dating of lateral moraine. The extent of the MIS-3 moraine is only 5-8 km from the present snout , but the ice cover occupied by the glacier valley during this time was (~400-600 m) thick which is now preserved as a highest lateral moraine. The second major glacial advance occurred during Last Glacial maxima (17-23 ka) having less ice thickness (150-200 m) as compared to the MIS-3, with the advance of 1.5 km from the present snout. The third glacial advance took place during the mid-Holocene with the glacial advance of 0.8 km from the present snout. The Hummocky ground moraines were also present below the present snout of the glacier showing the standstill condition of the glacier. The mounds of moraine present proximal to the present glacier depicts the response of glacial during Little Ice Age (LIA). Comparing with the results of other climate proxies, we suggest that in the Kali Ganga Valley, MIS-3 glaciation is triggered by the enhanced monsoon, LGM, Mid-Holocene and Little Ice age glaciation is driven by the low summer temperature having its connection with the Northern Hemisphere cooling events.

P-2462

Geomorphological and chronological evolution of Karadağ mountain (SW Turkey)

Cihan Bayrakdar¹, Zeynel Çilgin², Faize Sarıç³, Onur Altınay¹, Onur Yasan³, Naki Akçar⁴

¹Department of Geography, İstanbul University, İstanbul, Turkey. ²Department of Geography, Munzur University, Tunceli, Turkey. ³Department of Geography, Çanakkale Onsekiz Mart University, Çanakkale, Turkey. ⁴Institute of Geological Sciences, Bern University, Bern, Switzerland

Abstract

Karadağ is one of the mountains subjected to the Pleistocene glaciations along with Beydağları, Akdağ and Sandıras in the Teke Peninsula (Teke Region). Within a 30 km straight distance from the northeast of Fethiye Bay to the top of the mountain, the elevation rises 2418 m at the summit surpassing many peaks over 2300 m. The mountain mainly features as a karst terrain having numerous karstic depressions at higher elevations close to the peaks. Glacial landforms also found on the north facing slopes of this area.

There are plenty of quantitative glacial research and dating studies aiming to reveal chronology of the glaciations in Pleistocene in the Teke Peninsula. But most of the studies are on the mountains glaciated in Pleistocene, such as Sandıras and Akdağ. On the other hand, there are only a few glacial studies concerning Beydağları in which the glaciations were mentioned superficially. And lastly, there has not been any studies on Karadağ until this work due to unknown glacial phenomenon. However, Karadağ has distinctive cirques and moraines on the slopes of higher elevation near the peaks. After field works, we carried out in Karadağ, we mapped five cirques which developed in different sizes and aspects and in front of them lie hummocky and frontal moraines descending up to 1800 m.

Here, we present initial results of a TÜBİTAK project aiming to reveal geomorphological, climatic and chronological features of a recently discovered glaciated mountain-Karadağ. ³⁶Cl surface exposure dating method was used to reveal geochronology and paleoclimatic variations of Karadağ. In addition, an automatic weather monitoring station was set up on the mountain to gather first hand climatic data for better understanding of the climate of Karadağ and the station has started to provide initial data. Spatial data which is obtained by the methods mentioned above was subjected to analyzes using geographic information systems and subsequently, maps and result output were created.

This work was financially supported by TÜBİTAK-ÇAYDAG (Project no: 117Y391).

Groundwater residence times and palaeohydrology in the Köprüören Basin (Kütahya, Turkey)

Sebnem Arslan

Ankara University, Ankara, Turkey

Abstract

In this study, stable isotopes ($\delta^2\text{H}$, $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$), tritium and radiocarbon (^{14}C) have been used to evaluate groundwater residence times and palaeohydrology in the Köprüören Basin which is located in Western Anatolia. 20 groundwater samples were collected in May and September 2012 and analyzed for $\delta^{18}\text{O}$ and δD contents. In addition, tritium contents of 11 samples and $\delta^{13}\text{C}$ and ^{14}C content of 5 samples were also determined to get information about the residence times. The results indicate that the $\delta^{18}\text{O}$ and δD contents of the samples, respectively, ranged from -10.84‰ to -8.55‰ and from -73.6‰ to -61.2‰ in the dry season and ranged from -10.81‰ to -8.28‰ and -73.3‰ to -60.6‰ in the wet season. The majority of the samples plotted along the Global Meteoric Water Line although some of them show deviations from this line. The reason for the deviations is attributed to evaporative enrichment. Tritium concentrations in all samples range from ~0 to 6 TU in the wet season and from ~0 to 7 TU in dry season. Accordingly, some of the groundwater samples recharge from modern precipitation, whereas some samples recharged before tritium from nuclear weapon tests. The $\delta^{13}\text{C}$ and ^{14}C contents of five samples range from -5‰ to -14.6‰ and from 8.2 to 78 pmc, respectively. The corrected ^{14}C ages for these samples are up to 11500 years before present, thereby indicating the presence of paleowaters in the basin. The depletion of $\delta^{18}\text{O}$ and δD probably point out that these paleowaters were recharged during a cooler climate.

Vertical groundwater flux estimation from borehole temperature profiles by a numerical model, RFLUX

Shaoheng Li¹, Linyao Dong², Jianyao Chen¹, Rui Li¹, Zhigang Yang¹, Zuobing Liang¹

¹School of Geography and Planning, Sun Yat-sen University, Guangzhou, China. ²Changjiang water Scientific Research Institute, Changjiang Water Resources Commission, Wuhan, China

Abstract

We developed a numerical model, RFLUX, which uses the heat tracer method for vertical groundwater flux estimation, and applied it to the Leizhou Peninsula, South China, to provide information to inform local groundwater resource utilization and management. The temperature–depth (TD) profiles of 24 boreholes, along with the observed ground surface temperature (GST) and surface air temperature (SAT) series in recent decades, were collected in this area. Underground TD data demonstrated the capacity to identify groundwater flow patterns, and local GST and SAT data demonstrated a strong correlation with each other over monthly, seasonal, and annual scales. In the RFLUX model, the average GST and SAT series were applied as an upper boundary condition, and a nonlinear initial condition was set using an analytical solution from the literature. The model results of selected TD profiles demonstrated that the annual vertical groundwater flux was about 0.15 m/a, which tended to be overestimated if a linear initial condition was used. This model can be easily applied with minor modifications, considering its clear purpose and simplicity.

P-2465

A new framework and application for groundwater modeling in coastal area

Rouyan Gong, Jianyao Chen

School of Geography and Planning, Sun Yat-sen University, Guangzhou, China

Abstract

We described the development and application of a new framework to simulate coastal evaporation in groundwater models. Traditionally, the ETS package of MODFLOW are based on a series of linear segments between depth to groundwater and evaporation flux rate. According to the exponential curves from the observed data here, exponential functions can better reflect the relationship in coastal area than linear segments. As a consequence, the errors of simulated processes was introduced, which via coastal climate change, the depth to groundwater and biological process into evaporation simulation.

The framework set the observed data and consider the influence on evaporation simulation, in this way, two methods of topography in evaporation simulation were provided. A traditional method is modeled as an annual source term, treated in linear segments that monotonically closes to maximum evaporation rate. The finer and coarse resolution taken into account the smaller cells response from variations of topography and the depth to groundwater. This paper established the groundwater modeling with 1.5×1.5 km cells in Leizhou Peninsula(LP). The finer resolution 500×500 m were averaged to same cells for convenience of model input, and the coarse resolution 2×2 km were interpolated. Model results indicate that a increased accuracy in predicted flow system between the new framework and traditional approaches. The use of the new framework provided the correlation between the evaporation rates and the resolution of topography. It was showed that using 500×500 m cells for evaporation simulation yielded the best results in groundwater modeling.

An Analysis of Formation Mechanism of Groundwater in the Liuxi River basin: Evidence from Isotopes and PAHs

Zhenglan Xie, Jianyao Chen

School of Geography and Planning, Sun Yat-sen University, Guangzhou, China

Abstract

Hydrogen and oxygen are basic components of water, and stable isotopes ($\delta^{18}\text{O}$ and δD) are natural tracers in nature; PAHs are derived mainly from anthropogenic inputs and can be used to identify the characteristics of human activities in the process of social development. This study is to analyze formation mechanism of groundwater on PAH composition, sources and stable isotopes ($\delta^{18}\text{O}$ and δD) in the Liuxi River basin. Based on isomer ratios and principal component analysis, coal combustion and vehicle emission were the main PAH sources in groundwater which indicated that groundwater in the study area mainly consisted of surface water of the last 40 years. In the basin, there were some differences of stable isotopes ($\delta^{18}\text{O}$ and δD), PAH composition and isomer ratios between groundwater and surface water, which showed that groundwater was a little replenished by surface water.

Paleoclimatical signals from large aquifers with case studies in China

Jianyao Chen

Sun Yatsen University, Guangzhou, China

Abstract

Major aquifers worldwide, under favorable conditions, can retain low temporal resolution information on climatic conditions at the time of recharge. Generally, this geochemical information can be used to better constrain reaction of the aquifer to environmental changes or even to assess long term groundwater sustainability. Understanding whether major aquifers at similar latitude world-wide share similar climatic responses and records is one of the objectives of the G@GPS (Groundwater@Global Palaeoclimatic Signals) network. Several flag basins were selected and many activities were carried out since 2011, when G@GPS was accepted as one IFG (International Focus Group) within INQUA and linked closely with the Commission of Groundwater and Climate Change of IAH. The presentation will cover the objectives, major activities and achievements in the past 5 years, with a focus on the case studies in China. ^{81}Kr and ^{85}Kr by using ATTA (atom trap trace analysis) to derive paleoclimate signals from deep aquifer was introduced in the workshop and training course in Zhanjiang, Guangdong Province on Dec. 8-13, 2014 and Dec. 1-7, 2018, and some results are to be presented, combined with those from ^{14}C . Paleoclimatic signal in the last 30-40 ka reconstructed using stable isotopes and dated groundwater indicates environmental changes and several recharge events. The signal was compared and verified by the high resolution data series from two caves in China. The signals from the large aquifers could provide a reasonable regional and global record of environmental change.

P-2468

Isotopic investigations for the assessment of geochemical processes of the continental intercalaire aquifer in southern Tunisia

Zahra Dhaoui, Kamel Zouari
National School of engineers of Sfax, Sfax, Tunisia

Abstract

Environmental tracers (^2H , ^{18}O , ^{14}C , ^3H , isotopes of Uranium) were applied to study the geochemical processes occurring within groundwaters from the continental intercalaire (CI) in Southern Tunisia.

Hydrochemical investigation shows a spatial variability of chemical facies which is linked to the lithology of the host rock. The mineralization is mainly controlled by the water–rock interaction in particular the dissolution of evaporitic minerals and the cation exchange reactions.

Stable isotopes show an enrichment in $\delta^{18}\text{O}$ and $\delta^2\text{H}$ contents suggesting the contribution of the Dahar sandstones outcrops in the current recharge of the CI aquifer in an arid context. These results are coherent with those of ^{14}C and ^3H that allow the qualitative identification of a current recharge which could probably be supplied by the recent infiltration of waters in Wadis and by the direct infiltration of meteoric water through the local sandstone outcrops of the basin.

However, the most depleted values in heavy isotopes indicate a paleorecharge of the aquifer under wetter conditions revealing a long residence time of groundwaters.

The disequilibrium between ^{234}U and ^{238}U is commonly used as a tracer of groundwater flow. Results from water samples using alpha spectrometry method indicate a range in ^{238}U concentrations and $^{234}\text{U}/^{238}\text{U}$ activity ratios (AR) of $0.044 - 1.285\mu\text{g kg}^{-1}$ and 1.2 to 8.84 respectively. The geochemistry of uranium isotopes in groundwater is controlled by many factors, essentially the influence of water rock interactions, the preferential dissolution of ^{234}U relative to ^{238}U due to alpha recoil and the mixing processes between different waters with distinct AR as well as ^{238}U concentrations.

Origin and preservation of methane in Scandinavian Ice Sheet meltwater in the groundwater of the Cambrian-Vendian aquifer system in Estonia

Rein Vaikmäe¹, Valle Raidla², Joonas Pärn^{2,1}, Werner Aeschbach³, György Czuppon⁴, Jüri Ivask¹, Andres Marandi², Stefan Schloemer⁵, Holar Sepp⁶, Kalle Kirsimäe⁶

¹Tallinn University of Technology, Tallinn, Estonia. ²Geological Survey of Estonia, Rakvere, Estonia. ³University of Heidelberg, Heidelberg, Germany. ⁴Hungarian Academy of Sciences, Institute of Geological and Geochemical Research, Budapest, Hungary. ⁵Federal Institute for Geosciences and Natural Resources (BGR), Hanover, Germany. ⁶University of Tartu, Tartu, Estonia

Abstract

The groundwater in the northern part of the Cambrian-Vendian aquifer system in Estonia is characterised by the most depleted oxygen isotopic composition known in Europe ($\delta^{18}\text{O}$ down to -23‰). The water originates from glacial meltwater recharge from the Scandinavian Ice Sheet in the Pleistocene (Vaikmäe et al., 2001). The aquifer system is characterised also by relatively high methane concentrations (up to 50% of the total gas content, about $1400 \mu\text{mol L}^{-1}$), the origin of which has so far remained unclear. In a recent study (Raidla et al., 2019) we focused on the origin of methane, the factors controlling its spatial distribution and its isotope geochemistry in the aquifer system. The data reveal a large spatial variability in methane content and $\delta^{13}\text{C}_{\text{CH}_4}$ and $\delta^2\text{H}_{\text{CH}_4}$ values (-6 to -105‰ and -220 to -297‰ , respectively). We argue that local oxidation processes have affected the initial isotope composition of methane rather than different origin of methane. Using the least modified $\delta^{13}\text{C}_{\text{CH}_4}$ values (-85 to -105‰) we conclude that the methane originates from the organic material overridden by the Scandinavian Ice Sheet that was carried into the aquifer system with infiltrating glacial meltwater. The estimated $\delta^{18}\text{O}$ values of the water where the methane was formed are in the range of $-17 \pm 1.5\text{‰}$ that supports the inference that the methane predates the LGM and was formed during the Middle Weichselian interstadial. The study shows that groundwater of glacial origin in the Cambrian-Vendian aquifer system could serve as an alternative palaeoenvironmental archive that can be used to study the variations in climatic and environmental conditions in Northern Europe during the glacial–interglacial cycles in the Pleistocene.

Precession and obliquity controls on South Africa monsoon revealed by fire emission

Anne-Laure Daniou¹, Marie-France Loutre², Didier Swingedouw¹, Thomas Laepple³, Pascale Braconnot⁴, Franck Bassinot⁴

¹CNRS, Bordeaux, France. ²PAGES, Bern, Switzerland. ³AWI, Bremerhaven, Germany. ⁴LSCE, Gif, France

Abstract

Subtropical southern Africa is dominated today by grass-fuelled fires which are controlled by marked rainfall seasonality, with wet austral summers during which fuel accumulates, and dry winters that increase fuel flammability. Microcharcoal (micro-particle produced during vegetation fire), a tracer of fire activity, was analysed from a deep-sea core off Namibia covering the past 170,000 years to study sensitivity of fires to changing climate and therefore to gain insights into fire activity for the near future. We observe clear cycles in fire activity during this period. Spectral analysis of the fire signal shows three distinct periodicities of 12.9, 23 and 54 kyrs. Maxima in fire activity occur during maxima of local summer insolation and maxima of precession (maxima of seasonality). We interpret changes in fire activity as a record of South African monsoon changes (strength and/or intensity) in agreement with results from a set of five simulations from a General Circulation climate model integrated for different key orbital configurations. Although fire activity and South Africa monsoon appear to be paced by orbital forcing through precession, observation of a 54 kyr period suggests a modulation of the response by the obliquity, or a non-linear response of the fire and monsoon to precession and obliquity. We finally propose a simple conceptual model to illustrate such a potential non-linearity, explaining the presence of 12.9, 23 and 54 kyrs periods in the fire record.

Abstract

The MIS 17 interglacial, ~715 - 675 ka, marks the end of the Mid-Pleistocene Transition as intensified, long and asymmetrical 100-kyr ice age cycles became eminently established. Increasing arrival of moisture to the Northern Hemisphere high latitudes, resulting from the northwestward migration of the Subpolar Front and the intensification of the Norwegian Greenland Seas (NGS) convection, has been put forward to explain the emergence of this quasi-periodic 100-kyr cycle. However, testing this hypothesis is problematic with the available North Atlantic precipitation data. Here we present new pollen-based quantitative seasonal climate reconstructions from the southwestern Iberian margin that track changes in the position and intensity of the westerlies. Our data compared to changes in North Atlantic deep and surface water conditions show that MIS 17 interglacial was marked by three major changes in the direction and strength of the westerlies tightly linked to oceanographic changes. In particular, we report here for the first time a drastic two-steps northward shift of the westerlies centered at ~ 693 ka that ended up with the sustained precipitation over southern European. This atmospheric reorganization was associated with northwestward migration of the Subpolar Front, strengthening of the NGS deep water formation and cooling of the western North Atlantic region. This finding points to the substantial arrival of moisture to the Northern Hemisphere high latitudes at the time of the decrease in summer energy and insolation contributing to the establishment of strong 100-kyr cycles.

Abstract

The study of past interglacial periods is important to understand our present and future climate, because they represent natural reference intervals for evaluating the timing and progression of the present warm stage (Tzedakis et al., 2009). Here we present preliminary results from the Project HELPING* ("Hydrological Evolution of Past INterGlacial), which aims to reconstruct at high temporal resolution the hydrological and environmental evolution of the period spanning 420 to 370 ka, corresponding to Marine Isotope Stage (MIS) 11, and including the interglacial period of MIS 11c. Our focus is the lacustrine succession in the Sulmona Basin (central Italy). The MIS 11c interglacial took place under an orbital configuration similar to that of the Holocene, so enhancing knowledge about its duration and internal dynamics could be useful in better understanding the present background of natural climate (Tzedakis et al., 2009). Sediment properties in the Sulmona Basin faithfully record regional hydrological and environmental change, which can be linked to Mediterranean and North Atlantic conditions thanks to well-known climate teleconnections (e.g., Giaccio et al., 2015). We obtained a high-resolution, multiproxy sedimentological and biogeochemical record (grain size, mineralogy, stable O and C isotopes on endogenic calcite, elemental composition and organic content). The record is anchored to a preliminary ⁴⁰Ar/³⁹Ar chronology developed on volcanic-ash layers (tephra) interbedded in the sediment. This allows us to place the observed climate and environmental variability onto an independent time scale. We reconstruct regional environmental evolution with a particular focus on short-term climate changes, then compare our record to the climatic framework apparent from several North Atlantic marine records to unravel potential forcing and mechanisms for intra-interglacial climate variability.

Date-driven modeling of Pleistocene global climate variability

Alexander Feigin¹, Dmitry Mukhin¹, Andrey Gavrilov¹, Juergen Kurths², Evgeny Loskutov¹

¹Institute of Applied Physics of RAS, Nizhny Novgorod, Russian Federation. ²Potsdam Institute for Climate Impact Research, Potsdam,, Germany

Abstract

A pronounce change in the glacial-interglacial regime that occurred about 1 million years ago – the so-called Middle Pleistocene transition (MPT) – is widely thought as an apparent manifestation of climate system’s nonlinearity. The MPT is observed in proxy records as a shift in glaciation periodicity (from 41 kyrs to approximately 100 kyrs) accompanied by both increasing of the ice/temperature oscillation amplitude and changing of the characteristic shape of the oscillations. Currently, there are ongoing debates about the roles of different orbital parameters, natural climate variability and other factors in the MPT.

We present here a data-driven dynamical model of global climate variability in the Pleistocene derived from benthic $d18O$ records (LR04 stack). Such a model is learned from direct data analysis and provides the maximal probability to produce the records we have in hands, or, in other words, is optimal in Bayesian sense. The model is constructed in the form of a stochastic nonlinear evolution operator parameterized by a universal approximator (artificial neural network) and forced by the insolation signals at different latitudes. The model also contains adjusting explicit dependence on time reflecting the slow cooling (and decreasing CO_2) trend that was permanent during the Pleistocene. The stochastic state-dependent term in the model is representative of shorter-scale (millennial and centennial) processes which are under temporal resolution of data we use.

The model shows that the MPT could not appear without both the gradual cooling trend and the intense millennial climate variability represented by a stochastic term (“internal forcing”) in the model. Substantially nonlinear response of the model to these factors determines the gradual transition to sawtooth relaxation oscillations in the middle Pleistocene. Regarding the insolation forcing, we have found that the only meridional gradient of the insolation, driven primary by the obliquity oscillations, is important for the Pleistocene dynamics both before and after the MPT. In particular, after the MPT the obliquity oscillations ensure through phase locking the occurrence of the climate cycles with periods in the range of approximately 80 to 120 years. The dynamical mechanisms underlying the detected model responses are presented in the companion presentation of Dmitry Mukhin.

Freshwater inflow to the East Sea, Korea during the last glacial period

Chang-Pyo Jun¹, Chang-Hwan Kim², Sangheon Yi¹, Seong-Joo Lee³

¹Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of. ²Korea Institute of Ocean Science and Technology, Uljin, Korea, Republic of. ³Kyungpook National University, Deagu, Korea, Republic of

Abstract

Freshwater inflow into the ocean is the important factor controlling the ocean circulation. To clarify variations of the freshwater inflow to the East Sea, Korea over the last glacial period, we conducted pollen analysis of 3.6m long core taken from the northern Ulleung Basin in the East Sea. We interpreted the signal of herbaceous pollen as a proxy of freshwater inflow to the East Sea, because the amounts of herbaceous pollen in the marine sediments tend to be mainly controlled by the intensity of freshwater inflow. High abundance peaks of the herbaceous pollen, recorded during the periods of 12-18 ka, 25-57 ka, and 95 ka, are highly correlated with the high C/N ratio that represents enhanced input of terrestrial organic matters. This interpretation is also supported by the fact that the fungal spore *Glomus* indicating intensified soil erosion is increased during this period. The freshwater inflow to the East Sea is mainly supplied from the Nakdong River and the Seomjin River along the southern coast of Korea, and the East China Sea coastal water (ECSCW). Comparison with precipitation from the Chinese Loess Plateau suggests that the ECSCW likely played an important role in controlling the freshwater inflow of the East Sea during the last glacial period.

A dynamical mechanism of the Middle Pleistocene transition revealed from data-driven models

Dmitry Mukhin¹, Andrey Gavrilov¹, Evgeny Loskutov¹, Juergen Kurths², Alexander Feigin¹

¹Institute of Applied Physics of RAS, Nizhny Novgorod, Russian Federation. ²Potsdam Institute for Climate Impact Research, Potsdam, Germany

Abstract

Many conceptual models of the Pleistocene dynamics have been proposed to date suggesting a variety of relevant dynamical mechanisms leading to the Middle Pleistocene transition (MPT), but so far there is no consensus about the most preferred one. Here we use a data-driven modeling approach for inferring the MPT mechanisms from proxy time series. We use Bayesian data analysis for revealing the dynamical model that is minimal but enough for describing data (see the companion presentation of Alexander Feigin). Mathematically, such a model provides the highest probability to produce the proxy records we have, and hence, yields statistically justified inferences. Thus, a model so obtained is fully independent of any physical conception and can be used for testing different climatological theories. In this work we restrict our consideration by the analysis of widely used LR04 stack based on benthic $d^{18}O$ records and show what MPT mechanisms are evident from this single time series. Other possible applications of the proposed methodology to different proxy records over the globe, e.g. emphasizing regional distinctions in climate dynamics, are discussed.

We find from the model phase space exploration that, from a dynamical point of view, the MPT was generated due to a long-term trend in climate leading to a noise-induced strongly nonlinear oscillation build-up. The obtained trend makes steady states of the system less stable allowing the phase trajectory to push forward to substantially nonlinear area of the phase space corresponding to colder states. As a result, the slow-fast (sawtooth) climate oscillations of large amplitude become approachable in the late Pleistocene; this gives indication that the large glaciations become possible to be initiated at higher temperatures than in the pre-MPT epoch. It is very important that such post-MPT sawtooth oscillations cannot arise in our model without shorter-scale (millennial and centennial) forcing treated as stochastic process in the model: due to such a noise the system is able to go far away from the attractor of the deterministic (noise-free) system. Also, the model detects the increasing power of such noise processes in colder climate. Finally, we detect and explain the mechanism of post-MPT climate response to insolation forcing: the obliquity oscillations both amplify the glacial-interglacial cycles and phase-lock the major deglaciations via the meridional gradient of insolation.

The difference of hemispheric climates under the influence of astronomical forcing

Zhipeng Wu^{1,2,3}, Qiuzhen Yin¹, Berger Andre¹, Zhengtang Guo^{2,3,4}

¹Georges Lemaître Center for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium. ²Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ³University of Chinese Academy of Sciences, Beijing, China. ⁴CAS Center for Excellence in Life and Paleoenvironment, Beijing, China

Abstract

The response of climate system to astronomical parameters is a very important scientific issue, but the internal processes and feedbacks are still not very clear. In order to discuss the difference of hemispheric climates under the influence of astronomical forcing solely, a more than 90,000-year long transient simulation starting from 511 ka BP is performed with only varying insolation forcing. The results of surface air temperature (SAT), sea surface temperature (SST) and sea ice are analyzed. Our results show that the most interesting difference between the Northern (NH) and Southern (SH) Hemispheres is in the sea ice variability. Precession plays a dominant role on sea ice in the NH mainly due to its response to the local summer insolation. The Arctic sea ice is also influenced, but to a less degree, by the northward oceanic heat transport (mainly via the Atlantic meridional overturning circulation). However, obliquity plays a dominant role on sea ice in the SH. First, a smaller obliquity leads to lower insolation in high latitudes and finally to a cooling and more sea ice formation. Second, a smaller obliquity leads to larger latitudinal temperature and pressure gradients, and then to stronger westerly winds, which cool the sea surface and leads to more sea ice formation in the Southern Ocean. For the SAT and SST, precession plays a dominant role at low latitude in the NH and SH, because both of them involves vegetation feedbacks and meridional oceanic heat transport. Compared to low latitudes, middle and high latitudes are more influenced by obliquity. This is partly due to the increased role of obliquity on the daily insolation towards the high latitudes, and is also due to the increased role of the atmospheric heat transport on the SAT at high latitudes. Precession is more important in the NH middle and high latitudes than SH due to the vegetation and sea ice feedbacks. More details on the atmospheric and oceanic processes and feedbacks will be presented.

Abstract

The vegetation record of the Quaternary in Europe is characterized by successive loss of tree species during glacial-interglacial (G-IG) cycles. Relative to central Europe, tree diversity in refugia in the Mediterranean remained high for much of the Quaternary, although the precise relation between (regional) extinctions, climate variability and local landscape factors is not known. Lake Ohrid, located at the Albanian / FYROM (Macedonian) border at 693 m asl, is the one of the deepest and largest lakes in Europe, and formed between 1.2 and 1.9 Ma ago. Lake Ohrid is a biodiversity hotspot and a glacial forest refugium, containing a continuous sediment infill of glacial-interglacial vegetation cycles since its establishment.

Within the International Continental Scientific Drilling Program (ICDP), the lake was drilled in 2013 and a 569-m long sediment core was collected. The palynological record of the DEEP site has now been analyzed at millennial-scale resolution down to the base of the continuous lake phase at nearly 1.4 Ma, and is supported by a well-constrained independent age model based on tephrostratigraphy, magnetostratigraphy, and complementary tuning of biogeochemical proxy data to orbital parameters. Here we report on the relation between the tree cover, glacial-interglacial climate variability and local palynological richness. There is an excellent correspondence between forested / non-forested periods at Ohrid and interglacial / glacial cycles of the Mediterranean marine isotope stratigraphy, suggesting a regionally relevant vegetation and climate record. Prior to 1.2 Ma, the Ohrid catchment had a clearly different configuration with shallower water, less pronounced vertical vegetation zonation, and high amounts of relict taxa, including occurrences of typical 'Tertiary elements' that currently occur in warm temperate and subtropical parts of the American and Asian continents.

Palynological richness of tree taxa, based on a moving window of species accumulation curves, shows relatively low variability in line with the refuge character of the site where, in glacial conditions, vegetation belts were compressed but tree diversity remained largely intact. After 1.2 Ma, lake levels increase and maximum tree richness is recorded. The reorganization of G-IG cycles during the Middle Pleistocene Transition is mirrored by several tree richness declines. Starting from 0.94 Ma, most relict tree taxa develop a discontinuous distribution and gradually disappear. Variations in richness vary on the same timescale as G-IG cycles, although the amplitude of these variations is generally not proportional to the intensity of glaciations as recorded in the global $\delta^{18}\text{O}$ benthic stack. A striking exception is the tree richness recovery at Lake Ohrid shows during MIS 9-7, coinciding with a reduction in G-IG amplitude. Precession-scale variability is significant in the record and is characterized by rapid alternations between mesophilous and lower montane vegetation that point to significant humidity variations.

P-2478

Relative effects of precession, obliquity and eccentricity on the interglacial climate over Eastern and Southern Asia

Anqi Lyu, Qiuzhen Yin, Michel Crucifix, André Berger
Université catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract

The long-term orbital changes have been proved to produce changes in global and regional climate, which are reflected in the geological records. *However, how astronomical parameters influence climate is not yet fully understood at regional scale.* Here, based on climate model simulations, we study the climate response of several sub-regions over Eastern and Southern Asia to continuously changing astronomical parameters under interglacial conditions (MIS-1, MIS-5, MIS-9, MIS-11 and MIS-19). The outputs are obtained with two methods. The first one is based on the transient simulations using the model LOVECLIM driven by varying insolation forcing (Yin and Berger, 2015). The second one is a Gaussian process emulator (Araya-Melo et al., 2015) calibrated on an ensemble of well-chosen snapshot simulations by the model HadCM3. *In order to assess the individual effects of each parameter, data are also obtained when obliquity and precession vary respectively. The results obtained by the two models are generally consistent.* Among the three orbital parameters, precession is the main factor regulating temperature and precipitation. In general, the relative effects of the three astronomical parameters are quite similar over the selected sub-regions over Eastern and Southern Asia although differences exist. In the next stage, more sensitivity experiments and regression analysis will be carried out.

⁵University for Advanced Studies (SOKENDAI), Tachikawa, Japan

Abstract

Marine isotope stage (MIS) 19 has been suggested as one of the best orbital analogs for present interglacial, because of the similarity of the orbital configurations between both interglacial periods. Therefore, paleoenvironmental reconstructions of MIS 19 will provide valuable knowledge to evaluate the anthropogenic impacts for present and future climate changes. Additionally, the abrupt climate changes associated with the ice melting in the North Atlantic are globally documented in the paleoceanographic and paleoclimatic records during the MIS 20–19 transition and late MIS 19, suggesting global climatic teleconnection during the periods. The Kuroshio Current, the largest western boundary current of the North Pacific ocean, transports a large amount of heat and water poleward, and strongly influences the East Asian climate, however, responses of the Kuroshio Current to the ice melting in the North Atlantic remains unknown. Here, we provide new ultra-high-resolution oxygen isotope ($\delta^{18}\text{O}$) records using benthic, and surface and subsurface planktonic foraminifers throughout MIS 19 from the Chiba composite section in east-central Japanese island. Vertical water temperature structure and their gradient (ΔT) based on the $\delta^{18}\text{O}$ profiles exhibit two and four southward displacement events of the Kuroshio Extension Front (KEF) on millennial-scale during MIS 20–19 transition and late MIS 19, respectively. Consistencies of the timing, amplitude, and periodicity with those of periodic disruption/reactivation of the Atlantic meridional overturning circulation (AMOC) due to iceberg discharges in the North Atlantic indicate that the freshwater forcing induce the abrupt latitudinal displacements of the KEF via atmospheric dynamics. Additionally, during MIS 19a two-phase warmings in the millennial-scale variations of the surface $\delta^{18}\text{O}$ and ΔT imply that the northward remigrations of the KEF and surface water temperature warming driven by reactivations of the AMOC were amplified by relatively strong boreal winter insolation associated with the low eccentricity-precession forcing.

Abstract

Paleoclimate archives tied to accurate and precise chronologies are crucial for developing a dynamical understanding of the causes and nature of Quaternary glacial terminations [1]. While numerous well-dated archives provide good chronological control through Terminations I and II, there is presently a lack of well-dated records spanning earlier terminations. A notable exception to this is a suite of remarkably well-dated Chinese speleothems that have been used to date the commencement of each termination over the past 640 kyr [2,3]. This has been achieved by correlating weak Asian Monsoon anomalies as captured by speleothem oxygen isotope signals with terminal Heinrich events in the North Atlantic. While this approach is well-suited to testing orbital hypothesis by comparing the timing of termination commencement with insolation metrics, it only provides precise age control at the beginning of each termination. This precludes assessment of the progression of climatic changes over the full course of the termination, and the timing at which full interglacial conditions are reached.

Here we present a composite speleothem record spanning glacial terminations IV and V from the Antro del Corchia cave system located on the western coast of central Italy. This record is anchored to a uranium-thorium based chronology and contains numerous proxies representing both local and regional climate, including Δ_{47} -based temperature data derived from a pool carbonate formed under very slow degassing conditions. By taking advantage of established links between speleothem proxies from this cave site and marine proxies from the North Atlantic, we fix the marine sediment data to a radiometric age scale. This allows us to constrain the timing of ocean circulation and SST changes occurring in the North Atlantic throughout the duration of Terminations IV and V, and compare these with terrestrial temperatures in central Italy.

How far modeling of sapropel S1 (Early Holocene) allow the understanding of sapropels occurrence since mid-Miocene?

Tristan Vadsaria¹, Gilles Ramstein¹, Laurent Li², Dutay Jean-Claude¹, Sébastien Zaragosi³

¹LSCE, Gif-sur-Yvette, France. ²LMD, Paris, France. ³EPOC, Bordeaux, France

Abstract

In a first part, we will revisit the classical causal link invoked for the first time by Rossignol-Strick et al (1982) with a new modeling approach using coupled OARCM (Ocean-Atmosphere Regional Circulation model) with high spatial resolution ($1/8^\circ$) enable to capture correctly the convection all over the Mediterranean basin both in location and intensity. Using this tool, through sensitivity experiments to Nile freshwater input, we investigate in details its impact on Mediterranean ocean dynamics and demonstrate the intensity of the stratification. We pinpoint the crucial role of Nile freshwater on stratification of eastern basin water masses. Moreover, using the recent modeling development of the ϵNd (tracer of the paleo-circulation) in the Mediterranean Sea (Ayache et al., 2016), we compared our results obtained in simulating the changes of ϵNd and compare to those depicted by the data (Vadsaria et al., 2019, Paleoceanography).

To better describe the climatic context of the sapropel S1, we developed a numerical platform able to downscale existing OAGCM simulations for the Early Holocene. That platform involves an Atmospheric Regional Circulation Model providing the dynamical downscaling in order to drive the Mediterranean Sea at $1/8^\circ$. Accounting for the simulated changes in hydrology, we quantified the respective impact of the different components of this budget in terms of runoff of the main rivers and changes of precipitation pattern. We demonstrate that the freshwater input from the Nile plays the major role in producing stratification of the eastern basin.

This numerical platform may be use for any past OAGCM simulation and therefore could be applied for other sapropel occurrences. Indeed, it has been shown recently that the triggering of sapropel S1 is a long lasting process associated with deglaciation (Grimm et al., 2015). Therefore, the hydrologic perturbation is not restricted to the Early Holocene and Nile River but is also due to the Fennoscandia ice sheet (FIS) melting. We show, using ICE-6G (Peltier et al., 2015) melting scenarios, but also the recent high-temporal resolving reconstruction of Patton et al (2017), that the freshwater coming from the melting of the FIS contributes to precondition the Mediterranean basin. In this new scenario, monsoon and Nile River freshwater act as an ultimate trigger to produce the sapropel S1. It would be necessary to study sapropels occurring in other contexts such as the sapropel S5 occurring in a warmer climate than the S1.

Abstract

We present a new speleothem trace element and stable isotope record, which extends previous paleoclimate evidence from Cuban speleothems to the last 96 ka. This is one of the few records from the climatically sensitive transition zone between Central and North America, the Caribbean and the western tropical Atlantic. Our multiple proxies provide geochemical evidence for pronounced environmental changes over the last glacial cycle in the American low latitudes and allow the comprehensive reconstruction of past precipitation and vegetation changes on orbital to millennial timescales.

Our results confirm the close link of Caribbean precipitation to North Atlantic (NA) climate variability, insolation and the strength of the Atlantic Meridional Overturning Circulation. The associated variations in Caribbean sea surface temperatures and the shift of the Intertropical Convergence Zone (ITCZ) led to substantial changes of the hydrological cycle. During Heinrich stadials and the Younger Dryas, climatic conditions on Cuba were comparably cool and/or dry. This is in agreement with previous evidence for the Holocene, when NA cold events coincided with drier conditions on Cuba. In contrast, warm Dansgaard/Oeschger cycles were accompanied by more humid conditions. However, our record suggests that this teleconnection was less dominant during MIS 4 to 2, displayed by a weaker response of Cuban precipitation proxies to NA climatic shifts than during MIS 5 in particular. We hypothesize, that this observation indicates a weakening of the northern branch of the Caribbean Low Level Jet when the ITCZ is in a generally more southern position. This is strikingly evident during the deglacial, when driest and/or coolest conditions prevailed in western Cuba from HS 1 into the Younger Dryas, including the Bolling/Allerod interstadial.

In addition, our proxies indicate a shift in the abundance of C4 vegetation and a decline of soil activity during colder and drier periods, in particular the Last Glacial Maximum and MIS 4, but also during Heinrich stadials.

In summary, our record provides a valuable climate reconstruction for the Caribbean realm for the last Glacial period and gives new insight into past variability of the Caribbean hydrological cycle.

P-2483

A multi-proxy approach to assessing multiscale monsoon variability over the past six glacial cycles

Fei Guo, Youbin Sun
Institute of Earth Environment, CAS, Xi'an, China

Abstract

High-resolution proxies from Chinese loess deposits can document the East Asian monsoon changes at glacial-interglacial to millennial time scales. Unlike the absolutely dated speleothem $\delta^{18}\text{O}$ records that exhibit persistent millennial changes over the past 640 kyr, well resolved loess proxies can only reflect abrupt monsoon changes over the last two glacial cycles. Here we present grain-size and elemental records from a 180-m loess core retrieved from the western Chinese Loess Plateau, extending high-frequency variations of Asia monsoon back to the last six glacial-interglacial cycles. The mean grain-size records display significant glacial-interglacial timescales and match well with the marine $\delta^{18}\text{O}$ record in terms of amplitude and periodicities. Because of varied sensitivity of grain-size and elemental ratios to grain-size sorting (winter monsoon) and chemical weathering (summer monsoon), precessional cyclicity are distinctive but with different intensities in these physical-chemical indicators. Moreover, large-amplitude and high-frequency oscillations were persistent during past glacial and interglacial intervals. Compared them with Chinese speleothem $\delta^{18}\text{O}$ and North Atlantic ice-rafted debris (IRD) records, loess proxies display similar magnitudes of abrupt climate changes, however the timing and amplitude of these abrupt climatic events are not easily correlated. Our results indicate that integration of speleothem, loess, ice and marine record permits better understanding of the origin and dynamics of abrupt climatic changes, particularly regarding its links with glacial and astronomical forcings.

Abstract

Climate models indicate that transient CO₂ forcing superimposed on Atlantic Meridional Overturning Circulation (AMOC) changes caused the dramatic climate changes of the last deglaciation (including Termination I). Across the last deglaciation, global atmospheric concentrations of CO₂ (pCO₂) increased from ~190 to ~280 ppm, with significant step-wise increases around 16.3, 14.8 and 11.7 kyr (Marcott et al., 2014). However, little is known about the impact of pCO₂ changes on vegetation across Termination I. It is well known that under full glacial low pCO₂, plants experienced strong constraints on photosynthesis, especially woody C₃ plants. At very low pCO₂, stomatal opening must adjust to maintain an adequate atmosphere-leaf CO₂ gradient resulting in a trade-off between carbon assimilation and water loss. As such, physiological drought under glacial conditions will have been reinforced by low pCO₂. Therefore, although rarely considered, a major reduction in CO₂ limitation must have occurred, modifying the impact of local and regional climate changes across Termination I.

The analysis of terrestrial (pollen) and marine (alkenone-derived Sea Surface Temperature, SST) indicators in the Iberian margin marine core IODP U1385A ("Shackleton site") throughout the last deglaciation, at high resolution (165 yr and 114 yr, respectively), allows us to track and compare changes in vegetation and SSTs with the shifts in global pCO₂. We observe that a major development of forest (corresponding to a biome shift) in SW Iberia, occurred at ~15.0 cal kyr BP, corresponding to a pCO₂ of 240 ppm. Furthermore, major jumps (of 10 to 20% increase) in temperate and Mediterranean forest are synchronous, within age model uncertainties, with abrupt pCO₂ increases observed at ~16.2, 14.6 and 11.8 cal kyr BP. We hypothesise that the increase in pCO₂ represents a gradual reduction of the physiological constraint on arboreal development that promoted forest response to episodic warmer and wetter conditions during the deglaciation. This overlooked role of pCO₂ could explain an intriguing feature observed in the U1385A and other Iberian margin records, namely the near absence of forest during HS1 but high forest cover during the YD, despite quite similar cold SSTs. Across these cold periods and the intervening warm and humid interstadial (Bölling-Alleröd), neither AMOC strength nor regional SSTs can account for the pattern of forest development. Our ongoing work aims to shed light on the potential impact of pCO₂ on forest response to deglacial climate changes across the Iberian Peninsula. This hypothesis, which is well grounded in plant physiology, should be explored through model simulations to establish the amplitude and critical thresholds of pCO₂ impacts on regional vegetation.

How the orbital forcing influences vegetation from high latitudes to low latitudes?

Qianqian Su, Anqi Lyu, Qiuzhen Yin, André Berger

George Lemaitre Centre for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract

It is noted that certain recurring vegetation patterns appear to be a result of climate changes linked to specific astronomical parameters. Proxy reconstructions show that the response of vegetation phases to orbital configurations is complex and varies with regions. There is limited knowledge of the links between terrestrial vegetation changes and orbital forcing. It is therefore instructive to explore systematically how the astronomical forcing controls vegetation development from high latitudes to low latitudes. By analyzing the components of vegetation in different latitudinal zones and annual precipitation and temperature, which are associated with specific orbital parameters, including obliquity, precession and eccentricity, we find that: (1) Vegetation were mainly influenced by obliquity and precession. But eccentricity also had a non-negligible effect. (2) Mostly the responses of tree and grass in a specific area to the same astronomical parameter were opposite. (3) At low latitudes, precession generally played greater important role on tree fraction than in northern high latitude area, whereas in northern high latitude area, obliquity showed greater importance on tree fraction than at low latitudes.

Abstract

Anthropogenic CO₂ release into the atmosphere leads to temperature projections for 2100 not experienced on earth since many million years. Those periods are poorly known due to low temporal and spatial data and ill-defined climate forcing. But, past warm periods (interglacials), occurring during the Quaternary, under variable boundary conditions (e.g. greenhouse gases concentration, sea level and ice sheets size, insolation and orbital forcing), can provide invaluable information on the dynamics and processes behind natural warm climates. In order to gain information on the possible dynamics of the ongoing/future climate, we are studying the warmest intervals from Marine Isotope Stage from 31 to 5e, in particular MIS31, MIS19 and MIS11, which in terms of orbital configuration, are the closest analogues to the present interglacial. This study is based on the SW Iberian margin sedimentary sequences from Sites U1385 and U1391, recovered during IODP Expedition 339. In this study we present records for the past sea surface temperature based in U^K₃₇-SST, paleo-productivity derivate from total alkenone and continental input reconstructions at orbital, millennial and sub-millennial scale for the past tree interglacials and its comparition with the present Interglacial, the Holocene. The results show that the older Interglacials are warmer and shorter. Interglacials before MIS 19 show maximal warmth at the onset of the interglacial period following obliquity forcing. Furthermore, the fact that these very warm periods co-occur with low pCO₂ concentrations, makes it crucial to understand climate dynamics on those times to better foresee antropogenic-forced climate change.

Abstract

The climatic variability and its effects on the biota operate on several characteristic time scales. On the time scale of millions to tens of thousands of years Milankovitch forcing prevails in the Quaternary. Shorter term or sub-orbital climatic variability is much less understood and explored in the fossil record. The multivariate analysis of the latest Pleistocene and Holocene pollen assemblages from the south western part of the Lithuania (Čepkeliai section) reveals persistent long-term trends in the plant composition as best explained by the centennial to millennial climatic oscillations. Besides the presence of the distinct climatic events, such as Holocene thermal maximum, Roman Climatic Optimum and Medieval Warm Period, spectral analyses of the data show the presence of common periodicities in the NMDS (non-metric multidimensional scaling) scores as well as the Tsallis entropy scaling exponents $1/q^*$ (which represents the diversity of the assemblages). At the centennial time scales statistically significant periodicities range from 176 up to 240 years in the period length which corresponds to the so called de Vries solar activity cycles. On the millennial time scales $\sim 1,900$ and $\sim 3,800$ year cyclicities appear. The duration of these cyclicities suggests their possible harmonic relations to the precession term of the orbital climatic variability.

Abstract

The study of past interglacials, periods of reduced ice volume like our present interglacial (the Holocene) is crucial for understanding the future climate. Marine Isotope Stage (MIS) 13 (478–533 ka) represents a Quaternary interglacial of primary interest and in recent years it has become the focus of much attention. One of the main reasons of this interest stems from the fact that MIS 13 is among the most glaciated and cooler interglacials of the past 800,000 years, and unexpectedly it is associated with an unusual strong summer monsoon, even though CO₂ and CH₄ levels are not particularly high. Conversely, a growing body of evidence indicates that the conditions during MIS 13 vary geographically, and several continental records document a rather warm interglacial coupled with relatively low global ice volume. In the Mediterranean region, the study of MIS 13 climate is, however, strongly hampered by the paucity of available records, particularly in the terrestrial realm as only two vegetation sequences contain a complete record of MIS 13.

Here we present the first high-resolution (centennial-scale) pollen record from IODP Site U1385 covering MIS 13, that allows the reconstruction of vegetation and atmospheric changes on orbital and suborbital timescales, in a direct comparison to alkenone-based sea surface temperature (SST). This site, also known as the “Shackleton Site”, was collected on the SW Iberian margin, a region highly sensitive to global warming that is considered a prime location for tracing past climate changes. Western Mediterranean atmospherically-driven vegetation changes and surface oceanic conditions are discussed in the light of a larger European and North Atlantic context to assess the influence of global and remote controlling factors throughout MIS 13.

Abstract

A quantitative study of the climate feedback processes for determining summer temperature in the northern high latitudes is needed for our understanding of climate system, including glacial-interglacial cycles. In this study, we focus on the differences of (1) dependence of the seasonal, especially summer, temperature change at northern high latitudes upon orbital parameters and of (2) climate feedback processes operating under different seasons.

In order to investigate the seasonal temperature changes, we use a coupled atmosphere-vegetation GCM with slab ocean of MIROC GCM (O'ishi and Abe-Ouchi, 2011) and performed numerous experiments by systematically changing the combinations of orbital parameters (maximum, minimum and present values for each parameter). We also focus on the role of vegetation feedback effect by comparing experiments with and without the vegetation model (LPJ), since several recent studies indicate its importance. A seasonal feedback analysis method (Lu and Cai, 2009) is also applied to understand the relative importance of surface albedo feedback, changes in cloud radiative forcing, changes in surface sensible and latent heat fluxes, changes in heat storage, and changes in the clear-sky downward infrared radiation in causing the seasonality of arctic surface amplification.

Results show that the efficiency of summer temperature change over land in the northern high latitude is about 50% larger by obliquity changes than by precession-eccentricity changes. This is mainly because obliquity changes promote a larger seasonal climate feedback, especially vegetation-snow-albedo feedback in the spring, than the precession-eccentricity changes.

Abstract

The subpolar gyre (SPG) is a major feature controlling climate and ocean circulation of North Atlantic region, with significant variability of cold and warm ocean currents feeding into the gyre. The western sector of the SPG, the Labrador Sea, is a major deep water formation site, thus also directly influencing the Atlantic Meridional Overturning Circulation (AMOC). Here we compare records of SPG circulation from selected sites off south Iceland, west and southeast Greenland and Newfoundland in order to establish a combined record of SPG circulation through the Holocene. Our records combine multi-proxy studies (foraminifera, diatoms, dinoflagellate cysts, sediment properties, biomarkers, elemental composition and environmental magnetics) from a range of marine sediment cores to test for large-scale changes in ocean circulation in the Holocene. The SPG region has experienced several major changes in ocean circulation, with a major reorganisation occurring during the deglaciation and again at approximately 7.5 kyr BP and 3-4 kyr BP. Especially during the late Holocene, climatic conditions were largely antiphase in the Labrador Sea to the general North Atlantic region climate due to influence of the Northern Annular Mode affecting the strength of the Atlantic component of the West Greenland Current as well as the flow of the Labrador Current. This again influenced the strength and expansion of the SPG and exemplifies that the SPG has undergone significant variability at multi-decadal to millennial time scales during the Holocene.

Abstract

The Ría de Ferrol is a confined tide-dominated incised valley located in the mesotidal passive Atlantic margin of Galicia (NW Iberia). The sedimentary evolution of the ria from the Last Glacial Maximum to the present was reconstructed using a multidisciplinary approach, combining seismic and sedimentary facies and supported by radiocarbon data, geochemical proxies and pollen and dinoflagellate cysts analyses.

Late Pleistocene and Holocene high-frequency sea-level variations were one of the main factors that modulated the type of depositional environments established within the incised valley, as well as their evolution. This evolution was modulated by the antecedent morphology, with a rock-incised narrow channel in the middle of the basin (the Ferrol Strait), which influenced the evolution of the ria as it became flooded during Holocene transgression.

During the lowstand of the Last Glacial Maximum (*ca* 20 kyr BP), the ria was a fluvial valley drained by a braided river system, whose sediments are mainly preserved in the inner sector. Sediments from ponds and stagnant areas were recovered in the sediment cores, dated to be older than 10790-11170 cal yr BP.

Facies from a tide-dominated estuary have been dominant within the incised valley during most of the Holocene, with sedimentary environments shifting toward the east at the time when sea level rose. Tide influence was enhanced by the structural straight. Extensive tidal flats dissected by estuarine channels of variable dimensions occupied most of the basin. Radiocarbon data showed ages from 8610-8910 to 5760-5940 cal yr BP. Slow sea-level rise after *ca* 4 ka BP finally forced rivers to retreat to the present position, causing the dispersion of their energy and leading to the final evolution of the area into a fully marine system.

Several erosive events and changes affecting the local development of biomes found in the sedimentary infill correlate with relevant changes observed in pollen sequences obtained at different mountain areas from NW Iberia. Thus they can be interpreted as local signals of the climatic variability affecting most of the North Atlantic during the Lateglacial and the Holocene.

Rapid sea-level rise and climate change: lessons from the early Holocene

Graham Rush¹, Roland Gehrels¹, Mark Bateman², Grant Bigg²

¹University of York, York, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom

Abstract

The '8.2 ka cold event' is recognised as the largest magnitude Holocene cooling event in the North Atlantic region. Freshwater input from the retreating Laurentide Ice Sheet drove a slowdown of the Atlantic Meridional Overturning Circulation (AMOC) which subsequently caused the observed climatic shift. A 160 year period of temperature cooling of 3.3 ± 1.1 °C and reduced precipitation are observed in Greenland, with contemporaneous climate shifts recognised in many other records around the North Atlantic region and further afield. In this presentation two new high-resolution sea-level reconstructions from both hemispheres will be presented with the aim of resolving the history of North Atlantic melt-water input prior to the 8.2 ka event.

Litho- and bio-stratigraphic data alongside high-precision radiocarbon dates have been collected from the Ythan Estuary (NE Scotland) and Swan Inlet (Falkland Islands) for the centuries prior to the 8.2 ka event. In the Ythan Estuary, two complimentary single core analyses utilise a foraminifera based transfer function and multiple high-precision radiocarbon dates to produce a robust high-resolution reconstruction. Swan Inlet is the first southern hemisphere location where a rapid flooding event preceding the 8.2 ka event has been discovered. Optically Stimulated Luminescence analysis shows that the observed sea-level rise, in the order of 2-4 m, occurred in Swan Inlet within a few centuries. This is further constrained by radiocarbon dating and a diatom-based transfer function to resolve the phase(s) and magnitude of this rise.

The combination of sea-level reconstructions from both hemispheres allows confirmation of a Laurentide melt-water source as the trigger of the 8.2 ka event by comparing the magnitudes in conjunction with sea-level fingerprint models. Identifying the freshwater source(s) and quantifying melt-water input allow climate models to be tested in order to apply them more confidently to future AMOC responses to scenarios of warming and ice melt. Thus, this work ultimately will help to improve understanding of the impacts of Arctic ice melt on oceanic changes and future climate, especially in the North Atlantic region.

Figure 1. The timing and magnitude of previously observed sea level jumps from sites shown in figure 2, highlighting the current disagreement.

Figure 2. Numerically predicted sea-level fingerprint due to the melt-water input from the retreating Laurentide Ice Sheet at 8.4 ka, normalized by a eustatic rise (0.4 m). The coloured squares represent sites of previous sea-level measurements shown in figure 1 and the white squares are sites from this study. (Adapted from: (Kendall *et al.* 2008)

Ocean and climate conditions in SW Greenland during the last 2 000 years

Mimmi Oksman¹, Christof Pearce¹, Arto Miettinen², Lærke-Corinn Ulner¹, Signe Hygom Jacobsen¹, Ralph Schneider³, Marit-Solveig Seidenkrantz¹

¹University of Aarhus, Aarhus, Denmark. ²Norwegian Polar Institute, Tromso, Norway. ³University of Kiel, Kiel, Germany

Abstract

This study presents multi-proxy data from a high-resolution marine sediment core from the SW Greenland shelf. This climatically sensitive region is influenced by warm water inflows from the Atlantic Ocean and cold water inflows from the Arctic Ocean, as well as meltwater release and ice discharge from the Greenland Ice Sheet. Variations in ocean surface temperatures and sea ice conditions in this region have a significant implications to the North Atlantic Deep Water Formation and Atlantic Meridional Overturning Circulation. The aim of this study is to reconstruct ocean surface conditions (sea surface temperatures; SST and sea ice conditions; SIC) and identify iceberg and meltwater discharge from the Greenland ice sheet during the last 2 000 years using microfossil assemblages (diatoms, dinocysts and benthic foraminiferas) and sedimentological proxies (XRF-scan, sediment grain size and IRD). The results of this study are compared with other temperature reconstructions from the Southeast Greenland, subpolar North Atlantic and the Norwegian Sea to identify possible temperature seesaw-pattern linked to the atmospheric forcing of the North Atlantic Oscillation (NAO) and to investigate variations in the strength of Atlantic-sourced warm water inflows.

The results reveal fluctuations in sea surface temperatures on a centennial and decadal timescales. The temperature record shows that cooler oceanic conditions prevailed over the Medieval Climate Anomaly (from ca. 1000 CE to 1500 CE), whereas warmer conditions prevailed over the Little Ice Age (from ca. 1500 CE to 1800 CE). Similar temperature trend was discovered in the subpolar North Atlantic while the opposite temperature trend prevailed in the Norwegian Sea region. This seesaw pattern is likely to be linked to the atmospheric forcing of the NAO, which regulates the strength of the Irminger Current carrying warm Atlantic waters to northwest North Atlantic. The relative percentage of the coarse grain material in the sediment ($>63 \mu\text{m}$) indicates decreasing amount of iceberg rafting during the last 2000 years, whereas sea ice proxies imply increasing sea conditions towards the present day.

Abstract

The abrupt 8.2 ka cold event has been widely described from Greenland and North Atlantic records. However, its expression in shelf seas is poorly documented, and the temporal resolution of most marine records is inadequate to precisely determine the chronology of major events. Here we present an annually-resolved temperature and water column stratification reconstruction based on stable isotope geochemistry of *Arctica islandica* shells from the Fladen Ground (northern North Sea) temporally coherent with Greenland ice core records. Our age model is based on a growth increment chronology obtained from four radiometrically-dated shells synchronised to estuarine and saltmarsh deposits in SW Scotland which suggests that our reconstruction covers the 8290-8100 cal BP interval. Our results indicate that a sudden sea level rise (SSLR) caused the North Sea water column to stratify between ages 8320-8220 cal BP. Thirty years later, cold and stormy conditions inhibited water column stratification but an eventual incursion of sub-Arctic waters into the North Sea re-established density-driven stratification. The water temperatures reached their minimum of ~3.8 °C 55 years after the SSLR. Intermittently-mixed conditions were later established when the sub-Arctic waters receded. This work is currently the only high or mid-latitude marine records with such a high temporal resolution. These reconstructions provide an insight on climatic reaction times to perturbations to the Atlantic Meridional Overturning Circulation.

Abstract

The Baffin Bay is a semi-enclosed basin connecting the Arctic Ocean and the western North Atlantic. This study aims to reconstruct the fluctuations in the advection of relatively warmer and saline Atlantic waters and the incursion of colder deep Arctic water masses flowing into the Baffin Bay through the multiple gateways in the Canadian Archipelago and the Nares Strait. A multiproxy study of a 738 cm long marine sediment core retrieved from the eastern Baffin Bay near Upernavik (core AMD14-204C; 73°15.663' N/57°53.987' W; 987 m water depth), allows the reconstruction of the paleoceanography and paleoclimate of the area. Results of benthic foraminiferal assemblage analyses, XRF data, CT-scans and radiocarbon datings of the core reveals that several fluctuations in the entrainment of Atlantic subsurface water into the West Greenland Current occurred during the Holocene, inferred by periods of high abundance of Atlantic water species. The two periods with strongest advection of Atlantic waters occurred around 8000-7500 cal BP and 6500-6000 cal BP coinciding with a decrease in the abundance of benthic sea ice species further implicating an increase in air temperature and thus a reduction of the sea ice cover. At ~3200 cal BP, possibly coinciding with the onset of the 'Neoglaciation', an abrupt transition to a benthic fauna dominated by agglutinated species indicate that enhanced carbonate dissolution influenced the area. This was likely in part caused by a reduction of the influx of Atlantic water, allowing increased influx of the cold, corrosive Baffin Bay Deep Water originating from the Arctic Ocean, entering the Baffin Bay through the Nares Strait. These cold subsurface water conditions persisted throughout the late Holocene, only interrupted by short-lived climate fluctuations superimposed on this cooling trend.

P-2496

The contribution of the glacial lakes of northeastern Quebec and Labrador (Canada) to the meltwater discharges of the early Holocene

Etienne Brouard¹, Martin Roy¹, Hugo Dubé-Loubert^{1,2}

¹University of Quebec at Montreal, Montréal, Canada. ² Ministry of Energy and Natural Resources of Quebec, Val D'Or, Canada

Abstract

The climate variability of the early Holocene is intrinsically linked to the drainage of large ice-dammed lakes that formed during the deglaciation of North America. The meltwater outbursts that resulted from the drainage of these lakes are believed to have altered the Atlantic Meridional Ocean Circulation, which likely triggered climatic events such as the 8.2 ka Event. The number and magnitude of the meltwater forcings that occurred during this interval of the deglaciation are now under focus due to a growing number of studies showing that the present-day increase in freshwater releases from the melting of Greenland may also potentially lead to a slowdown of the ocean thermohaline circulation and cause important climate feedbacks. Furthermore, recent studies suggest that the meltwater discharge from Lake Agassiz-Ojibway that presumably triggered the 8.2 ka cooling may have been smaller, while others point to a contribution from a series of glacial lakes surrounding Ungava Bay in northern Quebec-Labrador. These uncertainties arise from an inadequate understanding of the patterns of retreat of the Laurentide Ice Sheet (LIS), notably those related to the Ungava glacial lakes, which are limited by a lack of chronological constraints.

Here, we assess the potential impact of the drainage of the Ungava lakes on ocean surface conditions and climate through a reconstruction of the demise of the LIS over northeastern Quebec-Labrador using a global isostatic adjustment model combined with remote sensing mapping and new cosmogenic ages of deglacial landforms. Our reconstruction provides a 2500 years-window (10.1 – 7.7 cal. ka BP) on the retreat pattern extending from the Torngat Mountains to the Shefferville area and to the western Ungava Bay region. Using 100 years isochrones as ice margins, the reconstruction reproduces major lake levels and outlets that were documented in the field while respecting deglacial (continental) chronologies. Our findings suggest that 50% of the meltwater released (0.513 Sv; 10 days drainage) is related to the drainage of glacial Lake Naskaupi, which occurred between 8.3 and 8.2 cal. ka BP. While Ungava lakes were probably too small to trigger a major climatic event, the new chronological constraints on Lake Naskaupi suggest the drainage contributed to the meltwater forcing of the 8.2 ka Event.

Our methodology based on a multi-proxy model of deglaciation thus shows a strong potential to accurately scale the magnitude of the drainages of Ungava lakes during the early Holocene, an important step in assessing the impact of smaller freshwater forcing on the ocean and climate. This approach should be applied to other large proglacial lakes that formed during the last deglaciation, which would benefit from a re-evaluation of their volume and drainage chronology using reconstructions that incorporate the latest global isostatic adjustment models, absolute ages and field-based constraints.

Abstract

Quaternary environmental studies are essential to understand the speed and scale of modern day climatic and environmental change. During the late Quaternary significant environmental and relative sea-level variations have contributed to shaping present day coastal areas. This is particularly evident along formerly glaciated continental margins. A dynamic ice sheet extended off the western continental shelf of Ireland during the last glacial maximum (LGM), and its retreat left a strong signature in the form of submarine and terrestrial landforms. The period following the LGM was likely characterized by rapid and abrupt changes in relative sea-level along the western Irish coastline due to the former ice sheet presence. However, knowledge of the effects of these drastic changes along the coast is limited.

This research is a multi-disciplinary investigation into the elements that have shaped Galway Bay since the LGM. Seismic and multibeam data, sedimentological, micropaleontological, geochemical analysis and 17 radiocarbon dates of sediment cores from the bay provide the first post-LGM sea level and environmental reconstructions for the region. Analysis on the microfossil content and geochemistry of the cores in the bay show a continuous progression from shallow water, intertidal deposits to estuarine and open marine conditions. There is evidence of sea-level 70m lower than present day following deglaciation, submerged coastlines and paleo-fluvial channels. Throughout the post-glacial period to the present, the evidence from Galway Bay suggests constant transgression, with the seismic, geochemical, microfossil and sedimentary data all supporting sea-level rise across the bay. The data also show prolonged sea-level slow stand and that the bay was affected by global events such as meltwater pulses 1A and 1C, but not by others. The geochemical signal in the cores seem to provide a good record of local changes in environmental conditions, such as rainfall, changes in vegetation, and land use. The mapping of seafloor landforms coupled with hydrodynamic modelling reveals that the bay is lastly shaped by the strong tidal currents and storm events, which currently characterize the western Irish coastline. The overall picture of palaeoenvironmental change since the LGM will be compared with global signals to identify the specific drivers of change in this region.

Environmental controls on the carbon and oxygen stable isotope ratios of modern land snail shells in Australia.

Georgina Falster¹, Jonathan Tyler¹, Tobias Kluge², Florian Dux³, Russell Drysdale³, John Tibby¹, Allan Chivas⁴

¹The University of Adelaide, Adelaide, Australia. ²Heidelberg University, Heidelberg, Germany. ³The University of Melbourne, Melbourne, Australia. ⁴The University of Wollongong, Wollongong, Australia

Abstract

Land snails are present across Australia, and their shells have been found in sedimentary accumulations, including important archaeological and palaeontological sites. The carbon and oxygen stable isotope compositions ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) of these shells should preserve information about past climates, but to date have not been used in Australian palaeoclimate studies. The relationship between the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of modern land snail shells in Australia and contemporary climate variables had also never been tested.

We measured the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of land snail shells collected from Australian sites covering a wide climatic gradient. We compared these measurements with local climate variables, derived from gridded observational data. The strongest relationship observed is a negative correlation between shell $\delta^{13}\text{C}$ and annual precipitation amount. Where a collection site yielded more than one species, shells from different species preserve distinct $\delta^{13}\text{C}$. Shell $\delta^{18}\text{O}$ is also negatively correlated with precipitation amount, and the species offset is less pronounced.

We suggest that the negative correlation of shell $\delta^{13}\text{C}$ and precipitation reflects the vegetation $\delta^{13}\text{C}$ response to moisture availability. Absolute values indicate that in this case, the response manifests through changes in stomatal conductance of C_3 plants in response to moisture stress, rather than changes in vegetation composition (plants using the C_3 versus C_4 metabolic pathway). We test this supposition using a snail flux balance model in conjunction with the predicted distribution of vegetation $\delta^{13}\text{C}$ across Australia.

The negative correlation of shell $\delta^{18}\text{O}$ with precipitation follows a similar trend to the distribution of oxygen isotopes in precipitation in Australia, which in turn is largely driven by precipitation amount. Snail shell $\delta^{18}\text{O}$ is therefore probably a reflection of the effect of precipitation amount on the $\delta^{18}\text{O}$ of rainwater. To extricate source water (snail body fluid) $\delta^{18}\text{O}$ from the influence temperature in the shell $\delta^{18}\text{O}$, we measured the clumped isotope composition (ratio of $^{13}\text{C}^{18}\text{O}^{16}\text{O}$ to $^{12}\text{C}^{16}\text{O}^{16}\text{O}$; Δ_{47}) of a subset of shells. We used shell Δ_{47} to calculate the temperature at the time of snail shell growth. In controlled tests, snail shell Δ_{47} has been demonstrated to accurately record temperature. However, shell Δ_{47} values from these snails in their natural habitats do not have a straightforward relationship with annual or seasonal average temperatures. Snail shell Δ_{47} is therefore especially useful as a means to estimate snail body fluid $\delta^{18}\text{O}$.

Snail shells hence track precipitation amount via two mechanisms i.e. its influence on $\delta^{18}\text{O}$ of precipitation (seasonal precipitation amount), and its effect on vegetation $\delta^{13}\text{C}$ (annual precipitation amount). Our results indicate that the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of ancient land snail shells may provide insight into past rainfall in Australia, particularly if the dietary preferences and active season of the snails are known.

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²University of Chinese Academy of Sciences, Beijing, China. ³Institute of Earth Science, Chinese Academy of Sciences, Beijing, China. ⁴Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ⁵Laboratory for Marine Mineral Resources, Qingdao National Laboratory for Marine Science and Technology, Qingdao, China. ⁶Qingdao Institute of Marine Geology, Qingdao, China

Abstract

Precise measurements of U-Th concentration and isotope ratios in seawater play an important role in ocean study in both space and time, e.g., in dating corals and other marine carbonates in the Quaternary period. Here, we have investigated the U-Th concentrations and isotope ratios in East China Sea and Okinawa Trough. The precision and accuracy of U and Th is determined by NBS-CRM-112A and IRMM Th-035. IRMM Th-035 was measured for five times, giving an average $^{232}\text{Th}/^{230}\text{Th}_{\text{atom}}$ ratio of 87317 ± 1627 (2σ , $n = 5$). Nine surface seawater samples were collected from East China Sea, and five surface samples were collected from Okinawa Trough. Results showed that the U contents (salinity = 35‰) of surface seawater were from 3.122 to 3.401 ppb, with an average value of 3.211 ± 0.137 ppb (2σ , $n = 14$), and $\delta^{234}\text{U}$ was from 145.2 to 150.0 ‰, with a mean value of 147.1 ± 2.8 ‰ (2σ , $n = 14$). ^{232}Th concentrations were with a marked difference from East China Sea and Okinawa Trough, giving value from 0.171 to 1.155 pg/kg with an average of 0.516 ± 0.732 (2σ , $n = 9$) pg/kg for East China Sea, and from 0.306 to 0.388 pg/kg with a mean value of 0.335 ± 0.073 pg/kg (2σ , $n = 4$) for Okinawa Trough. The purpose of this study was providing accurate U-Th data for related environmental change research in the East China Sea and adjacent sea areas.

Stable and clumped isotope composition of land snail shells and their climatic implications

Jibao Dong¹, John Eiler², Zhisheng An¹, Xiangzhong Li¹, Weiguo Liu¹

¹State Key Laboratory of Loess and Quaternary Geology, Institute of Earth and Environment, CAS, Xi'an, China.

²California Institute of Technology, Pasadena, USA

Abstract

The widely-distributed land snails are excellent material for reconstructing terrestrial climatic changes using the carbonate clumped isotope (Δ_{47}). Here we studied the Δ_{47} of modern snail shells cultured under controlled temperatures or collected in the field and the fossils sampled on the Chinese Loess Plateau (CLP). Three species were raised at controlled temperatures and the *Achatina fulica* was sampled monthly for Δ_{47} analysis. On the whole, the Δ_{47} value of snail shells decreases with increased cultivation temperature. However, the Δ_{47} values decreased when snails grown larger and almost all of the Δ_{47} values fall below the calibration line of Bonifacie et al (2017) and it is $\sim 0.016\text{‰}$ smaller on average.

We further analyzed the snail shells collected in the field from two strikingly different climatic regions-Monsoonal and Mediterranean climatic areas. The Δ_{47} temperature (T_{47}) are consistent with the rainy season temperature when the snails are active, irrespective what climatic conditions they live in. This suggests that snail shells record their growing season temperature. Moreover, our results show that the mean T_{47} of modern snails is $\sim 12^\circ\text{C}$ higher than the glacial fossils and the average $\delta^{13}\text{C}_{\text{shell}}$ is 2.7‰ more negative. We argue that the $\delta^{13}\text{C}_{\text{shell}}$ couldn't record the C_3/C_4 changes on the CLP and it may mainly reflect the condition of aridity with negative value reflecting reduced aridity. Additionally, the mean $\delta^{18}\text{O}_{\text{shell}}$ and the reconstructed body water $\delta^{18}\text{O}$ of modern snail are 2.8‰ and 5.3‰ more positive, respectively, and the body water $\delta^{18}\text{O}$ is also positive than the precipitation $\delta^{18}\text{O}$ during the growing season. This may be related to high degree of evaporation enrichment of environmental water $\delta^{18}\text{O}$ in the body/ingested by modern snails under warm condition. Thus, it is difficult to use the $\delta^{18}\text{O}_{\text{shell}}$ to directly reconstruct precipitation $\delta^{18}\text{O}$ on the CLP.

$\delta^{18}\text{O}$ of modern land snail from sub-humid to arid climate zones in China and their relation to environment

Xiulan Zong^{1,2}, Jibao Dong¹, Yougui Song¹

¹State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²University of Chinese Academy of Sciences, Beijing, China

Abstract

Many studies have investigated the stable isotopes of land snail shells from diverse geographical and climatic units. Generally, shell $\delta^{18}\text{O}$ is related to the isotopic composition of environmental water ingested by snails (e.g. precipitations), relative humidity (e.g. Yapp, 1979; Balakrishnan and Yapp, 2004) and the temperature of carbonate precipitation. Here, we studied modern land snails from 15 localities, from Dalian (121.62°E, 38.93°N) on the east coast to Jiayuguan (98.30°E, 39.77°N) in the west inland in China. The longitudinal span exceeds 2000 km, covering from sub-humid to arid climate zones. Our results show that mean $\delta^{18}\text{O}$ from the western localities are more positive than those from the east, in another words, the mean $\delta^{18}\text{O}$ values decreased from arid (-0.9‰) to sub-humid conditions (-4‰). Noticeably, the amplitude of $\delta^{18}\text{O}$ is up to ~10‰ in Xi'an city. This allows us to speculate that temperature change alone cannot induce such large variations in $\delta^{18}\text{O}$, because this would require extremely large changes in ambient temperature. Furthermore, the calculated $\delta^{18}\text{O}$ of snail body water are more positive than the local precipitation $\delta^{18}\text{O}$ values during snail growing season. Thus, contrary to previous studies (e.g. Lécalle, 1985), we conclude that shell $\delta^{18}\text{O}$ values may not reflect the $\delta^{18}\text{O}$ of meteoric waters, and we infer that it may reflect the evaporation enrichment of environmental water/snail body water and the relevant relative humidity.

Quantitative evaluation for driving factors of carbonate oxygen isotope composition in lake sediments

Guoliang Lei¹, Hucai Zhang², Yun Zhu¹

¹Key Laboratory for Subtropical Mountain Ecology (Ministry of Science and Technology and Fujian Province Funded), Fujian Normal University, Fuzhou, China. ²Laboratory of Plateau Lake Ecology and Global Change, College of Tourism & Geography Science, Yunnan Normal University, Kunming, China

Abstract

The isotope composition of authigenic carbonates is one of the commonly used paleoclimate proxies for lake sediments. However, the $\delta^{18}\text{O}$ variations in carbonate sediments are often characterized by high uncertainty in the paleoenvironmental interpretation due to the multiplicity of material sources and complication of sedimentation processes. Here we selected the Xiaohushan section (XHS), which formed during the Late Pleistocene by AMS ^{14}C ages, from the Gaxun Nur paleolake to quantitatively evaluate the processes driving the change of carbonate $\delta^{18}\text{O}$. XHS section is located in Ejina Basin with an altitude of 908 m a.s.l.. The meteorological data (1951-1980) from Guaizihu meteorological station shows that the average annual rainfall is about 37.9 mm, with an annual temperature of about 8.4°C, with an annual extreme maximum rainfall of about 103.0 mm and a minimum rainfall of about 7.0 mm. Roughly 60% ~ 70% of the annual precipitation occurs between July and September, with potential evaporation of around 3769.6 mm, and relative humidity of about 35%.

The sediments of XHS section were rich in authigenic carbonates. The result of XRD analysis showed that calcite, dolomite and aragonite in sediment were mainly carbonate minerals. On the layer from 590cm to 500cm, calcite disappeared with relative content increasing of dolomite. The $\delta^{18}\text{O}$ of carbonate showed abnormal increasing with positive amplitude of about 6.1‰, which can't be interpreted by environmental processes. Here we try to quantitatively evaluate the processes driving $\delta^{18}\text{O}$ change of XHS section. The mineral typology, grain size, TOC and carbon isotopes of organic matters were also analysed. Our results showed that both the concentrating effect due to lake water evaporation and phase change of carbonate minerals could lead to a change in carbonate $\delta^{18}\text{O}$, the later of which can cause the isotopic fractionation and serve as one significant factor in changing the carbonate $\delta^{18}\text{O}$ values. In the XHS samples, the $\delta^{18}\text{O}$ signal in the dolomite was enriched by 7.65‰~11.02‰ than that in the calcite. Therefore, it was estimated that the isotope fractionation could account for 70% of the variance in the $\delta^{18}\text{O}$ values between both minerals. All these suggest that there exist isotopic fractionation in the $\delta^{18}\text{O}$ values among different forms of carbonate minerals and this phenomenon should be taken into account in the sediment-based paleoclimate reconstruction.

P-2503

A high-resolution climate proxy record of the terminal Pleistocene to early Holocene from lacustrine carbonates, southern Ontario, Canada.

Jacob Walker¹, Fred Longstaffe¹, Paul Karrow²

¹University of Western Ontario, London, Canada. ²University of Waterloo, Waterloo, Canada

Abstract

Understanding how environments responded to climate warming from the terminal Pleistocene to Holocene is crucial for improving our ability to predict the impacts of future climate change. While climate changes throughout this period have been well characterized on a global scale, there is still a lack of high-resolution climate records, particularly those that identify how climate has changed on a local scale. High-resolution climate records are especially needed in southern Ontario, which hosts the southern Great Lakes. Identifying the climatic variations associated with the terminal Pleistocene-Holocene transition in this region should offer critical insights into how the Great Lakes responded to past change. Such information is crucial for assessing how the Great Lakes will respond to ongoing, anthropogenically induced warming. Proxy records obtained from the lacustrine sediments of the Great Lakes have at best a century-scale resolution due to low sedimentation rates. The water column conditions recorded by the proxies also have been averaged over the very large watersheds in which the Great Lakes are situated. To overcome these limitations, we have generated a high-resolution (decadal-scale) record of environmental change using oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotope compositions of endogenic carbonate (marl) and coeval biogenic carbonate (shelly fauna) from an ancient kettle lake deposit at St. Agatha, Ontario, Canada. We have generated a well-constrained age-depth model using shelly fauna and organic macrofossils for the thick St. Agatha marl deposits (~4m; ~0.75mm/yr). Our records capture the end of the Bølling-Allerød, the Intra Allerød Cold Period (IACP), and the Younger Dryas cold period (YD). We observed a synchronous decrease of ~4‰ in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ of both marl and coexisting shelly fauna during the end of the Bølling-Allerød interstadial with the most dramatic decrease in isotopic compositions occurring in the IACP. The $\delta^{18}\text{O}_{\text{marl}}$ increased by ~2.5‰ directly following the YD, suggesting that this time period was characterized by increasing warming over a relatively short time period. Our results also show that southwestern Ontario did not experience noticeable Pre-Boreal Oscillation (PBO) cooling before the start of the Holocene, contrary to what is reported in the literature for larger spatial scales. Our data yet again demonstrate that climate anomalies pertinent to global scale investigations are not always an accurate representation of environmental change at the local scale. Our future work will focus on multiply-substituted clumped isotopes (Δ_{47}) of the marl and biogenic carbonate. Such data will help us to better distinguish between hydrologic (net flux) and temperature effects on endogenic and biogenic carbonate $\delta^{18}\text{O}$ at St. Agatha, and thus further quantify climate change over this critical period of time (~13,500 to 8200 cal BP).

Ugandan crater lakes, past and present: Identifying drivers of hydroclimatic change using isotope mass balance modelling

Laura Hunt^{1,2}, Keely Mills², Matthew Jones¹, David Ryves³, Mark Cuthbert⁴, Immaculate Ssemmanda⁵

¹School of Geography, University of Nottingham, Nottingham, United Kingdom. ²British Geological Survey, Keyworth, United Kingdom. ³School of Geography and Environment, Loughborough University, Loughborough, United Kingdom. ⁴School of Earth and Ocean Sciences, Cardiff University, Cardiff, United Kingdom. ⁵Department of Geology, Makerere University, Kampala, Uganda

Abstract

Water resources play an important role in providing domestic supplies for remote communities in western Uganda, as well as sustaining local agriculture, aquaculture, and tourism. Current and projected climate change and population growth in the region is putting water bodies under unprecedented pressure. Through reconstructing the response of lakes to historic climate variability and human impacts, we can further understand the potential impact of future changes on lake water balance and therefore on water availability.

Uganda has over 80 crater lakes, associated with the western branch of the East African Rift System, that are a natural laboratory for investigating the response of tropical lacustrine environments to climate and human driven change. The lack of long-term environmental monitoring in the region requires the use of proxies recorded in lake sediments to infer past lake conditions. Previous studies of the crater lakes have utilised multi-proxy approaches including diatoms, pollen, charcoal, and pigments to reconstruct a history of environmental change in the lakes extending back over 2,000 years.

While some environmental parameters related to water quality are relatively well constrained for the Ugandan crater lakes, past lake water balance and local hydroclimatic conditions, i.e. water quantity, remain poorly understood. This project aims to interpret records of lake carbonate $\delta^{18}\text{O}$ and quantitatively infer changes in water flux over time, by developing isotope mass balance models for the crater lake systems.

Here we test this approach with the previously published record from Lake Kasenda (Ryves et al., 2011). Through the last 1,300 years the $\delta^{18}\text{O}$ values in the Kasenda sediments are relatively positive, but a number of large negative isotope excursions are also seen in the isotope record. These could be the result of a number of interacting drivers including flooding, intense precipitation, and/or influx of groundwater into the system. By conducting sensitivity tests on an isotope mass balance model based on the present day Kasenda system, we are able to identify the most likely driver(s) of water balance change at Lake Kasenda, and better interpret these distinct negative isotopic excursions.

When compared to other palaeolimnological work from a number of other crater lakes in the region it appears that Lake Kasenda experienced relatively persistent freshwater conditions during regionally climatically arid phases (e.g. the late 18th Century drought); it is suggested that this could be a result of groundwater connectivity. Furthering our understanding of the possible 'buffering' of the impacts of hydroclimatic change at Lake Kasenda by groundwater is of interest for predicting individual lake response to future change. The ability to identify lake systems, and therefore communities and ecosystems, most vulnerable to future change will help inform sustainable management of these water resources.

Abstract

Climate change and water availability is a major concern in subtropical Asia and Africa, with summer monsoon precipitation being one of the main sources of precipitation. Yet, summer monsoon rainfall has been found to be strongly tied to large volcanic eruptions through asymmetric forcing (Oman et al. 2006) caused by the stratospheric injection of sulfate aerosols (Figure 1). Here we use polar ice cores to identify the locations, magnitudes and timing of large volcanic eruptions in the past 2,500 years. We further identify the eruptions' imprint on hydroclimate variability in the monsoon regions that are now home to more than 60% of Earth's population. More specifically, we integrated written and natural archives to show that volcanic eruptions repeatedly suppressed the agriculturally-critical Nile flood. Previous work linking eruptions to Nile flow noted coincidences in timing between Nile "failure" and a handful of eruptions (Eldgjá, 939 CE, Laki, 1783 CE (Iceland), Katmai, 1912 (Alaska)). Using a state-of-the-art ice-core volcanic reconstruction (Sigl et al. 2015) with Nilometer data (the world's longest-known documentary hydrological record; Kondrashov et al. (2005)) we show a persistent suppression of the Nile through time, with modelling used to characterize the underlying mechanism as the radiative and dynamical impacts of eruptions on the Monsoon (Manning et al. 2017). Egypt's monsoon-mediated vulnerability to remote volcanic eruptions is a salient lesson for all monsoon-dependent agricultural regions, presently including many of the world's most populous states.

Figure 1 | Boreal summer precipitation response to Mt. Pinatubo eruption. Ensemble mean difference for 1992 May-September averaged precipitation over land, computed from the output of 60 historical NorESM simulations with and without Mt Pinatubo forcing. Units are in mm/yr. The box (5-55°N, 60-135°E) marks the region Feng et al.(2013) used for defining their warm season Asian precipitation index. The red star marks the location of the Nilometer on Roda Island, Cairo, used to reconstruct monsoon-driven streamflow variability since 622 AD.

Late Pleistocene precipitation changes using stable isotope analysis of a speleothem from the Majuanas Cave System, Cuba

Mercedes Liedtke¹, Andre Viau¹, Matthew Peros², Jesus Pajon³, Julio Valdes⁴

¹University of Ottawa, Ottawa, Canada. ²Bishop's University, Sherbrooke, Canada. ³Cuban Museum of Natural History, Havana, Cuba. ⁴National Research Council of Canada, Ottawa, Canada

Abstract

A stalagmite was collected in the Salón de la Permenencia-01 of the Majaguas Cave, which is a part of the Majaguas-Cantera Cave System in western Cuba. The use of this stalagmite as a natural climate archive is advantageous not only because stalagmites can record continuous episodes of growth that are thousands of years in duration but also because they are easily and reliably dated using U/Th dating methods. With this method, the stalagmite (which is currently active) was dated and shown to have undergone three periods of growth: from 100 ka to 68 ka; from 11 ka to 10 ka; and during the late Holocene to the present. The stable isotopes of oxygen and carbon from this stalagmite show considerable variability during the period from 100 ka to 68 ka and provide information on the factors influencing Caribbean region precipitation and other climatic events during the late Pleistocene. Due to the lack of high-resolution paleoclimatic records from western Cuba, this study will add to our knowledge of past climate variability for Cuba and the Caribbean as a whole for the time periods from 100 ka to 68 ka, the late glacial period, as well as the last few thousands years.

Abstract

The oxygen isotope composition of speleothems is a widely utilised paleoclimate proxy that is responsible for the current state-of-knowledge of past Asian monsoon dynamics, the timing of glacial-interglacial cycles, and the insolation control on inter-tropical convergence zone position, among other climate processes.

Because speleothems are deposited by cave drip water, and this is derived from meteoric precipitation, it is critical to understand the empirical relationship between precipitation and cave drip water $\delta^{18}\text{O}$.

Here, we present the first global analysis, based on data from 148 drip sites, 38 caves, and five continents. Globally, drip water $\delta^{18}\text{O}$ is most similar to the amount-weighted precipitation $\delta^{18}\text{O}$ where mean annual temperature (MAT) is $< 10\text{ }^\circ\text{C}$. For seasonal climates with MAT $> 10\text{ }^\circ\text{C}$ and $< 16\text{ }^\circ\text{C}$, we demonstrate that drip water $\delta^{18}\text{O}$ records the recharge-weighted $\delta^{18}\text{O}$.

Our analysis implies that speleothems (formed in near isotopic equilibrium) are most likely to have $\delta^{18}\text{O}$ that directly reflect meteoric precipitation only in cool climates. In warmer and drier environments, speleothems will have a seasonal bias toward the precipitation $\delta^{18}\text{O}$ of recharge periods and, in some cases, the extent of evaporative fractionation of stored karst water.

Moisture variations since the last deglaciation revealed by the loess sediments over the core area of arid central Asia

Yue Li, Yougui Song

State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China

Abstract

Climatologically, humid east Asia and arid central Asia (ACA) constitute the mid-latitude Asian continent. ACA is located in the hinterland of the Eurasian continent, and the special geographical position far from any ocean brings typical continental temperate climate. The arid environment, sparse vegetation cover and fragile ecosystems make the ACA very sensitive to climate change. Thus, understanding of climate changes in ACA and possible mechanisms on multiple timescales is indispensable for the assessment of present and future climatic dynamics in the region, especially under ongoing global warming.

The water resources are extremely valuable due to scarce precipitation and high evaporation in ACA. As yet it has been well established that the Westerlies play an important role in driving hydrologic climate feature in ACA. However, Holocene moisture evolution in ACA remain controversial possibly due to differences in study sites, disputed implications of paleoclimatic proxies and, in particular, obscure seasonality of precipitation. The eastern sector of ACA receives most of its annual precipitation during summer, and the west does during winter. Here, we investigate moisture variabilities since the last deglaciation in the different sectors of ACA, with moisture proxies from loess sediments, on the multi-millennial time scale. The results show that:

- Summer-dominated precipitation showed a gradual wetting trend since the last deglaciation, while winter-dominated precipitation distinctly increased in the initiation of Holocene and late-Holocene.
- Summer-dominated precipitation is forced by the greenhouse gases (GHG). Increased GHGs lead to the higher humidity over the Eurasian high-latitudes and thus the more water vapors carried by the Westerlies, which yields more precipitations in the water vapor supply-limited eastern sector.
- Changed atmospheric circulations and increased water vapors in sources are responsible for the present picture of winter-dominated precipitation during the last deglaciation. Holocene winter-dominated precipitation are mainly related to the capacity of the Westerlies to transport water vapors, which is controlled by the insolation gradient between mid-and high-latitudes and winter insolation at mid-latitudes.
- Comparison of the stacked Indian monsoon records with the precipitation proxies indicates the Asian monsoon didn't penetrate our study area even if when the monsoon is stronger.

Our study provides more comprehensive information about the precipitation variabilities in the ACA and explores the driving mechanisms of moisture evolution since the last deglaciation. This contribution would facilitate prediction of the future climate in the ACA.

P-2509

Observations and implications of high level spatial variability found in instrumental regional hydroclimate records for subtropical Southeast Queensland, Australia

Heather A Haines, Jon M Olley
Griffith University, Brisbane, Australia

Abstract

Subtropical Australia is a region with a short and sparsely documented hydroclimate history. What is abundantly clear is the strong nature of extreme events in this region as evidenced by recent devastating flood (1974, 2011, 2013) and drought (1939-1945, 1996-2010) events. As such the long-term hydroclimate of this region needs to be better understood so that adaptation and management of future events can be implicated. However, instrumental records only begin in the mid-1800s and much of the data collected prior to 1900 is considered unreliable. Proxy sources to extend these instrumental records are also lacking due to few lake, coral, or caves systems in the region to provide paleoclimate data. Yet there are several forest environments across the subtropics that can be used to develop long-term tree-ring hydroclimate reconstructions. This process has recently been applied in several studies in Southeast Queensland (SEQ) with rainfall and drought reconstructions presented. However, as these are individual site based studies and not networks of tree-ring records it is important to understand the spatial extent which they can be considered representative of.

Here we look at 140 instrumental rainfall stations across SEQ to identify trends in both temporal and spatial variability from 1908-2007. Pearson correlation analysis between each station has categorised them into 80%, 85%, and 90% correlation groupings with annual deviations from the mean developed for each group. Analysis of above and below average rainfall phases for each of the correlated groups indicates that rainfall is not uniform across SEQ and can in fact be categorised into several well correlated instrumental groups. Additional assessment of all instrumental streamflow gauges of longer than 50 years duration within SEQ indicates that the spatial groupings also apply to the river networks as rainfall is the main contributor to regional hydroclimate inputs. Strong connections between the regional hydroclimate records and the El Niño Southern Oscillation as well as the Interdecadal Pacific Oscillation are observed.

Assessment of the currently available tree-ring reconstructions from SEQ to the hydroclimate groups developed indicates that single site tree-ring records are best considered representative of the spatial groups they are contained within. It is clear that they cannot represent all of SEQ let alone larger areas which are lacking in both rainfall and streamflow data. The implications this has on long-term hydroclimate understanding for this and other similar regions is discussed.

P-2510

A Two-Core chironomid-based Mid- to Late Holocene ecosystem reconstruction of the Tibetan lake Taro Co

Andreas Laug¹, Falko Turner¹, André Pannes¹, Junbo Wang², Stefan Engels³, Torsten Haberzettl^{4,5}, Mauro Aliverini⁶, Marieke Ahlborn⁴, Jianting Ju², Antje Schwalb¹

¹TU Braunschweig, Institute of Geosystems and Bioindication, Braunschweig, Germany. ²Chinese Academy of Sciences, Institute of Tibetan Plateau Research (ITP), Beijing, China. ³Birkbeck University of London, Department of Geography, London, United Kingdom. ⁴Friedrich-Schiller-University Jena, Institute of Geography, Jena, Germany. ⁵University of Greifswald, Institute of Geography and Geology, Greifswald, Germany. ⁶Friedrich-Schiller-University Jena, Institute for Geosciences, Jena, Germany

Abstract

The Tibetan Plateau stores Earth's third largest amount of ice and supplies water for a major part of Asia, home to almost two thirds of the world's population. To better predict water availability under ongoing and future global warming, lake level reconstructions for periods with different past climatic conditions are important. The Tibetan lake Taro Co (4,567 m a.s.l., maximum depth 132 m) is a large (483.2 km²) endorheic freshwater lake located in the western part of the Central Tibetan Plateau (31°03'–31°13' N, 83°55'–84°20' E).

Here we present chironomid based reconstructions of changes in lake ecosystem conditions using two sediment cores from the central basin (TOC 11-04, 68 m water depth) and from a prodelta close to the southern shoreline (TRGC 14-06, 29.4 m water depth), respectively. The two-core setting depends less on local signals like chironomid community thresholds at certain water depths or head capsule transportation and therefore presents the unique opportunity to separate local from lake-wide ecosystem signals.

Preliminary results for both cores show very low chironomid concentrations with less than ten head capsules per gram dry weight in the oldest part of the cores (7350 and 10500 cal. yr BP, respectively). Chironomid concentration increases rapidly at about 5200 cal. yr BP in the central core, whereas in core TRGC 14-06 they remained low until a hiatus in sedimentation between about 10500 and 5000 cal. yr BP. In both cores the oldest zone differs greatly from the rest of the core and shows the lowest percentages of the otherwise dominating *Micropsectra radialis*-type. Further changes in the chironomid abundances and assemblages are observed at about 2400 cal. yr BP in both cores and at about 3600 cal. yr BP as well as 250 cal. yr BP in core TRGC 14-06. Both cores show similar concentrations of chironomid head capsules except for the time window between 5000 and 3600 cal. yr BP, when concentrations are two to four times higher in core TRGC 14-06.

This phase as well as the zone boundary connected to the concentration decline at approximately 3600 cal. yr BP most likely show a local signal potentially connected to changes in the inflow of the closest tributary river and therefore sedimentation of head capsules. The second change in the chironomid assemblages only observed in core TRGC 14-06 at about 250 cal. yr BP may have resulted from anthropogenic influence that is better visible in this core because of the proximity to the shore. Contrastingly, the other two boundaries at 5200 and 2400 cal. yr BP most likely represent lake-wide ecosystem changes and match changes in the intensity of Monsoon- and Westerlies visible in multiple archives of Central Asia.

P-2511

Foraminiferal assemblages and Stable Isotope analysis as indicators of Past Climate Change in Bays and Estuaries

Mark McKay

Texas A&M University, Corpus Christi, USA

Abstract

Both Nueces and Baffin Bay are secondary bays located in Southeastern Texas. Nueces Bay is very anthropogenically disturbed due to deposition of dredging spoil from Corpus Christi Bay and also diversions (from the Nueces River) of fresh water in flows. Baffin Bay is also disturbed, but to a lesser extent. Salt water inflows come through Corpus Christi Bay which has a direct connection to the Gulf of Mexico. Baffin Bay also has fresh water inflow which are minimal as only ephemeral creeks provide fresh water inflows. There is no direct connection to the Gulf of Mexico as this bay exists behind a barrier island and only has access to a legume system (Laguna Madre), and is there for hypersaline. Both bays provide a stable environment for uncovering the effects of anthropogenic climatological and ecological influence in the region.

Physical/Chemical measurements, along with microfossil assemblage and oxygen and carbon isotope have helped provide a better understanding of the climatic history of the region. These and other measurements (dendrochronology, etc.) help elicit a greater understanding of regional airmass and climatic teleconnections.

Late-Pleistocene climate and vegetation of north-central India: Clues from sedimentology, molecular distribution of n-alkane and stable isotopes

Deepak Jha¹, Koushik Saha², Prasanta Sanyal¹, Manoj Jaiswal¹

¹Department of Earth Sciences, Indian Institute of Science Education and research Kolkata, Mohanpur, India.

²Department of Geology, North Bengal University, West Bengal, India

Abstract

Indian Summer Monsoon (ISM), an important component of the global climatic system, played a vital role in shaping the food budget of the agro-based economy like India. High-resolution proxy based climatic records of ISM is limited. Moreover, the time period Late-Pleistocene is characterized by the dramatic oscillation of climatic condition which severely disturbed the Pleistocene biotic evolution. Hence, it is important to improve our understanding of Late-Pleistocene climate variability and its response to vegetational shifts. However, paleoclimatic reconstruction from fluvial sediments of Yamuna river dominated, Yamuna-Betwa interfluvium is rather limited (Sinha et al., 2005). Hence, to improve our understanding of paleoclimate variability from the central part of the Indo-Gangetic plain, we provide a continuous reconstructed multi-proxy record of precipitation and terrestrial vegetation changes during the last ~25 ka. The chronology of the sedimentary core (8 m) is established using Optically Stimulated Luminescence (OSL) dating of quartz grains. For the first time, we have coupled micro-morphological features of paleosols and soil carbonate (SC), molecular distribution pattern of n-alkanes with stable isotope study such as $\delta^{13}\text{C}_{\text{OM}}$ of bulk soil organic matter, $\delta^{18}\text{O}_{\text{SC}}$ and $\delta^{13}\text{C}_{\text{SC}}$ of SC and $\delta\text{D}_{n\text{-alkane}}$ and $\delta^{13}\text{C}_{n\text{-alkane}}$ of n-alkanes from the paleosols of a sedimentary core of Betwa river bank to understand the climate-vegetation relationship.

The stable isotope values suggest that low rainfall condition with a higher abundance of C₄ plants at ~20 to 23 ka which corresponds to Large Glacial Maximum (LGM). Micro-morphological study of paleosol bearing horizon contain b-fabric, clay coating, pedorelicts suggest arid condition prevailed before the Holocene (~10 ka). The early Holocene intensification at ~10 ka is clearly observed in $\delta^{18}\text{O}_{\text{SC}}$ and $\delta^{13}\text{C}_{\text{SC}}$ values and $\delta\text{D}_{n\text{-alkane}}$ and $\delta^{13}\text{C}_{n\text{-alkane}}$ value which was supported by the presence of high terrestrial organic matter input. The highest increase in C₃ plants observed during last ~1.4 ka. However, the overall weak relationship of rainfall amount and pCO₂ concentration with vegetational shift suggests an important role of other factors for such as substrate control and plant functional type.

Linking long-term CO₂ induced leaf stomatal conductance decrease to vegetation greening through g_{smax} - NDVI comparison in Scandinavia

Hugo de Boer¹, Friederik Wagner-Cremer², Marjolein Vogels²

¹Department of Environmental Sciences, Utrecht University, Utrecht, Netherlands. ²Palaeoecology, Department of Physical Geography, Utrecht University, Utrecht, Netherlands

Abstract

The inherent CO₂ regulated link between climate and vegetation affects the hydrological cycle. Reduced water loss through leaf stomata under current CO₂ increases has the potential to induce a wide range of changes in the global hydrological cycle such as H₂O fluxes, run-off rates, cloud formation and precipitation. Especially in the northern latitudes, photosynthetically active, and thus transpiring leaf area is maintained for an increasingly longer period throughout the year due to the lengthening of the growing season under ongoing warming.

The increasing CO₂ availability moreover allows plants to optimize carbon uptake versus water loss through adjustment of their leaf stomatal conductance. The resulting increases in water use efficiency, defined as the ratio of carbon uptake to actual water loss, regulates the canopy transpiration and therewith the evapotranspiration of the vegetated areas.

On plant leaf level, the structural maximum stomatal conductance (g_{smax}) adaptation can be quantified by microscopic analysis of the epidermal cell morphology in modern and fossil plant leaf material, providing an important tool to determine the long-term trends in plant hydrological properties under anthropogenic CO₂ increase.

The g_{smax} records produced for the past 150 years spanning the anthropogenic CO₂ increase reveal a substantial decrease in g_{smax} . The hydrological properties of plant foliage are thus indicating a downregulation of the vegetation transpiration with the potential to act on the hydrological cycle. This pattern however is not clearly visible in the instrumental records and increasing leaf area through CO₂ fertilization has been offered as a buffering mechanism.

We here test this hypothesis by directly comparing g_{smax} records from Scandinavia with satellite imagery based NDVI data of the regions covered by the proxy data. Our results show that g_{smax} rate of change is by far exceeding NDVI increments leaving a large part of the vegetation induced changes unexplained.

P-2514

Diagnosing the controls of Holocene drought in North America: P, E, or surface water- and energy-balance feedback?

Patrick Bartlein

University of Oregon, Eugene, USA

Abstract

The Holocene paleoenvironmental record of the mid-continent of North America clearly shows the impact of the mid-Holocene (8.2 to 4.0 ka) “gigadrought” that killed trees, drained lakes, and otherwise affected water resources in way that, if repeated today, would have devastating effects. Although well-documented for over 40 years now through Tom Webb’s mapping of the dynamics of the Prairie-forest border, the specific climatic mechanisms responsible for the drought are still not understood, and subsequent work by Webb’s students and colleagues has shown that while the gigadrought generally had an abrupt onset and ending, some aspects of the paleohydrological record were time-transgressive or diachronous, suggesting multiple factors may have been acting in concert.

Drought has multiple controls. Moisture availability (as indexed by moisture-flux divergence or precipitable water vapor) and precipitation-producing (or suppressing) mechanisms (generated by the mid-tropospheric atmospheric circulation), together govern the precipitation component of P - E. The evaporation component also has multiple controls: supply, related to soil-moisture availability and surface-water storage, and demand, as indexed by vapor-pressure deficit and the difference between actual and potential evapotranspiration, are each related to atmospheric and surface conditions. There is also the possibility of feedback through the surface water and energy balances, as expressed by Bouchet’s (1963) “complimentary relationship”: as the surface dries, net radiation is partitioned into decreasing latent and increasing sensible heating, which steepens the vapor-pressure gradient which further dries the surface. All of these controls operate simultaneously.

One approach toward diagnosing the specific controls of (paleo) hydroclimatic variation is to exploit the thousands of individual cases provided by transient (e.g. TraCE-21k), and multi-model (PMIP) simulations using the standard tools of modern climate diagnostics (as applied to reanalysis data sets) such as the construction of composite anomalies, as well as area-average time series of long-term mean differences.

Month-length adjusted TraCE data (supplemented by offline simulations of surface water-balance variables using SPLASH v1.0), reveal the changing nature of drought throughout the Holocene. In the early Holocene, simulated precipitation was greater than present, supported by atmospheric circulation and moisture flux into the interior of the continent, but evaporation, in particular evaporative demand, was much greater than present. The trends in net radiation (driven by insolation) and latent and sensible heating are suggestive of significant reinforcement of evaporation through feedback, despite the greater-than-present precipitation. The middle Holocene was characterized by little change in precipitation, and a general reduction in evaporative demand, likely related to the attenuation of the summer insolation anomaly, and the late Holocene was characterized by a general relaxation of all of the components of the surface water- and energy-balance toward the present.

Late Pliocene-Earliest Pleistocene eolian sequence on the NE margin of the Tibetan Plateau and its record on Asian monsoon evolution

Xiaomin Fang^{1,2}, Jinbo Zan^{1,2}, Weilin Zhang^{1,2,2}, Maodu Yan^{1,2}

¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Tibetan Plateau Earth Sciences & CAS Key Laboratory of Continental Collision and Plateau Uplift, Beijing, China

Abstract

Eolian loess and red clay sediments from the Chinese Loess Plateau (CLP) contain a wealth of information about variations in the Asian monsoon and the aridification history of the Asian interior. To date, however, late Pliocene-early Pleistocene loess-red clay deposits have only rarely been reported from the western CLP, which significantly hinders our understanding of the distribution of eolian deposits and the palaeoenvironmental evolution of the region. Here, we present magnetostratigraphic, lithologic and rock magnetic results for two recently-drilled boreholes from the central Linxia Basin. Our results demonstrate that the loess-red clay sequences from the lower boreholes have an age range of ~3.7–2.4 Ma, and they represent the first direct evidence of upper Pliocene-lower Pleistocene eolian deposition in the western CLP. This sequence underlies basin-widely distributive late Quaternary loess sequences. The major trends of the magnetic susceptibility and grain size records from the lower parts of the two boreholes are highly correlative with those of contemporaneous loess-red clay sequences in the eastern CLP, suggesting that these parameters can be used both for stratigraphic and palaeoclimatic correlation and as powerful tools for identifying late Pliocene-early Pleistocene aeolian deposits in the western CLP. Spatially, a clear decrease and increase in magnetic susceptibility and grain size is observed between the central and western CLP, indicating that the modern spatial pattern of the East Asian monsoon regime in the western CLP has been maintained since at least the late Pliocene.

A review of Marine Isotope Stage 4 mountain glacier moraine chronologies

Alice Doughty¹, Michael Kaplan²

¹Bates College, Lewiston, USA. ²Lamont-Doherty Earth Observatory, Columbia University, Palisades, USA

Abstract

Mountain glaciers waxed and waned over the last glacial cycle in response to changes in climate. While most glacial geologists have focused on reconstructing the paleoclimate conditions for the Last Glacial Maximum (LGM; ~21,000 years ago; Marine Isotope Stage (MIS) 2), a few have unveiled MIS 4 (~60-70,000 years ago) as a time when mountain glaciers were close to or larger than their MIS 2 extents. Moraines that predate the LGM are relatively rare due to preservation issues but a growing number of publications are finding and dating MIS 4 moraines. This presentation is a review of all published MIS 4 moraine chronologies, their site locations, and possible mechanisms for explaining extensive mountain glaciers during MIS 4.

^{10}Be and ^{26}Al exposure history of the highest mountains in Wales: evidence from Snowdon and the Glyders

Philip Hughes¹, Neil Glasser², David Fink³

¹The University of Manchester, Manchester, United Kingdom. ²Aberystwyth University, Aberystwyth, United Kingdom. ³Australian Nuclear Science and Technology Organisation (ANSTO), Menai, Australia

Abstract

Cosmogenic ^{10}Be and ^{26}Al exposure ages from samples collected from the mountains of Glyders (1001 m) and from Snowdon (1085 m) in Wales provide new insights into the glacial history of the highest mountains in the British Isles outside of Scotland. Sample elevations range from 598 to 1013 m and taken from centimetre-thick quartz veins on bedrock and also one boulder. The summits of the Glyders are characterised by intensely modified frost-shattered surfaces and have long been recognised as exemplars of mountain summit periglacial activity in the British Isles. However, numerous glacially-transported boulders on the highest ground indicate that ice overran the summits. Bedrock samples at c. 960 m yielded ^{10}Be exposure ages of 72 ka and 153 ka. In addition, a glacially-transported boulder at 985 m gave a ^{10}Be age of 57 ka. This boulder sample is important because it negates issues of inheritance that are possible with bedrock samples and it provides the closest estimate of the timing of ice thinning and the true exposure age of the Glyders summits. All ^{26}Al ages were consistent indicating non-complex histories. These results clearly confirm the Glyder summits were overtopped by the Welsh Ice Cap during marine isotope stage (MIS) 4, when ice in this area was thicker than at the global last glacial maximum (LGM) in MIS 2. The summits were revealed as ice thinned during the transition from MIS 4 to 3. Both the geomorphological evidence and our new cosmogenic ages support recent ice cap modelling predictions that the summits then stood as nunataks above the LGM ice sheet surface in MIS 2. The oldest ^{10}Be (and ^{26}Al) age of ~150 ka from the frost-shattered summit tor displays significant nuclide inheritance and previous work has demonstrated evidence of gibbsite in the summit soils. The wide range in ^{10}Be apparent exposure ages and the evidence of glacially-transported boulders on intensely frost-shattered bedrock suggests erosion of the Glyder summit surfaces largely proceeded by plucking/quarrying rather than abrasion. This would have occurred under cold-based conditions with ice flow dominated by internal deformation rather than sliding. In contrast, at altitudes below 900 m ice-scoured rock surfaces on both the Glyders and neighbouring Snowdon yield exposure ages consistent with deglaciation after the global LGM in MIS 2. Based on these ages and similar results from other summits in North Wales the Welsh Ice Cap rapidly thinned after c. 20 ka leading to a phase of alpine-style glaciation. However, on Snowdon, arête crests yielded very young apparent ages of ~5 ka. These young ages reflect continual stripping of the arête rock surfaces through the current interglacial.

Glacier-climate reconstructions of a Big MIS 4 in southernmost South America

Carly Peltier^{1,2}, Michael Kaplan², Joerg Schaefer^{1,2}, Rodrigo Soteres³, Esteban Sagredo³, Juan Carlos Aravena⁴

¹Columbia University, New York, USA. ²Lamont-Doherty Earth Observatory, Palisades, USA. ³Pontificia Universidad Católica de Chile, Santiago, Chile. ⁴Universidad de Magallanes, New York, Chile

Abstract

While globally integrated records such as the LR04 stacked benthic $d^{18}O$ record suggest that the global climate was less extreme during MIS 4 than it was during MIS 2, local and regional-scale paleo records have recently put that assumption into question. At the Strait of Magellan in southernmost South America we map and date an MIS 4 moraine that was assumed to be an older advance of the last glacial maximum. We now know that the lobe extended all the way out to the Atlantic during MIS 4, beyond Primera Angostura and the MIS 2 limit, meaning that the Strait of Magellan lobe would have coalesced with the Otway lobe and at least some deposits in the area are younger than previously thought. We apply the University of Maine Ice Sheet Model to reconstruct the climate conditions needed to allow the lobe to grow to our mapped extents and compare the climate of MIS 4 to that of MIS 2. We also compare our Strait of Magellan record with that of the similarly timed MIS 4 in the Southern Alps of New Zealand (Schaefer et al., 2015) and place it into the larger Southern Hemisphere context by looking at the Antarctic and offshore climate records that extend into MIS 4.

P-2519

A rapid, deterministic age-depth modelling routine for geological sequences with inherent depth uncertainty

Stephen Obrochta¹, Bryan Lougheed²

¹Akita University, Akita, Japan. ²Laboratoire des Sciences du Climat et de l'Environnement (LSCE-IPSL) CNRS, Gif-sur-Yvette, France

Abstract

Traditional approaches to age-depth modelling typically assume no uncertainty for the depth value of dated intervals. However, such an assumption may not be fully valid in the case of poor coring recovery or significant sediment deformation, as well as in the case of a large subsampling interval. In consideration of these issues, we present a new age-depth modelling routine, *Undatable*, which includes uncertainty in both age and depth. *Undatable* uses Bayesian radiocarbon (¹⁴C) calibration software (*MatCal*) and a deterministic approach with a positive sediment accumulation rate (SAR) assumed *a priori* which, combined with efficient programming practices, allows for the rapid production (in a matter of seconds in many cases) of age-depth models for multiple types of geological archives. *Undatable* has so far been successfully applied to coral archives, as well as sediment archives from estuarine, lacustrine and deep-sea environments. Through the inclusion of a bootstrapping option, the software performs particularly well in the case of a large scatter in age-depth constraints by expanding the uncertainty envelope of the age-depth model. Unlike other deterministic models, increasing the density of age-depth constraints results in increased precision in *Undatable*, even at centennial scale, thus emulating the results of probabilistic models. In addition to the code itself, we also provide an interactive graphical user interface (GUI) that allows users to experiment with multiple age-depth model settings to investigate the sensitivity of a given dataset to multiple parameters.

CLIMCOR: a 7 year project to develop new generation of drilling/coring tools for the French and international scientific communities

Denis-Didier Rousseau¹, Michel Calzas²

¹CNRS/INSU Laboratoire de Météorologie Dynamique, Paris, France. ²CNRS/INSU, Plouzane, France

Abstract

Fundamental paleoclimatic data, geochemical or geophysical, cannot be recovered without sophisticated technological equipments to retrieve top quality records. After the initial revolution of the 80s-90s in paleoclimate science and technology, it is now time to launch a new generation of technical equipments & approaches on various paleoclimate archives. The increasing complexity of the mechanisms to decipher in climate models render mandatory to improve not only the quality, but also the temporal & spatial coverage as well as the range of proxies acquired in paleoclimate archives. One key objective is notably to access very high quality data and high-resolution records that could extend their temporal coverage further back in time, in more contrasted climate conditions than the last two millennia or the Last Glacial Maximum, so that the calibration of the Earth system models could encompass a larger range of boundary conditions.

The available drilling/coring equipments in France did not allow such important jump in the quality of the data, and therefore in the knowledge of past climate variations at extremely high resolution.

A preliminary initiative named C2FN (Centre de Carottage et de Forage National, supported by the CNRS, at the National Institute of Earth Sciences and Universe, gathered the present coring equipments, at the technical division of INSU or on oceanographic vessels, under an official umbrella, aiming at coordinating the different efforts conducted in marine, ice & continental drillings.

The CLIMCOR project (<http://climcor-equipex.dt.insu.cnrs.fr/> 17.68 M€) intended to support this effort by providing the French scientific community with top-notch technological support for the new generation of drilling/coring tools & for an upgrade of the Marion-Dufresne vessel capacity to collect oceanographical data as crucial complements of paleoclimatic data. Beside paleoclimatic reconstructions based of both ice and marine sediment coring, there is an urgent need to improve our understanding of the role of oceans in the current climatic machinery at the global level. With its oceanographical fleet & the skill of its marine researchers, France is a major actor in this scientific field, providing for example other international bodies involved in climate change issues. Besides CLIMCOR developed a new cyber-database, to properly archive the upcoming data obtained from the cores.

CLIMCOR will increase the competitiveness of the French paleoclimate and marine science community at the international level. It will contribute to bring key constraints on the possible range of future climatic evolutions. The technological developments aimed by CLIMCOR have resulted in new patents. While the C2FN infrastructure gathers renowned engineers in their respective fields, strong interactions with French companies are a daily routine for them. Our presentation is showing the completion of the different developments achieved in the ice, marine & terrestrial coring activities for the benefit of the French and international communities.

Temporal Variability of Planktic and Benthic Reservoir Ages of Surface, Deep, and Intermediate Waters in the LGM-to-Deglacial Southern South Pacific

Kevin Küssner¹, Michael Sarnthein², Pieter M. Grootes³, Frank Lamy¹, Elisabeth Michel⁴, Gesine Mollenhauer¹, Thomas Ronge¹, Giuseppe Siani⁵, Ralf Tiedemann¹

¹Alfred Wegener Helmholtz-Zentrum für Polar- und Meeresforschung, 27515 Bremerhaven, Germany. ²Institute of Geosciences, University of Kiel, 24098 Kiel, Germany. ³Institute for Ecosystem Research, University of Kiel, 24098 Kiel, Germany. ⁴LSCE, 91198 Gif-sur-Yvette Cedex, France. ⁵CNRS-Université de Paris-Sud, 91405 Orsay Cedex, France

Abstract

To meet the challenge of an accurate and precise timing and correlation of glacial and deglacial events in Southern Ocean circulation and to uncover their links to other ocean basins and global climate change we employ the absolute chronology presented in the varve-counted atmospheric ¹⁴C record of Lake Suigetsu (Bronk Ramsey et al. 2012, Schlolaut et al. 2018). This record shows a suite of narrow-standing age-calibrated ¹⁴C plateau boundaries that, in turn, provide a series of robust age tie points with semi-millennial resolution to which likewise highly resolved marine ¹⁴C records from any site with high sedimentation rates in the global ocean can be tuned (¹⁴C Plateau Tuning Technique; Sarnthein et al. 2007, 2013, 2015). We apply this technique to two sediment records from the eastern and western continental margins each in the Pacific sector of the Southern Ocean to derive accurate and precise estimates of the differences between (coeval) atmospheric and surface, intermediate, and deep-water ¹⁴C ages and their trends and short-term variability over peak glacial and deglacial times. For the LGM, our results show surface water reservoir ages of 1000 to 1800 ¹⁴C yr, intermediate water ages of 2300 to 2900 yr, and apparent deep-water ages ranging from 3900 to 4600 yr in the Southwest Pacific. In total these ages provide important new insights into the role and strength of overturning processes both in the North Atlantic and North Pacific and the speed of changes in ocean stratification and the ocean release of dissolved inorganic carbon as compared to glacial-to-deglacial changes in atmospheric pCO₂ and ¹⁴C concentration.

Quaternary dune evolution on Fraser Island, Australia; environmental and archaeological implications.

James Shulmeister¹, Daniel Ellerton¹, Allen Gontz², Patrick Hesp³, Graziela Miot da Silva³, Patrick Moss¹, Nicholas Patton¹, Tammy Rittenour⁴, Talitha Santini⁵, Kevin Welsh¹

¹University of Queensland, Brisbane, Australia. ²San Diego State University, San Diego, USA. ³Flinders University, Adelaide, Australia. ⁴Utah State University, Logan, USA. ⁵University of Western Australia, Perth, Australia

Abstract

Fraser Island (K'gari) in South-East Queensland, Australia is the world's largest sand island and contains an exceptional record of coastal dune field development. The island lies at the northern end of the world's largest down drift system with the bulk of sands feeding the dune field originating 1000 km to the south, between the Hawkesbury and Hunter Rivers. The dune field is remarkable because of the well-developed vegetation cover, including the largest area of true rainforest on dunes. It also shares some of the world's largest soils (megapodzols) with the Cooloola Sand Mass to the south. Remarkably, there has been very little research into the geochronology of the dunes and the environmental implications of the dune field. A provisional OSL chronology for the dunefields will be presented.

The island can be divided into three separate dune fields. The largest (southern) section is a parabolic dune field that is a continuation of the adjacent Cooloola Sand Mass. There is a narrow band of Holocene dunes along the eastern section of this coast but based on correlations with Cooloola, most of the dune field is Middle-Pleistocene in age with dune units ranging up to over 700 ka in the far west. North of the parabolic dune field, there is a broad area of transverse sand dunes, nested inside a large dune activation phase that started as a series of large parabolic dunes. Based on soil characteristics these dunes are likely to be early Holocene or very Late Pleistocene in age. The very far north of the island has a mix of deeply eroded dunes on the western side and very young (late Holocene to modern) dunes in the east. This northern part of the island is likely the remnant of an older, largely eroded dune field, and has only recently been connected to the rest of the island.

In the southern part of the Island, dunes of likely MIS 5e age blocked previously eastward draining valleys creating very extensive lakes. These lakes have gradually contracted over the last glacial cycle but large lakes still persist (e.g. Lakes Birrabeen, Boomanjin, Mackenzie). We conclude that large persistent lakes are a feature of Fraser Island during the last glacial cycle. This makes the island one of the few places in eastern Australia with truly permanent freshwater and has likely implications for human occupation and biodiversity.

P-2602

Late Quaternary deposition-deflation cycles preserved within playa-lunette systems on the High Plains, Kansas, USA

Mark Bowen¹, William Johnson²

¹Minnesota State University, Mankato, Mankato, USA. ²University of Kansas, Lawrence, USA

Abstract

Playas are upland-embedded depressional wetlands occupying the lowest position within closed watersheds, and lunettes are isolated dunes that form along the margins of some playas. Collectively referred to as playa-lunette systems (PLSs), they are important landscape elements of semi-arid and arid regions around the world. During wet phases, runoff delivers sediment and organic matter to playas, where it accumulates, while lunettes are stabilized by vegetation and pedogenesis dominates. During dry phases, regional dust inputs combined with accumulation of sediment deflated from playas outpaces pedogenesis and existing surface soils are buried as lunettes aggrade. Thus, the combined stratigraphic records of PLSs are potential archives of high-resolution paleoenvironmental data, with an abundance of carbon and luminescence dateable material, to reconstruct past geomorphic processes. Due to a relatively high surface area-to-depth ratio, playas are particularly sensitive to changes in climate, and PLSs may represent the most complete paleoenvironmental records for semi-arid and arid landscapes. Research on the High Plains of Kansas, in the central United States, indicates that playa morphology is a strong control on lunette distribution and morphology. Lunettes are only associated with playas with a surface area >5 ha, and ~10% of these playas have a lunette. Nearly 90,000 playas have been mapped on the High Plains, with ~12,200 playas with a surface area >5 ha, suggesting 1,200 or more PLSs are distributed throughout the High Plains.

To reconstruct past environments and geomorphic processes affecting High Plains PLSs, soil cores were extracted from seven PLSs in Kansas to maximum depth possible using a hydraulic coring rig. Cores were imaged and analyzed for bulk density, magnetic susceptibility, and spectral color. Detailed core descriptions consisted of horizonation, Munsell color, structure, redoximorphic features, and carbonate occurrence. Soil-sediment samples were collected and analyzed for stable carbon isotopes, and twenty-five samples collected from buried soils were numerically dated via AMS ¹⁴C to provide stratigraphic age control. Age data indicate that lunettes preserve lengthy records of environmental change, with most extending to at least 40,000 cal yr BP (MIS 3). Lunettes are dominated by several-meter-thick stratigraphic sequences of 2 to 10 cm thick dark-light intercalated zones interpreted as incipient soil (A/C)-sediment layers. Playas are composed of thick, cumulic soils frequently welded to pedocomplexes dating to the Pleistocene-Holocene transition underlain by several meters of gleyed clays. Stable carbon isotope and magnetic susceptibility data indicate repeated small-scale shifts in climate throughout much of the late Pleistocene and into the early Holocene, with increased aridity throughout much of the Holocene. Geomorphic processes in the late Pleistocene regularly alternated between alluvial-lacustrine in playas and pedogenesis on lunettes to aeolian deflation from playas and deposition on lunettes, while the early-to-middle Holocene was dominated by aeolian processes.

A paleodust database for the last glacial-interglacial cycle: state of the art

Samuel Albani¹, Yves Balkanski², Natalie Mahowald³, Gisela Winckler⁴, Stephanie Kienast⁵, Thomas Stevens⁶, Valter Maggi¹, Barbara Delmonte¹

¹Department of Environmental and Earth Sciences, University of Milano-Bicocca, Milan, Italy. ²Laboratoire de Sciences du Climat et de l'Environnement, IPSL/CEA-CNRS-UVSQ, Gif-sur-Yvette, France. ³Department of Earth and Atmospheric Sciences, Cornell University, Ithaca NY, USA. ⁴Lamont Doherty Earth Observatory, Columbia University, Palisades NY, USA. ⁵Department of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada. ⁶Department of Earth Sciences, Uppsala University, Uppsala, Sweden

Abstract

Natural archives show that the dust cycle experienced variability in the past in response to global and local climate change. The growing number of paleodust archives and the inclusion of the dust cycle in climate models has promoted synthesis efforts in the compilation of global dust data sets, based on dust mass accumulation rates as a quantitative metric that allows inter-comparison among different sites, among different kind of natural archives, and between models and paleodust observations.

We review our most recent efforts in reconstructing the past global dust cycle with model simulations and the compilation of a paleodust database based on dust mass accumulation rates and particle size distributions for the Holocene. We also give a perspective on ongoing work aimed at providing adequate tools for paleoclimate model validation over the full last glacial-interglacial cycle, considering that the representation of the dust cycle will be an option in the upcoming PMIP4-CMIP6 experiments.

P-2604

Reconstructing the late Pleistocene climate sequence at Alexandra Cave, Naracoorte, South Australia, using Optically Stimulated Luminescence dating and palaeoenvironmental proxies

Priya Priya, Lee Arnold, Liz Reed
University of Adelaide, Adelaide, Australia

Abstract

The drivers of the Australia-wide megafaunal extinction during the late Pleistocene remains poorly resolved. Hypotheses include individual or synergistic combinations of climate fluctuations, human impacts through hunting or habitat alteration by landscape burning. Moreover, the relationship between extinction dynamics and long term glacial - interglacial timescales is not yet understood. Using a series of complementary geochronology, palaeoecological and geochemical techniques on a sedimentary sequence in Alexandra Cave, Naracoorte, this study provides improved reconstructions of past climates in south-east South Australia around the time of megafaunal extinction. Ten luminescence dating samples constrain the age of the sedimentary sequence to 17.7 – 106.3 ka. Palaeoenvironmental reconstructions undertaken using charcoal, carbon isotopes and geochemical analysis reveal high fire frequency and precipitation during Marine Isotope Stage (MIS) 5, while MIS 4 and the Last Glacial Maximum were arid, with low fire frequency. MIS 3 was wet, with little fluctuation in the environment, with the exception of a change in biomass burning at 36 – 50 ka. These findings suggest that climate change likely played a minor role in the demise of megafauna locally, whereas changes in fire regime could have acted as a more significant driver or consequence of megafauna extinction.

Dust from the Sahara and Sahel to the Atlantic: Evidence from the mineralogy and geochemistry of paleosols, Canary Islands, Spain

Daniel R. Muhs¹, Joaquín Meco², James R. Budahn¹, Gary L. Skipp¹, Kathleen R. Simmons¹, Alejandro Lomoschitz², Juan F. Betancort²

¹U.S. Geological Survey, Denver, USA. ²Universidad de Las Palmas de Gran Canaria, Las Palmas, Spain

Abstract

It is well known that African dust is transported seasonally to the Atlantic Ocean at present. Less certain is how long this process has been ongoing and where dust sources in Africa are found. On the basaltic Canary Islands off the west coast of Africa, we studied sections of carbonate-rich dune sand (carbonate sand=70-95%; basaltic sand=5-30%) on the islands of Lanzarote (14 meters; 11 paleosols) and Fuerteventura (8 meters; 5 paleosols). On nearby Gran Canaria, we also studied a paleosol developed on basalt and overlain by marine deposits. On Lanzarote and Fuerteventura, paleosols are distinguished from unaltered carbonate dune sand by their pedogenic structure and color and higher silicate clay and fine silt contents. On these two islands, radiocarbon ages of land snails indicate that all but the youngest paleosols (of Holocene age) are older than ~40-50 ka, minimum-limiting ages. ⁸⁷Sr/⁸⁶Sr values of the marine carbonate skeletal grains indicate the host sands are ~600 ka to ~800 ka, maximum-limiting ages. On Gran Canaria, basalt underlying the paleosol studied and marine deposits overlying the paleosol are both ~400 ka. On all three islands, the presence of quartz (absent in local basalt) in paleosols indicates that the soils are derived, at least in part, from an external source, likely long-range-transported dust. The clay mineralogy of the paleosols is dominated by smectite, mica, and kaolinite. Mica, absent in basalt, is also likely derived from an external dust source because true cases of pedogenic mica are extremely rare. In principle, kaolinite could be derived from in situ chemical weathering of basalt, but this seems improbable in the arid climate of the Canary Islands. Such an interpretation is also supported by the presence of unaltered marine skeletal aragonite at all depths in the sections on Lanzarote and Fuerteventura. Thus, chemical weathering in these paleosols has been minimal and a pedogenic origin for kaolinite is unlikely. Geochemical signatures, using immobile trace elements (Sc-Hf-Th; Cr-Hf-Th; La_N/Yb_N-Eu/Eu*; Gd_N/Yb_N-Eu/Eu*), also show that the paleosols are derived from a mix of African dust and detrital basaltic sand. Thus, we interpret mica to be derived from eroded Aridisols and sediments in the Sahara and kaolinite to be derived from kaolinite-rich Alfisols in the Sahel. Quartz could be derived from either region of Africa. These interpretations are consistent with the mineralogy of modern dust collected at various points along the western African coast. Results indicate, therefore, that dust transport from Africa to the Atlantic Ocean has been ongoing for much of the Quaternary. Furthermore, dust sources in both the Sahara and Sahel have existed for much of the Quaternary, whenever conditions were dry enough for a vegetation-free Sahara and when extended droughts brought about a dry Sahel region.

P-2606

A quantitative method for analysing Quaternary aeolian dune accumulation records

David S.G. Thomas^{1,2,3}, Richard M. Bailey¹

¹University of Oxford, Oxford, United Kingdom. ²University of Witwatersrand, Johannesburg, South Africa. ³East China Normal University, Shanghai, China

Abstract

Luminescence dating has, since Singhvi *et al.* (1982), become the primary method for dating aeolian deposits, to the point where it is regarded as a standard method in both Quaternary palaeoenvironmental studies and investigations of long-term dunefield dynamics. By 2018, over 4000 luminescence ages from desert dunefields worldwide had been published, as recorded in the INQUA Dune Atlas database (Lancaster *et al.*, 2016; <https://www.dri.edu/inquadunesatlas>). Environmental and climatic interpretations of these dated dune sediment records have however proved problematic (Hesse, 2016) and sometimes controversial (Thomas and Burrough, 2012), and it has remained challenging to test hypotheses of the systematic response of dunefields to changes in external forcing in the past (Chase, 2009) and to make predictions of the future.

A numerical method for handling and modelling age data at the dunefield scale, provides an approach that addresses many of the issues associated with past age interpretations (Bailey and Thomas, 2014). This takes account of key factors including sediment preservation, sampling bias, and dating errors that can complicate the interpretation of past accumulation records⁷ (Fig. 1). The *Accumulation Intensity* method quantifies dune sediment accumulation from age datasets, rather than simply using the ages themselves as proxies of change. This allows periods of dune accumulation, over 10^2 - 10^5 years, to be identified from compilations of dated sand sea stratigraphic sequences.

This approach is applied to dunefield age datasets from southern Africa, Asia (China, India, Israel and UAE) and Australia (examples given in the poster) providing model outputs that allow dunefield accumulation histories to be directly compared and analysed against local, regional and global records of Quaternary environmental and climatic dynamics (Thomas and Bailey, 2017). This generates the potential to test hypotheses of long term controls on dunefield development, as well as identifying significant gaps and limitations in some existing dune age archives.

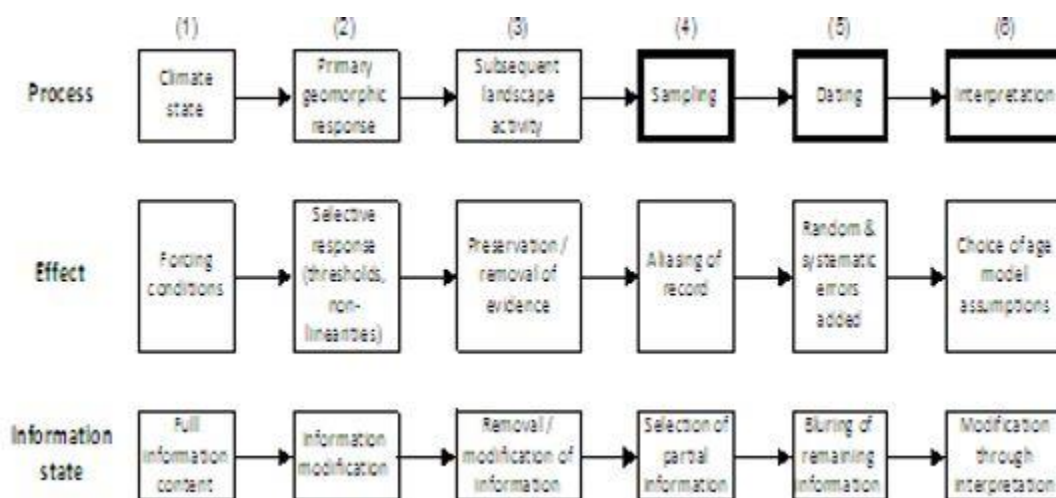

Figure 1. Factors that impact the integrity of ages derived from dune sediments (Bailey and Thomas, 2014)

Subsurface expression of the Cooloola Sand Mass dune morphosequences, southeastern Queensland, Australia

Allen Gontz¹, Daniel Ellerton², Nicholas Patton², James Shulmeister², Tammy Rittenour³, Adrian McCallum⁴

¹San Diego State University, San Diego, USA. ²University of Queensland, St Lucia, Australia. ³Utah State University, Logan, USA. ⁴University of the Sunshine Coast, Sippy Downs, Australia

Abstract

The Great Sandy Coast of southeast Queensland is home to the world's largest sand islands which are fed by the world's longest down drift sand transport system. The sand islands, coupled with onshore sand masses represent one of the world's oldest continually active coastal dune fields. The long period of activity has resulted in the development of very deep (over 30 m) podzol soil sequences. The Cooloola Sand Mass is one of the onshore sand masses and has recently been studied to understand the evolution of the system and how changes to the dune field relate to variations in climate and sea level as well as the influence of fire and other destabilization events.

Over the period of four years, approximately 250 km of high-resolution ground penetrating radar were collected in the Cooloola Sand Mass and adjacent Fraser Island. On Cooloola, a simultaneous surficial geomorphic mapping effort was undertaken to remap the dune sequences identified by Ward (2006). This effort included hand coring, OSL dating and GIS mapping. The surficial mapping (see Patton et al., submitted; Ellerton et al., submitted) resulted in the identification of eight (8) dune morphosequences. GPR data were acquired across morphosequence boundaries and within morphosequences to characterize the subsurface relationships between morphosequences. In most locations, the GPR was able to image the subsurface architecture to 28 m and resolve primary and secondary sedimentary structures as well as horizons related to present and formerly truncated or buried soil sequences.

This presentation highlights a composite GPR transect that crosses the entire Cooloola Sand Mass from the high coastal bluffs in the east, over the highest portions of the dunefield, to the low elevation hummocky plains in the west near Tin Can Bay. A GPR facies interpretation based on the radar characteristics was developed. Each of the facies were plotted spatially and compared to the surficial mapping effort of Ellerton et al. (submitted). While the GPR data were able to identify boundaries between the major surficial units, the boundaries were often not collocated with those from the surficial mapping efforts. We attribute this to the post depositional reworking that has occurred and mantles the original boundaries. The team is currently attempting to reconcile several aspects of the subsurface and how it spatially and temporally relates to the surface expression of the morphosequences, soil sequences, geophysical stratigraphy and chronology to better understand the Quaternary evolution of the Great Sandy Coast.

Sedimentological observations of aeolian sand deposits in permafrost regions

Julian Murton

University of Sussex, Brighton, United Kingdom

Abstract

The circumpolar permafrost zones contain widespread deposits of aeolian sand and silt. Some of these deposits are currently accumulating, especially in polar deserts, in regions of sandy tundra and adjacent to floodplains, but most of them predate the Holocene, and provide a rich archive of environmental change in periglacial regions beyond the limits of Pleistocene glaciation. Many of them accumulated during cold stages of the Pleistocene, when the permafrost and periglacial zones extended equatorwards and the climate of the mid and high latitudes was generally drier, windier and dustier than at present. This permafrost aeolian archive, however, remains to be systematically investigated because the aeolian deposits have commonly been mis-identified, for example as deltaic or fluvial in origin.

This poster summarises the aeolian sand facies and sedimentary structures that characterise present and past permafrost regions. The main types of facies relate to dune and sand-sheet deposits. Distinctive sedimentary structures commonly associated with them and formed under cold-climate conditions include vertical cracks (unfilled thermal contraction cracks), sand veins and wedges (infilled thermal contraction cracks) and various sand-ice composite veins and wedges. Additionally, palaeosols and peaty layers within frozen aeolian sands are commonly involuted, and in situ roots from grasses and sedges are often well preserved and suitable for radiocarbon dating. Examples of facies and sedimentary structures are presented from the Tuktoyaktuk Coastlands of western Arctic Canada and the Yana River basin of northern Siberia, and compared with those from the lowlands of northwest and central Europe. The aeolian sedimentary environment that characterised much of the unglaciated subcontinent of Beringia and its extension into central and western Eurasia during Marine Isotope Stage (MIS) 2 is discussed.

How reliable are granulometric proxies in paleoenvironmental studies?

György Varga¹, Fruzsina Gresina², János Kovács^{3,4}, Zoltán Szalai^{1,2}

¹Geographical Institute, Research Centre for Astronomy and Earth Sciences (MTA), Budapest, Hungary. ²Institute of Geography and Earth Sciences, Faculty of Science, Eötvös University, Budapest, Hungary. ³Department of Geology and Meteorology, University of Pécs, Pécs, Hungary. ⁴Environmental Analytical and Geoanalytical Laboratory, Szentágotthai Research Centre, University of Pécs, Pécs, Hungary

Abstract

Grain size data of loess-paleosol samples provides valuable information on the physicochemical environment of sedimentary mechanisms from particle entrainment and transport to deposition. As post-depositional alterations can also be reconstructed from grain size parameters, particles sizing is also a valuable component of multi-proxy paleoclimatic investigations. However, diverse aspects of aeolian sedimentation (wind strength, distance to source area or possible further source regions and modes of sedimentation and transport), provenance of dust material as well as post-depositional weathering and various aspects of paleosol formation (weathering intensity, syn-sedimentary soil-forming material addition) can only be reconstructed from precise and appropriate grain size data via a correct sedimentary and paleoclimatic interpretation.

In this study, particle size data of terrestrial aeolian dust deposits (primarily paleosols in loess sequences) were determined by laser scattering instruments (Fritsch Analysette 22 Microtec Plus, Horiba Partica La-950 v2 and Malvern Mastersizer 3000 with a Hydro LV unit), while particle size and shape distributions were gathered from Malvern Morphologi G3-ID automated static image analysis measurements. This paper systematically reviews the grain size data obtained from different laser diffraction measurements, and it is aimed at to (1) provide new data on dependence of laser scattering particle sizing on optical setting of devices; (2) present new results of comprehensive comparison of widely used laser scattering devices; and (3) demonstrate the importance of accurate description of applied measurements methods and settings for a more practicable repeatability and comparability of grain size data of research groups using different devices.

Our results showed a clear dependence of laser diffraction results on several factors frequently ignored in previous studies. In the course of our investigations, grain size distributions of 10 selected samples were measured by using 3 state-of-the-art laser diffraction instruments. The applied 68 different optical settings of the instruments have resulted 2040 grain size data-series.

Major findings include that measurements using the Mie theory provide more accurate data on the grain size distribution of aeolian dust deposits. However, different applied complex refractive index settings have had significant effects on the measured volumetric amount of fine-grained fraction of the investigated sedimentary samples. Significant differences between the Mie and Fraunhofer approaches have also been found for the finest grain size fractions, while only slight discrepancies were observed for the medium to coarse silt fractions.

Support of the National Research, Development and Innovation Office NKFIH K120620 (for G. Varga) is gratefully acknowledged.

Dune-field pattern of blowouts and sinuous ridges for a vegetated aeolian system, western Pampas, South America

Alfonsina Tripaldi¹, Steven L. Forman², Luis Díaz Balocchi³, Liliana Marín²

¹IGBA-Universidad de Buenos-CONICET, Buenos Aires, Argentina. ²Baylor University, Waco, UAE. ³CADIC-CONICET, Ushuaia, Argentina

Abstract

The role of vegetation in active and non-active dune fields has been a matter of attention in aeolian research, particularly in regards of landscape reactivation, stabilization and related dune mobility. It is well known the existence of vegetated dunes with simultaneous sand accumulation, such as parabolic dunes coastal foredunes and sand sheets. Stabilized dune fields are common in semi-arid to semi-temperate environments and reflect a shift from the dominance of aeolian processes to ecologic succession resulting in landscape stabilization in response to climate change and/or anthropic impacts. In the western Pampas of southern South America ($\sim 34^{\circ}\text{S}$), the San Luis paleo-dune field is a vegetated savannah-like environment (grassland with scattered woodlands) of a stabilized aeolian system with a rich sedimentary record spanning the last ~ 50 ka. This aeolian system shows dunes of different morphology, size and orientation, with cross-cutting relationships, indicating dune formation at different times, consistent with the stratigraphic record. Uncertainty remains on driving forces for the evolution of this landscape, particularly with recent landscape stability ca. 1000 years ago and partial reactivation in the 1930s. Specifically, the relation between dune depositional/erosional events and the formation of compound aeolian bedforms often defies known process-based reasoning. Here we present observations on compound and complex blowout dunes (variable mean length of 835-1700 m and mean width of 500-1130 m) and unusual, multiple-sets of sinuous ridges (mean length, amplitude and slopes of ~ 620 m, ~ 2.5 m and $\sim 3^{\circ}$, respectively) (Fig.1). Our aim is to contribute to the understanding of aeolian geomorphology and to improve the use of dunes and aeolian sand sheets as a geoproxy of landscape response to past environmental and climate changes. The working hypotheses is that the compound and complex blowout dunes were inherent emergent elements of this aeolian landscape, and the two different orientations (NW and SW transport directions) correspond to distinct and successive aeolian phases during the late Pleistocene. Three possible explanations are evaluated and discussed for formation of sinuous ridges: 1) The forms were initially linear dunes, later modified to the present morphology, with stabilization by grassland succession, 2) Sinuous ridges were originally a primary dune form, such as barchanoid-ridges and stoss and lee slopes were extensively modified with stabilization and changes in wind direction and, 3) These sinuous ridges are some type of zibar form that originally grows in conflict with vegetation and reflect long wavelength and low amplitude aeolian transport.

Terrestrial mollusk records from Chinese loess sequences and changes in the East Asian monsoonal environment

Naiqin Wu, Fengjiang Li

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The terrestrial mollusk fossils found in Chinese loess strata have been studied for over one hundred years. However, the greatest progress in these studies has been made only in the last two decades. In this work, we review the advancements, advantages and limitations of terrestrial mollusk studies in Chinese loess deposits. Improvements in research methods and approaches have allowed the extraction of more detailed paleoenvironmental and paleoclimatic information from mollusk assemblages. The broadened research scope and content have yielded many new findings and results. The mollusk record has thus become one of the most important proxies in the paleoenvironmental and paleoclimatic reconstruction of loess-paleosol sequences in China. The greatest progress in the studies of terrestrial mollusks in Chinese loess sequences can be summarized as follows: (1) modern mollusk assemblages can be classified into four ecotypes, based on their temperature and humidity requirements, including eurytopic, semi-aridiphilous and sub-humidiphilous, cold-aridiphilous, and thermohumidiphilous types; (2) Quaternary mollusk assemblages can be modified into the following three ecological types: glacial loess, interglacial paleosol, and interstadial weakly-developed paleosol assemblages; (3) mollusk records successfully reveal long-term climatic and environmental changes reflective of the history of East Asian monsoonal variations since the Late Cenozoic, and the succession of mollusk species also indicate short-term environmental changes such as millennial climate variability during Last Glacial Maximum and unstable climatic fluctuations during glacial and interglacial periods; and (4) more recently, new analytical approaches have offered increased research potential in areas such as paleotemperature reconstruction using the isotopic compositions of modern and fossil mollusk shells, combined with higher accuracy ^{14}C dating of Quaternary loess deposits, which will greatly improve future loess paleoenvironmental research.

Beyond the determination of paleowind direction - perspectives in the magnetic fabric study of loess

Balazs Bradak

Department of Physical Geography, ELTE Eotvos Lorand University, Budapest, Hungary. Research Center for Inland Seas, Kobe University, Kobe, Japan

Abstract

Abstract

Although there are many doubts about the application of magnetic fabric methods in the determination of paleowind direction, magnetic fabric studies have been applied on loess since the early studies in the 1980th.

In the ideal (?) magnetic fabric (MF) of aeolian loess, formed of elongated magnetic minerals, the orientation of the long axis is determined by the maximum principal susceptibility, and that of the shortest axis by the minimum principal susceptibility. Theoretically, if the dust was deposited on a nearly horizontal surface the bedding-dominated fabric will be defined by minimum susceptibility, its orientation being the bedding pole. The maximum and intermediate susceptibility axes will lie in the bedding plane, with the orientation of maximum susceptibility indicating the paleo-wind direction (Fig. 1).

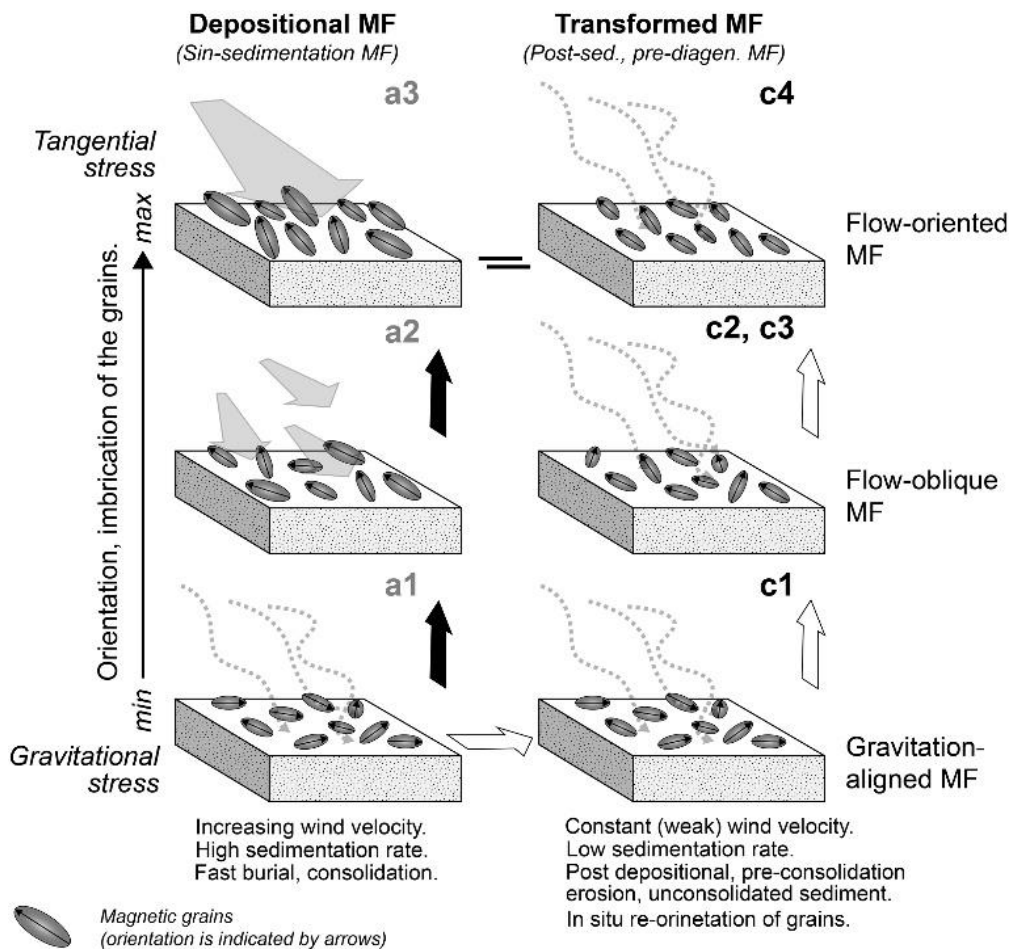

Figure 1. The steps of the flow-oriented loess magnetic fabric development in various sedimentary environments (Paks, Hungary). Depositional MF was developed by sin-sedimentary processes, and transformed MF was developed by the realignment of the magnetic grains from gravitational MF before diagenesis, but after the deposition of the grain (Bradák et al. 2018)

There are numerous phenomena which can bias the goal of magnetic anisotropy research into loess, among them, the determination of paleo-wind direction, such as redeposition, pedogenesis and seismic activity (Fig. 1 and 2).

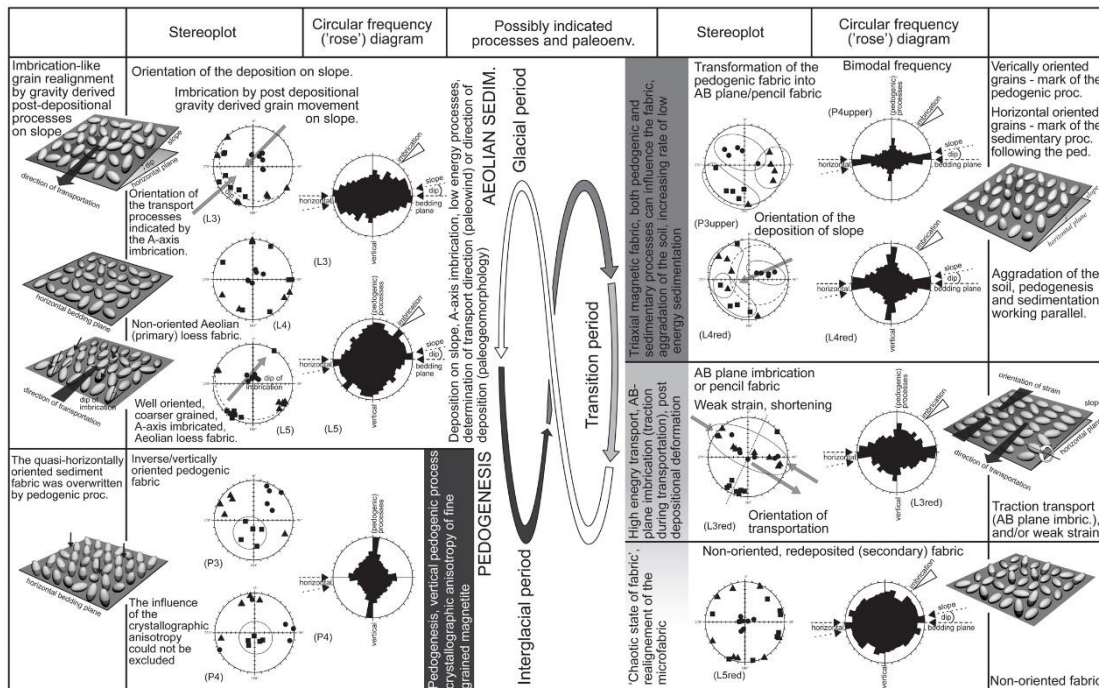

Figure 2. Various magnetic fabric and paleoenvironment in the Cérna Valley loess succession (Hungary).

Characteristic differences between sedimentary, post sedimentary (redeposition by water lain processes) and pedogenic environment can be characterized by various magnetic fabric of the studied (Bradák-Hayashi et al. 2016)

The goal of the poster is to summarize the recent developments and future perspectives in the study of magnetic fabric of loess, especially, but not limited to some key section from Hungary (e.g. Paks profile) and its significance in the reconstruction of palaeoenvironment and processes.

Intermittent aeolian deposits in Tasmania indicate rapid climate oscillations over the last glacial cycle.

Peter McIntosh¹, Adrian Slee¹, Bernard Walker²

¹Forest Practices Authority, Hobart, Australia. ²University of Tasmania, Hobart, Australia

Abstract

Tasmania lies at c. 42°S and has experienced multiple glaciations. In contrast to areas like New Zealand where large braided rivers carried glacial erosion products including large amounts of silt from uplifted mountains to the sea, providing a source of loess, loess is not present in Tasmania, but local near-source aeolian deposits are widespread. These deposits have accumulated as lunettes downwind (west) of seasonally-dry lakes, as longitudinal dunes in the drier parts of the semi-arid Tasmanian glacial landscapes, as near-source dunes downwind of river floodplains and as lenses of white quartzose sands and silts in gravelly colluvial and alluvial deposits. These lenses of aeolian origin are interpreted to have accumulated in dry and windy conditions when little erosion and runoff was occurring on hillslopes. Intervening colluvium is interpreted as indicating milder and wetter conditions.

Aeolian deposits have been dated at over 40 locations in Tasmania, with the oldest being over 200 ka. The Maynes Junction section near Maydena in southern Tasmania is particularly valuable for climatic interpretation: TL and radiocarbon ages for three pale quartz-rich silty and fine sandy layers (separated by weathered colluvium) indicate dry windy conditions at c. 20 ka, 30 ka and 90 ka. A strongly developed clayey palaeosol in colluvium c. 21 ka at Maynes Junction indicates an interval of mild conditions (and possibly forest vegetation) immediately before the LGM. This 23-21 ka interval is provisionally named the Tasmanian Mild Interval (TMI). Stratigraphy at Dunlin Dune in northern Tasmania also indicates a wet period producing soil podzolisation at about 21 ka, possibly a result of periodic high rainfall in eastern Tasmania during the Last Glacial as a result of moist easterly winds associated with southward-tracking depressions in the western Tasman Sea. This climatic inference is supported by pollen analysis of a peat core from the Freycinet Peninsula (Mackenzie 2010) showing an increase of wet-favouring taxa between 22 and 17 ca ka.

When all dated erosion products in Tasmania are plotted, aeolian deposits (and inferred cool windy conditions) occur mostly in four age ranges: 90-74 ka, 59-48 ka, 38-23 ka and 21-17 ka and colluvial and alluvial deposits and soil development (inferred to have occurred in moist and cool conditions) during the intervening periods: 74-59 ka, 48-38 ka, 23-21 ka, and from 17 ka to the present (the Holocene).

Abstract

Diffuse reflectance spectroscopy (DRS) parameters, such as redness index and hematite/goethite ratios are popular in the study of loess-paleosol sequences. The suggested parameters, however, have their limitations: only some parts of the whole reflectance spectrum have been used, and the spectra of some important components may have been excluded from the analysis.

A mathematical statistical method, hierarchical cluster analysis, was applied to the loess-paleosol succession at Malá nad Hronom (Slovak Republic) to characterize the entire reflectance spectrum and classify sediment groups. The sedimentary units were classified into seven different cluster groups such as sediments, weak and well-developed paleosols. The distribution of the spectral features in the reflectance spectra was located using the key-wavelength, given by the Wilk's lambda analysis. The key-minerals, which play an important role in the classification, were determined by characteristic extrema in the second derivative of reflectance spectra of the seven reference minerals (hematite, goethite, muscovite, illite, montmorillonite, kaolinite and calcite).

Mineral groups influence together certain curve sections within the measured range, therefore curve sections modified by individual minerals were to differentiate only in a few cases. The mentioned mineral groups refer to characteristics of the formation environment and to climate change during the Pleistocene.

Abstract

Loess sequences provide valuable archives for understanding landscape development and environmental change during the Quaternary. The association of these deposits with Palaeolithic archaeological remains helps establish the relationships between the timing of early human occupation and environments through the production of high-resolution chronologies and intra/inter-regional correlation of these sequences. In Eurasia, many loess-filled basins have been extensively studied, however, until recently, there was a paucity of investigations in the Southern Caucasus (Wolf et al., 2016). This region, however, has great significance for improving our understanding of hominin dispersal and behaviours during the Palaeolithic, as attested by the presence of several archaeological sites of global importance (Dmanisi, Gabunia et al., 2000; Nor Geghi 1, Adler et al., 2014).

Here, we present preliminary results from ongoing investigations at several newly discovered loess sequences in the Debed valley, northern Armenia. These sequences are characterised by alternations of loessic layers and soil formation, reflecting at least four phases of aeolian sedimentation and landscape stability. Three of these sequences have yielded stratified archaeological remains, comprising principally Middle Palaeolithic stone tools. Through the integration of detailed sedimentological analysis, micromorphology and luminescence dating we have further investigated these sequences and have developed a chronostratigraphic record for landscape change and Middle Palaeolithic occupation in the region.

Investigation of quaternary sand movement and soil forming periods with different dating methods in the Nyírség blown sand area, Hungary

Botond Buró¹, József Lóki², Gábor Négyesi², György Sipos³, Mihály Molnár¹

¹Isotope Climatology and Environmental Research Centre, Institute for Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary. ²University of Debrecen, Department of Physical Geography and Geoinformatics, Debrecen, Hungary. ³University of Szeged, Department of Physical Geography and Geoinformatics, Szeged, Hungary

Abstract

In the Carpathian Basin the Nyírség is the second largest sand dune area (ca. 4600 km²), formed on the alluvial deposits of the Tisza River and its tributaries. When the weather was dry, wind-blown sand was blown out and the wind started to develop the aeolian landforms. The first significant sand movements in the Nyírség was in the Upper pleniglacial and the Late glacial. The main landforms of the Nyírség were developed at this time. The aeolic transformation of the land was not completed in the Nyírség at the end of the Pleistocene. In the Holocene moved the sand on the small area, mainly anthropogenic impact.

Our aim is clarify the age of the wind-blown sand movement and soil forming periods, with different absolute (Radiocarbon dating methods, OSL), and relative (Archaeological finds, Pollen analysis) dating methods.

We have collected charcoal samples for the radiocarbon age determination from many sand quarry (Gyüre, Gégény, Kántorjánosi, Nyíradony, Nagyvarsány, Máriapócs, Lövőpetri and Petneháza, Kótaj, Vásárosnamény) which contain fossil soil layer. For the OSL measuring the samples were collected from Baktalórántháza, Gégény and Kántorjánosi, Gyüre, Lövőpetri, Kótaj and Vásárosnamény. We collected samples from 5 places for the pollen analysis (Nyírtanya, Máriapócs, Nyírbéltek-Nyírlúgos, Nyírábrány, Vámspércs), and visited an archeological excavation (Nyíregyháza–Oros).

The results of our investigation confirmed the previous thesis. In the Nyírség the first significant sand movements were in the cold and drier period of the Upper pleniglacial and Late glacial (Baktalórántháza, Nyírtanya, Vámspércs, Gyüre, Lövőpetri, Máriapócs, etc.). At the end of the Pleistocene the sand movements not completed in the Nyírség (Gégény, Kántorjánosi, Nyírábrány). Sand movement in the first half of the Holocene, in the Preboreal and in the Atlantic Phase took place due to climatic and anthropogenic effects also (Gégény, Kántorjánosi, Kótaj).

In the Subatlantic Phase, there were many little sand movement periods, mainly caused by anthropogenic impacts (Nyíradony, Nyíregyháza-Oros, Nyírlugos).

The C-14 datas show us, paleosols in the Nyírség developed Bölling-Allerød/Younger dryas, Preboreal, Boreal and Atlanti phases.

According to radiocarbon ages, the first paleosols development period might happened in the Bølling-Allerød Interstadial and continued in the Younger Dryas. Also during the Holocene (Preboreal, Boreal, Atlantic, Sub-Atlantic) soil layers were formed several times in the Nyírség. The soil layer formation were interrupted by several sand movement periods in this area.

The research was supported by the European Union and the State of Hungary, co-financed by the European Regional Development Fund in the project of GINOP-2.3.2.-15-2016-00009 'ICER'.

P-2617

Postglacial landscape adjustment driven by relative sea level changes and climatic variation, Savary Island, British Columbia

Travis Gingerich¹, Olav Lian^{2,1}, Libby Biln¹, Christina Neudorf³, Jordan Bryce¹

¹Simon Fraser University, Burnaby, BC, Canada. ²University of the Fraser Valley, Abbotsford, BC, Canada. ³Desert Research Institute, Reno, NV, USA

Abstract

The coastline of British Columbia (BC) has experienced relative sea level (RSL) changes of more than 200 m since the end of the last (Fraser) glaciation. The timing of sea level change is relatively well-known in this region, although the landscape's response to sea level change and postglacial climatic variation is less understood. Savary Island, off the southern coast of BC contains a geomorphic and stratigraphic history of relative sea level change and climate-driven postglacial landscape adjustment. This island is comprised mainly of glacial advance outwash sand and gravel (Quadra Sand), and is distinctly different from the surrounding islands which are chiefly bedrock. Throughout the central part of Savary Island, large parabolic sand dunes lie under a mature Douglas-fir forest.

This study sought to constrain the timing of relative sea level retreat, dune initiation, and dune stabilization on Savary Island. To this end, two well-established optical dating protocols were applied: the single-aliquot regenerative dose (SAR) protocol, and the multiple-aliquot additive-dose with thermal transfer correction (ADTT) protocol. SAR and ADTT optical ages were then compared with independent ¹⁴C ages from the same sediments, and with local well-defined relative sea level curves. Multiple variations of the SAR technique yielded optical ages that underestimate both the ¹⁴C ages and the sea level curve, whereas optical ages calculated using the ADTT method were within the expected age range, although their analytical uncertainties are larger. As such, we suggest that the ADTT method is more reliable for Savary Island sediments, but the reason for this is presently unknown.

Using the ADTT optical ages, the postglacial landscape adjustment chronology of Savary Island is as follows: RSL was at ~8 m above present sea level (apsl) at 11.5 ± 1.1 ka BP, resulting in littoral reworking and sorting of Quadra Sand. This age agrees with nearby RSL curves which indicate that RSL was at ~8 m apsl at ~12.5 ka BP. Aeolian deposition began to dominate no later than 9.1 ± 0.8 ka BP and persisted as recently as 5.9 ± 0.5 ka before vegetation stabilized the dunes and aeolian deposition largely ceased. During the phase of aeolian activity, weak palaeosols found within the sedimentary record suggest that short periods of landform stabilization occurred during the aeolian phase, lasting for perhaps hundreds of years. Charcoal ¹⁴C ages indicate aeolian activity was occurring between 9.5-9.6 ka ago and 8.2-8.3 ka ago. Dune initiation occurred near the end of the established Holocene xerothermic interval, a warm and dry period, and the stabilization of dunes occurred as climate became cooler and wetter. These findings suggest that in warmer and dryer climatic periods, dune development may dominate in BC coastal environments.

P-2618

MIS6-MIS3a Fluvio-Aeolian sequence from the Qaidam basin margin, northeastern Tibetan Plateau, China

Noam Greenbaum¹, Joel Roskin², Lupeng Yu³

¹Dept. of Geography and Environmental Studies, University of Haifa, Haifa, Israel. ²Geomorphology and Portable Luminescence Laboratory, Leon Recanati Institute for Maritime Studies, University of Haifa, Haifa, Israel. ³School of Resource and Environmental Sciences, Linyi University, Linyi, China

Abstract

Middle to Late Pleistocene (MIS's 6-3a) dune-damming of a small second order basin, at an elevation of 3437 m a.s.l, at the northeastern margin of the Qaidam basin caused an accumulation of a >12.5m fluvio-aeolian sedimentary sequence. This continuous fluvial sequence (9 meters) dated to 119-38.6 ka (MIS5e-MIS3a), includes >30 sedimentary units composed of fine gravel units at the base and fining-upward sedimentary units from fine angular gravels and granules to fine sand and silt at the middle and upper parts of the section. These units, unconformably overlap flanks of a dune, characterized by steeply-dipping sand units, OSL dated to ~143-134 ka (MIS6) which is one of the oldest Quaternary records of dune-damming. The contacts between the fluvial units are erosional, but other - mainly at the middle and upper part of the section, are composed of reddish silty-clay layers that contains carbonates and other pedogenic indicators indicating unconformities, representing significant time gaps.

A massive sand-dominated unit dated to ~15 ka that marks an horizontal breaching of the dune dam truncating the top of the dune, while the natural reservoir at the back of the dune, was probably almost full with fluvial sediments. This breaching unit together with another overlying sedimentary units dating until ~ 12 ka, represent the last deglaciation period during which a second dune-damming phase blocked the basin. These Aeolian-fluvial phases completely changed the morphology and drainage of the Qaidam basin. The fluvial units are associated with specific deglaciation periods, whereas periods of enhanced wind power led to significant eastward dune mobilization up the slopes of the Qaidam basin margins resulting in damming of local streams.

The upper part of the section (3.5 m) is aeolian and composed of massive, fine sandy-silty loess separated by pedogenic unconformities into two paleosols underlying the current soil, with calcic B horizons. Dated to the Holocene (10.1 ka-present) this part of the section suggests a period of loess accumulation with changing rates of deposition and a wind power relax since the last deglaciation.

The sediments of the margins of the Qaidam basin accumulated by: (a) intense dune mobilization, (b) consequent long-term dune damming, (c) filling of backdune reservoirs which was followed by dune breaching by major floods. These processes, were probably controlled by the paleoclimate of glacial-interglacial cycles.

Distribution, chronostratigraphy and palaeoenvironments of the Quaternary aeolian deposits of West Siberia

Valentina Zykina

Sobolev Institute of Geology and Mineralogy Siberian Branch Russian Academy of Sciences, Novosibirsk, Russian Federation

Abstract

The Quaternary aeolian deposits widespread in West Siberia and consist of loess and dune sands.

West Siberian loess province is located in the central part of the mid-latitude Eurasian loess belt extending from Western Europe to China. Loess deposited during upper part Lower and Middle Pleistocene occupy weakly uplift territories - the CisAltai plain, low and middle Altai mountains, western slopes of Salair and the Kuznetsk depression. During the Late Pleistocene loess distribution expanded abruptly, it developed widely in West Siberian plain and Kazakhstan. The loess-soil sequence of West Siberia consists of rhythmically alternated thick layers of loess and complexes of fossil soils interbedded by 1-2 more thin loess horizons. The complete loess-soil sequence in Brunhes Chron of West Siberia includes ten soil complexes alternated with thick loess layers. The structure of pedocomplexes in the West Siberian loess-soil sequence well reflect the structure of global odd warm stages consisting of closely spaced warm events interfered with brief cold intervals. Pleistocene warm and wet periods corresponded to soil formation in conditions of weak air circulation. In mountain areas loess horizons and paleosoils keep the main structure and morphological features, specific for them in the West Siberian Plain. Paleosoils of low Altai mountain and south West Siberian plain in Middle Pleistocene were formed for a long time under warmer and wetter climate than the modern climate. Climate in low Altai mountain during Late and Middle Pleistocene area was warmer and wetter than in plain territories. The presence in microstructure of loess indications of cryogenic processes and traces of aeolian treatment on quartz grains evidence that loess layers were formed by wind in cold conditions. Cold times were associated with climate drying and more intense air transport of dust. The loess deposition in the Siberia was accompanied by the formation of large deflation surfaces and closed deflation basins in an environment of cold deserts. On the bottom of deflation basin of Lake Aksor with deep more 70 m was formed carbonate crust, desert pavement with ventifacts and splitting pebbles and boulders with desert varnish. In the Last Glaciation (MIS 2) aeolian sands covered vast territory of West Siberian plain and formed aeolian relief. West Siberian plain was an area of vast cold desert. The aeolian topography consists of ridges (large dunes - grives) oriented along the wind direction and deflation basins. The distribution and orientation of the aeolian landforms produced during glacials suggest their origin by transport with mostly western winds. The western transport was largely responsible for erosion and deposition in middle latitudes during glacial stages. Its increase during glaciations coincided with intense winter monsoons in eastern Asia.

Luminescence chronology of environmental evolution of the Ob Plateau loess-paleosol sequence in the Late Quaternary

Nikolay Volvakh¹, Redzhep Kurbanov^{2,3,4}, Anna Volvakh¹, Valentina Zykina¹, Andrew Sean Murray⁵

¹Sobolev Institute of Geology and Mineralogy Siberian Branch Russian Academy of Sciences, Novosibirsk, Russian Federation. ²Moscow State University, Moscow, Russian Federation. ³Institute of Geography RAS, Moscow, Russian Federation. ⁴Schmidt Institute of Physics of the Earth RAS, Moscow, Russian Federation. ⁵Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Roskilde, Denmark

Abstract

Loess deposits cover wide areas in the south of the West Siberia. It forms uneven-age covers overlying each other and divided by palaeosols. More than 150 sections are known there. They have a clear stratigraphy, based on palaeopedology and on C14 dating (Zykina, Zykina, 2012).

To establish the age of the horizons and to get detailed geochronology for this region OSL dating was used as it is the most widely accepted technique for accurate dating of such deposits. Despite the fact, that south of West Siberia is a huge loess area, there is a lack of detailed dating and dating older than the limit of C14 method. Only in the Middle Siberia there is reference well-dated section Kurtak (Zander et al., 2003).

Lozhok section was chosen since it is the key profile of the Late Pleistocene loess formation of Ob Loess Plateau in Novosibirsk region. Ob Plateau is presented by a series of steep ridges presented by up to 100 m thickness Pleistocene loess-palaeosol sequence. The whole sequence of the Lozhok section consists of Middle-Late Pleistocene loess-palaeosol deposits (Zykina, Zykina, 2012), in this study we consider its Late Pleistocene part. A 8,5 m depth section exposes the Bagan and Eltsovka loesses (both correlate to MIS-2), the Iskitim pedocomplex (MIS-3), Tulino loess (MIS-4) and Berdsk pedocomplex (MIS 5 c, e). This profile contains an unique record of dust dynamics over the last 130000 years. Using modern multidisciplinary methods allowed to reveal several palaeoenvironmental changes expressed by increasing of humidity (Sizikova, Zykina, 2015). Accurate OSL dating helped to identify the nature of these changes and its connection with some global events. It allowed to estimate more precisely average rates of loess accumulations during three cold periods and to define the time of hiatuses in the section. Obtained OSL dating were put in the base of geochronological scheme of studied region. It allows to make detailed age correlations with adjacent areas and to compare periods of loess and palaeosol formation in different regions.

The work is done on state assignment of IGM SB RAS. The reported research was funded by Russian Foundation for Basic Research and the government of the Novosibirsk region of the Russian Federation, grant № 18-45-543007 and RFBR grant №19-05-00513.

High-resolution luminescence chronology for the coastal loess-paleosol sequences in the Jiaodong Peninsula and Miaodao Archipelago, Eastern China

Shuangwen Yi¹, Lin Zeng^{2,3}, Jiang Wu¹, Yao Wang¹

¹School of Geography and Ocean Science, Nanjing University, Nanjing, China. ²School of Resources and Environmental Engineering, Ludong University, Yantai, China. ³CAS Key Laboratory of Coastal Environmental Processes and Ecological Remediation, Yantai Institute of Coastal Zone Research, Chinese Academy of Sciences, Yantai, China

Abstract

During Pleistocene glaciation, the shallow continental shelf exposed and formed the desert-loess depositional system due to lowered sea level and strengthened East Asian Winter Monsoon (EAWM) in the marginal sea of Eastern China. As a consequence, the loess-paleosol sequence in the Jiaodong Peninsula and Miaodao Archipelago is a special type of eolian sediment related to the dynamic changes of coastal zone environment, and an important archive for paleoclimate and sea level changes of the coastal zone of Eastern China. However, this loess-paleosol sequence is still poorly understood due to the lack of independent age control, which have limited the interpretation of their palaeoclimatic and palaeoenvironmental information. In this study, high-resolution luminescence dating which based on quartz SAR OSL and K-feldspar post-IR IRSL (pIRIR₂₉₀) measurements, are employed to the two loess-paleosol sequences located in the Jiaodong Peninsula and Miaodao Archipelago, respectively. Our results show that quartz SAR OSL and K-feldspar pIRIR₂₉₀ ages are more or less indistinguishable from one another up to ~70 ka. Beyond this age, the K-feldspar pIRIR ages increased systematically with deposition depth, agreeing well with the expected ages as far as ~130 ka. On the basis of our fully independently-dated timescale, we are therefore able to propose, for the first time, a new age model for the loess deposits in Jiaodong Peninsula and Miaodao Archipelago accumulated since the last interglaciation (corresponding to S1 palaeosol in CLP). Using our newly obtained luminescence dating ages, it appears that there is a marked loess accumulation variability since the last interglaciation, which possibly indicates the desertification process of this coastal zone in the late Pleistocene.

New map of Quaternary deposits of the Russian territory and adjacent offshore areas, scale 1:2 500 000

Andrei Zastrozhnov¹, Valentina Shkatova¹, Yevgenia Minina¹, Valery Astakhov^{1,2}, Svetlana Yakovleva¹, Margarita Chuyko¹, Ludmila Pestova¹, Yevgeny Gusev³

¹A.P.Karpinsky Russian Geological Research Institute, St. Petersburg, Russian Federation. ²St. Petersburg State University, St. Petersburg, Russian Federation. ³All-Russian Research Institute for Marine Geology, St. Petersburg, Russian Federation

Abstract

The new Quaternary Map of the Russian Federation, scale 1:2500000, has been produced in the department of Quaternary Geology and Geomorphology in VSEGEI in co-operation with VNIIOkeangeologia. The map covers all Russian territory with internal seas and adjacent offshore areas. This is a result of cartographic generalization of geologic data obtained since the publication of an analogue map of the same scale in 1973.

The legend is built on the traditional for Russia stratigraphic-genetic principle. The legend is in the matrix form: genetic types of deposits proceed along the horizontal axis whereas geological age of the units increases vertically downwards. The mappable unit called stratogen is a depositional body of a certain genetic type with defined geological age. The alphabet consists of 24 pure genetic types to whom specific colours are assigned (alluvial, glacial, marine etc.). The addition of geological age make the number of stratogens ca 340. The size of genetically individual polygons are limited by the scale of the map. Therefore in many cases the mapped unit is presented as a paragenetic association of several adjacent depositional bodies with disparate genetic labels. Such an association is designated by a colour of the dominant genetic type and by a series of genetic indices separated by commas. For the uniformity of their display on the map we used a special digital database of symbols developed in VSEGEI. This database is also employed for geomorphic and palaeogeographic elements: karst, landslides, mud volcanoes, ice limits, sea transgressions, permafrost boundaries, recent faults, thin cover sediments, etc.

For the global and regional correlations the map legend incorporates the following charts: International Chronostratigraphic Chart, the scale of marine isotope stages, International and Russian Magnetostratigraphic scales and General Stratigraphic Scale of Russia. The latter has the lower boundary at 2.6 ma and is divided into the Holocene, Upper, Middle, Lower Neopleistocene, Eopleistocene and the Gelasian stages. The Holocene and Neopleistocene are subdivided into climatostratigraphic steps roughly corresponding to MIS. They are the source of special indices used in the map for designating the age of the mapped units. E.g. all₁ means alluvium of the first thermochron step of the Upper Pleistocene corresponding to MIS 5.

The map layout is accompanied by small-scale inset maps of structure-formation zonation, permafrost and seasonal frozen rocks distribution, glaciations and marine transgressions and by the Glaciomorphological Map. The map database also includes Correlation Table of Regional Stratigraphic Units, Catalogues of Key Sections and Explanatory Note.

Our map reflects the present understanding of the structure of Quaternary deposits within the Russian Federation and adjacent offshore areas and brings a solid basis for interregional correlations. The map is designed in a digital form and can be downloaded via VSEGEI website (<http://vsegei.ru/ru/info/quaternary-2500/>).

Complementary data of the Quaternary Map of Spain: active faults, extent of glaciations and key sites

Ángel Salazar¹, Julian García-Mayordomo¹, Luna Adrados², Juana Vegas³

¹Instituto Geológico y Minero de España, Tres Cantos, Spain. ²Geolag, San Claudio - Oviedo, Spain. ³Instituto Geológico y Minero de España, Madrid, Spain

Abstract

The basic information of geological maps about formations sometimes needs other kind of complementary data that helps to inform about significant subjects such as the relationship between the formations and the internal and external geodynamic, to indicate geological materials that cannot be represented with their real dimension at the map scale, but singular, or to highlight remarkable sites of special science interest. As a general rule, the usefulness of complementary data will increase as the scale of the map decreases and as the geological complexity and diversity of the territory rises.

Adding information about active faults to the Quaternary Map of Spain is not a simple cosmetic exercise. In the SE of Spain there is a set of small intermountain sedimentary basins originated during the upper Miocene (Tortonian) with continuous deposition until the Pleistocene (basins of Granada, Guadix - Baza, etc.) and related to sets of faults of the Betic orogen (Iberian – Africa plate boundary). Therefore, the Quaternary-Active Fault Database of Iberia or QAFI is an important source of complementary data for the Quaternary Map of Spain and helps to understand these tectonic relations (Figure 1). The QAFI is an inventory of faults showing evidence of activity during the Quaternary. The QAFI is a project created, supported and periodically updated on the basis of the available scientific literature by the Instituto Geológico y Minero de España (IGME, Spain) and the Laboratório Nacional de Energia e Geologia (LNEG, Portugal).

To catalogue geosites of interest has been a usual task of the IGME in recent decades. The IGME, in collaboration with experts from other scientific institutions, has also developed the "Global Geosite Project" (IUGS - UNESCO) in Spain, result of which was the selection of 20 geological frameworks of international significance for conservation. One of these frameworks is named "Vertebrate deposits of the Spanish Pliocene and Pleistocene" and it includes 20 selected paleontological sites, most of them in karstic environments, spread out from the north (Cantabrian Mountains and Pyrenees) to the south (Betic range), with a great faunal diversity and an almost a continuous record of the Quaternary (Figure 2). These deposits are the minimum of key sites that should be indicated in the maps of the Quaternary of Spain and in the European one.

Quaternary glaciers of the Spanish mountains were small and scattered, except in Piryenees. and their moraines are impossible to represent at the map scale. Therefore, the limits of the last glacial maximum is an important dataset for the Quaternary Map of Spain and the only way to show these glaciated areas.

Geological mapping of end-moraine systems in Northern Italy: a long-lasting story of survey, stratigraphy and age-assessment

Giovanni Monegato¹, Gianfranco Fioraso², Franco Gianotti³

¹CNR - Institute of Geosciences and Earth Resources, Padova, Italy. ²CNR - Institute of Geosciences and Earth Resources, Torino, Italy. ³Departement of Earth Sciences, Università degli Studi di Torino, Torino, Italy

Abstract

The end-moraine systems in the Alpine piedmont plain in Northern Italy have been surveyed and interpreted since the XIXth Century, including the first attempts to interpret their origin. Moraine systems were used by Penck and Brückner (1909) for their model of Quaternary glaciations and subsequently many of them had been surveyed in three different editions of the Italian Geological Map.

The stratigraphy of these systems in the old map series (the I and II edition of the Italian Geological Map, dating back to the last century, at a scale 1:100,000) reflected the Penck and Brückner (1909) model of four different glaciations, and they were mapped using a mix of litho- and climatostratigraphic units. These criteria were also applied to correlate end-moraine systems of different glacial basins and their outwash plains, including the terraced surfaces. However, the lacking of data hampered their precise age-attributions, so until the last series of geological maps (CARG Project, at a scale 1:50,000, encompassing the last two decades) their age was based mostly on the soil development and few biostratigraphical data.

In the CARG Project, geological maps were surveyed at a more detailed scale (1:5,000 and 1:10,000), using an allostratigraphic approach and applying the Unconformity-Bounded Stratigraphic Units (UBSU). The detection of discontinuities became relevant in the unit subdivision of the end-moraine systems. Dedicated drillings, combined with systematic application of cross-dating methods (e.g.: ¹⁴C, palynology, paleomagnetism, cosmogenic ¹⁰Be), also allowed to better depict the stratigraphic architectures of the end-moraine systems, highlighting significant differences from one system to another. Some glacial apparatus show more than four units ascribable to different glaciations (e.g.: Ivrea and Rivoli-Avigliana morainic amphitheatres), whereas others show remnants of less glaciations (e.g.: Piave and Tagliamento morainic amphitheatres). Using this approach, the resulting correlation with the outwash deposits became stronger thanks to the detailed study of subsurface stratigraphy; this also let to develop a more constrained stratigraphy throughout the Po Plain. The relationship between the end-moraine systems and the deposits of the related mountain catchments were performed through allostratigraphic profiles, which also showed the ice-elevation of the younger glaciations in the lower reaches of the valleys. In some cases, the low distance with the coastline allowed to trace the discontinuities from the end-moraine systems to the continental/marine transitions and to separate units ascribed to different glaciations. The resulting architecture of the end-moraine systems at the scale of the whole Po Plain, from the Piedmont Plain to the Veneto-Friuli Plain, can now be used as a tool for better depicting the evolution of the glacial advances in the southern slope of the Alps.

The Penultimate Glacial Maximum in the English West Midlands

Sebastian M. Gibson^{1,2}, Philip L. Gibbard^{1,3}, Mark D. Bateman⁴, Julian B. Murton⁵

¹Cambridge Quaternary, Department of Geography, University of Cambridge, Cambridge, United Kingdom. ²Climate and Environment Dynamics Group, Department of Geography, University of Cambridge, Cambridge, United Kingdom.

Abstract

The penultimate glacial event is the most extensive glaciation across the Northern Hemisphere within the last 430 kyr. Globally, its maximum extent is constrained by the marine isotope stratigraphy to c.140 kyr, during Marine Isotope Stage (MIS) 6a/b. The terrestrial glacial event occurs some c.40 kyr earlier across the European continent and the British Isles. On the continent the glacial maximum is considered to be during the Drenthe Stadial (c.165 kyr / MIS 6c) of the Saalian Stage. In the British Isles, the Wolstonian Stage was traditionally considered to represent the penultimate glaciation between the Hoxnian (c. MIS 11) and Ipswichian (c. MIS 5e) interglacial stages. A sequence of sediments from Wolston, Warwickshire, England, forms the stratotype locality of the Wolstonian glaciation. However, the site is devoid of interglacial sediments, with the underlying Baginton Gravels being cross-correlated as the upper reaches of a pre-430 kyr ancient river; thus the Wolston sequence had been considered by some to be deposited during the preceding Anglian/Elsterian Stage glaciation (MIS 12). Recently, new work on the glacial sediments across the English West Midlands has led to a revision of the previous climatostratigraphical interpretation. Optically-stimulated luminescence (OSL) and post-infra-red stimulated luminescence (pIRSL) dating of glaciofluvial demonstrate that the glacial advance represented in the English Midlands occurred during the penultimate glaciation and not the older Anglian/Elsterian event. The relative timing of the penultimate glaciation across the English West Midlands is shown in Figure 1. This glaciation is considered to have reached its maximum extent north of Moreton-in-Marsh, Warwickshire. The deposition of the terminal moraine, previously attributed to the Anglian Stage, is here proposed as the regional event stratigraphic stratotype to represent the penultimate glacial maximum during the Wolstonian Stage as the Moreton Stadial (c.180 kyr / MIS 6c). Here the glacial ice terminated against a natural topographical barrier, the Jurassic Escarpment, which did not exist in its current form during earlier glaciations.

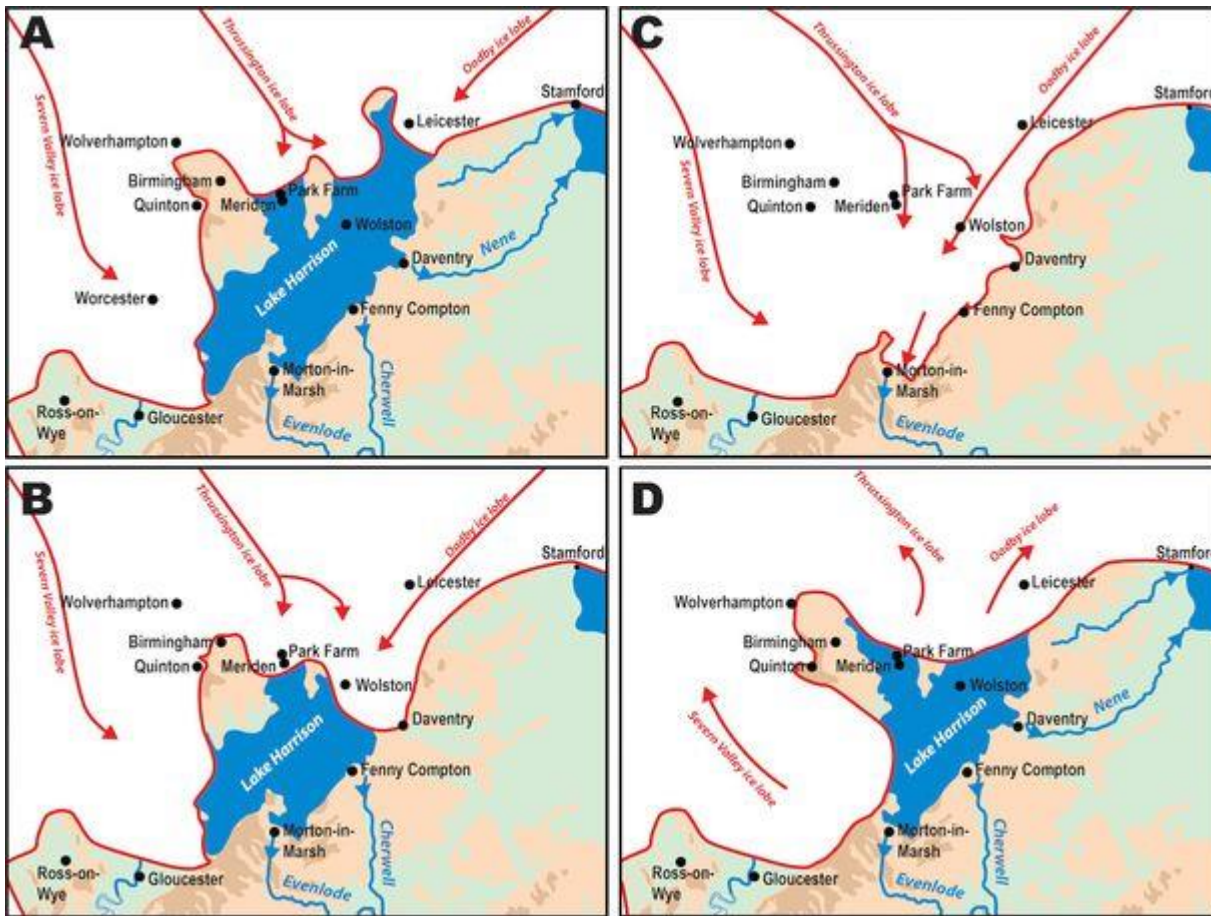

Figure 1. The history of Lake Harrison during the Wolstonian glacial period, reconstructed from Shotton (1953) and (Bishop, 1958). [A] The initial height of Lake Harrison. [B] The gap at Daventry was blocked by ice advancing from the north-east, maximum lake height of 132.5 m OD (Bishop, 1958). [C] The Penultimate Glacial Maximum at Moreton-in-Marsh. [D] Wolstonian de-glaciation and renewed expansion of Lake Harrison post-Wolstonian PGM.

Investigations into the late Quaternary evolution of the Bristol Channel

Philip GIBBARD¹, Philip HUGHES², Christopher ROLFE³

¹University of Cambridge, Scott Polar Research Institute, CAMBRIDGE, United Kingdom. ²University of Manchester, Manchester, United Kingdom. ³Department of Geography, University of Cambridge, CAMBRIDGE, United Kingdom

Abstract

A synthesis of publicly-available bathymetric and borehole evidence derived principally from the EMODnet and the proposed Atlantic Array projects, combined with a wealth of other existing disparate data sources, has revealed important insights into the Pleistocene history of the Bristol Channel. The history of the latter shares much in common with the English Channel. Although it was initiated during the Neogene, sediment boreholes throughout the Bristol Channel confirm the area was glaciated in the Pleistocene. Till underlies marine deposits and in some areas is visible morphologically as submerged morainic landforms. In the central and eastern Bristol Channel the submerged valley course of the proto-Severn is visible in new high-resolution bathymetric surveys. This former river course, and associated tributaries, cross-cut glacial sediments in the Bristol Channel, it is therefore presumably of Devensian (Weichselian) late-glacial age. At least two phases of glaciation are recorded in the Bristol Channel, one related to the southern limits of a Late Devensian Welsh Ice Cap which reached into Swansea Bay and another older glaciation that is associated with ice that filled the entire outer and central Bristol Channel. The age of the older glaciation is still open, although it predates the Late Devensian. On Lundy, an island in the outer Bristol Channel, exposure ages from glaciated bedrock suggest an earlier Devensian age for ice retreat. However, it remains possible that the 'older' Bristol Channel glaciation is represented by more than one event, with tills found in borehole records being of different ages in the outer and central areas. It is evident therefore, that Pleistocene glacial and fluvial activity, combined with subsequent post-glacial marine transgression (from c. 10.0 14C ka BP), directly account for current morphometries of the Bristol Channel and Severn Estuary, and the current geography of the SW British Isles.

This work is a contribution to the IQUAME project.

Quaternary Map of Poland in scale 1:2 500 000, an input to the new edition of IQUAME 2500 GIS

Leszek Marks, Joanna Rychel, Katarzyna Jóźwik

Polish Geological Institute – National Research Institute, Rakowiecka 4, 00-975 Warsaw, Poland

Abstract

Completion of a Polish part of the International Quaternary Map of Europe to a scale of 1:2 500 000 (IQUAME2500) will be finished by the end of 2019. Not only the Polish Geological Institute – National Research Institute is to contribute to the international IQUAME2500 project but it also develops its own digital Quaternary Map of Poland as well as an appropriate web viewing service (WMS). Primary input data comes from the digital databases of the Geological Map of Poland 1: 200 k and the Detailed Geological Map of Poland 1: 50 k. The authors' compilation of the latter covers the whole territory of Poland. Several other maps in different scales produced during a bilateral cooperation with the adjacent countries (Belarus, Germany, Lithuania, Slovakia and Ukraine), together with data from a new edition of the Geological Map of Poland 1:500 k will be also used for the purpose of the project. The Polish data is collated and processed in the ArcGIS environment. The methodology of the performed works follows the 'IQuAME 2500 – Semantic Transformation' guidelines provided by the German Geological Survey and mostly consists in mapping national dictionaries to the IQUAME vocabularies, then reclassifying and generalising the original geological units. In accordance to the IQUAME requirements the map will be semantically compliant with the European INSPIRE directive (Directive 2007/2/EC of the European Parliament and the EU Council from March 14, 2007) as well as with the international Geoscience Markup Language (GeoSciML). The structure of the work database remains flat but at the same time it reflects main elements of the GeoSciML data model. This solution follows the one applied in the OneGeology initiative (the international initiative of geological surveys and organizations) and will facilitate easier transition to the proper GeoSciML files in the next steps. The data portrayal of the Quaternary Map of Poland will be based on symbols from the first IQUAME edition as well as the 'Guidelines for the review' prepared by the German Geological Survey.

The study is a contribution to the scientific project financed by the National Fund for Environmental Protection and Water Management as one of the tasks performed by the Polish Geological Survey (project 22.1514.1801.00.1).

P-2801

The future of Quaternary geomorphology lies underground

Trevor Faulkner

GEES, University of Birmingham, Birmingham, United Kingdom

Abstract

Little detail is known about the Quaternary evolution of upland Britain and Ireland. Multiple glaciations shaped these landscapes, but the maximum extent of the last British-Irish Ice Sheet is still being clarified, and its vertical variation is poorly constrained in space and time. Almost nothing is known about earlier upland glaciations, partly because surface evidence was subsequently reworked. Help is at hand, by studying British and Irish karst caves in glaciated northern and western areas. Caves have a special 'museum' property to preserve evidence of palaeo-environments, from their location, morphology, hydrology, dimensions and contents. Caves tend to develop at successively lower levels during each deglaciation, as recharge and discharge points follow glacially-eroded valleys downwards. Diameters of phreatic passages and entrenchment depths of vadose canyons can also act as timescale proxies, perhaps confirmed by sediment dating. By using integrated studies of museum attributes and working backwards in time and upwards in elevation, cave history, the varying glacial, deglacial and interglacial climatic regimes, and the uplift and erosion of the local topography can be deduced, and extrapolated beyond the immediate karst area.

Early successes with this approach include: the evolution of a Welsh landscape (Simms and Farrant, 2011); the development of a Yorkshire dale (Waltham *et al.*, 2010) and at Victoria Cave after MIS13 (Lundberg *et al.*, 2010); postglacial entrenchment (Checkley and Faulkner, 2014); deglacial speleogenesis (Murphy *et al.*, 2015); and the ten-stage development of Toerfjellhola in Norway since MIS12 (Faulkner, 2013). Further resolution of more surface and underground glacial karst histories will require a holistic multi-disciplinary collaboration among geological, geomorphological, sedimentological, glaciological, hydrological, meteorological, seismological and speleological communities.

An investigation of taphonomic processes in speleothem palynology.

Bianca Dickson, Kale Sniderman, Jon Woodhead

The School of Earth Sciences, The University of Melbourne, Melbourne, Australia

Abstract

Fossil pollen, preserved in depositional environments such as lakes and bogs, is widely used to reconstruct vegetation change through time. The corresponding reconstruction of past vegetation communities using fossil pollen trapped in speleothems has recently been demonstrated to be a viable alternative where other more conventional depositional records are not available. In addition, speleothems offer a potential advantage in the ability to tie pollen spectra to robust radiometric dates across a wide range of ages, i.e. far beyond the radiocarbon limit, and independent of calibration issues associated with radiocarbon dating. However, despite speleothem palynology's emerging importance, little is known about the taphonomic processes that influence the dispersal of pollen onto and preservation of pollen within speleothems as compared to lakes and bogs.

In this project we explore taphonomic processes involved in speleothem palynology, by comparing multiple fossil pollen sequences from caves, coupled with nearby, coeval lacustrine pollen records. This approach allows us to cross-calibrate the two proxies, providing a more faithful climate and vegetation reconstruction while also highlighting any taphonomic biases between the two archives. Our research site lies within the Southwest Australian Floristic Region (SWAFR) — a region with extraordinary plant species richness (the Region contains 7380 native vascular plants, 49% of which are endemic, many under threat) characterised by tectonic stability and deeply-weathered, infertile soils. This project hopes to provide new insights into questions such as, how does such a biodiverse ecosystem evolve given such infertile substrates? Ultimately, our new records will contribute to our greater understanding of the evolution of the SWAFR.

P-2803

Croatian caves as a study sites for the reconstruction of the Quaternary environments

Robert Lončarić, Maša Surić

Department of Geography, Center for Karst and Coastal Research, University of Zadar, Zadar, Croatia

Abstract

Although relatively small in surface, Croatia appears to be well-suited for the Quaternary environmental reconstructions from several different aspects. It is located on the crossroad of continental European and maritime Mediterranean influences that varied and shifted along with Quaternary climate changes. Besides, almost half of its continental territory and vast submarine part is karstic, with probably more than 10000 known caves. Speleothem-based studies have already been conducted in dozens of them revealing the Quaternary history with more or less success. At first glance, continental (subaerial) caves generally offer good potential due to accessibility throughout the year, distributions over a relatively restricted area but within different altitudes and climate settings, abundance of speleothems etc., but during the cave monitoring and laboratory work numerous obstacles emerged – from the meteorological, biological and technical hindrances at the research sites to the ^{14}C and U-Th dating issues. Nevertheless, certain progress of the palaeoenvironmental reconstruction from MIS 10 to the Recent is evident. Valuable environmental records have also been archived in thousands of years old ice accumulated in several ice-caves located in the highest Croatian regions.

Submerged (submarine) caves, with present number of more than 230 discovered along the eastern Adriatic coast, offer an additional Quaternary story related to the sea-level changes. Their occurrence below the sea surface is already irrefutable evidence of former lower sea-level stands, as well as speleothems within them. Moreover, in ideal situation, speleothems with their interrupted growth and alteration of spelean and marine deposits can record sea-level fluctuations. In spite of numerous setbacks caused by boring marine organisms, high initial Th and/or low U concentration, Late Pleistocene–Holocene relative sea-level changes along the Croatian coast has been partially reconstructed. Sea-level oscillation which can be attributed to MIS 5a interstadial that was marked with two distinct sea-level highstands (double peak) was one of the best resolved.

Additional challenges for palaeoenvironmental reconstruction are common in submerged features that are in-between aforementioned continental and submarine end members, namely in i) submerged springs (*vruljas*) which once were caves, then coastal springs and presently have hydrological function as submerged fresh- or brackish water spring and ii) coastal anchialine caves which also host fresh, brackish and sea water habitats. Both types are relatively common (>150) along the Croatian coast and are subject of multidisciplinary researches.

Seasonal variations of uranium concentration and isotope in river and cave waters in NE Sichuan, central China and implications

Houyun Zhou

School of Geography, South China Normal University, Guangzhou, China

Abstract

Uranium (U) concentration and isotope ($^{234}\text{U}/^{238}\text{U}$) ratio in speleothems have been increasingly used as proxies for past climate and environment, especially for soil moisture conditions. This is particularly important for reconstructions of the Asian summer monsoon (ASM) using speleothem oxygen isotope ($\delta^{18}\text{O}$) because interpretation of speleothem $\delta^{18}\text{O}$ caused intensive controversy in recent years. Although U concentration and $^{234}\text{U}/^{238}\text{U}$ ratio in speleothems from NE Sichuan, central China were previously proved to be appropriate proxies for past climate and environment and to support interpretation of speleothem $\delta^{18}\text{O}$ as indicators of the ASM intensity and rainfall amount, it's not clear whether the arguments were verified by modern cave monitoring.

Here we present the monthly U concentrations and $^{234}\text{U}/^{238}\text{U}$ ratios of river and karst cave waters which were collected from NE Sichuan, central China during the period from 2011.7 to 2012.7. Both the U concentrations and $^{234}\text{U}/^{238}\text{U}$ ratios show higher values during relatively dry period, i.e. the winter and spring seasons; lower ones in summer and autumn seasons. The U concentration and $^{234}\text{U}/^{238}\text{U}$ ratio display significant positive correlations in both river water and cave water, which is different from the negative correlation usually observed between U concentration and $^{234}\text{U}/^{238}\text{U}$ ratio in groundwater.

The seasonal variation of U concentration is in line with long-term variation of U concentration observed in speleothems in NE Sichuan, where higher speleothem U concentrations correspond to colder and dryer climates and vice versa. The variations of U concentration, on both seasonal and millennial time scales, can be interpreted with changes in redox conditions of soil layer and limestone capping karst cave. Higher rainfall leads to more moisture reserved in soil layer and limestone, which results in more reductive conditions and less mobility of U in soil layer and limestone, and eventually less U in river and karst cave waters. An opposite picture can be observed with lower rainfall. Therefore, the U concentration is an appropriate indicator of rainfall amount and summer monsoon intensity.

The seasonal variation of $^{234}\text{U}/^{238}\text{U}$ ratio is opposite to long-term variation of $^{234}\text{U}/^{238}\text{U}$ ratio in speleothems which displays lower values in cold-dry climates and higher ones in warm-humid climates. The mechanisms controlling $^{234}\text{U}/^{238}\text{U}$ ratio warrant further investigation. Caves as a tools for dating and reconstruction of relief changes in mountain areas – a case study from Tatra Mts.

Helena Hercman¹, Jacek Szczygieł², Michał Gąsiorowski¹, Marcin Błaszczuk¹

¹Institute of Geological Sciences, Polish Academy of Sciences, Warsaw, Poland. ²Faculty of Earth Sciences, University of Silesia, Sosnowiec, Poland

Abstract

The problem of the Tatra Mts. valleys development is discussed for a long time. Up to date, glacier activity during the Last Glacial Maximum is supposed to be a major factor determining present mountain valleys hydrology and morphology. However, the initial numerical dating results of speleothems shown that main karst springs were originated earlier than 200 ka and valleys incision in Quaternary was estimated as 80 - 100 m.

Presented research focuses on determining the age of the recent system of karst water circulation in several of main Tatra Mts. valleys: Bystra, Kościeliska and Chochołowska, which is directly related to age of valley incision and morphology. The key to getting the information is study of karst systems located at the bottom of the valleys or on a small elevation. The caves constitute a kind of "traps" and give a much greater chance of the preservation of sediments (and deposition processes records) in a period of intense denudation at the surface. Close relation between karst forms, karst drainage system, cave morphology and valleys as erosional base makes it possible to study changes in mountain morphology, valleys levels, determination of the periods of intensive valley incision etc. basing on karst studies. The evolution of cave system can be reconstructed basing on sedimentological characteristic of cave deposits and their numerical dating. As a major proxy of karst system age, the age of the oldest speleothems in active cave level can be used. Speleothems are autochthonic deposits which are formed under vadose conditions, so the age of oldest speleothems gives estimation of minimum age of cave passage drying caused by erosional base lowering (e.g. creation of a new, low-lying karst spring).

Intensive studies of caves morphology in conjunction with U-series speleothems dating suggest minimum two stages of karst drainage development. In the older stage, now abandoned caves drained massifs. The oldest dated speleothems from the high-located caves (e.g. Czarna Cave, Miętusia Cave) are at least 1.2 Ma old. The direction of paleoflow changed as a result of the water captures depending on valley incision, e.g. drainage of Gąsienicowa Valley by Kasprowa Niżnia Cave in Bystra Valley. The age of active system of big karst springs may be estimated as more than 300 ka (middle Pleistocene). In the later stages, the evolution of cave systems was controlled by glaciation-deglaciation cycles.

The study was supported by project funded by the National Science Centre, Poland (grant no. 2016/21/B/ST10/01483) and by the bilateral mobility cooperation PAN-17-22.

Abstract

Presented research focuses on determining the age of the recent allogenic karst drainage in mountain area and its relation to age of the valley incision. The key to achieving this goal is a study of fluvial modelled karst drainage conduits located at the altitude close to valley's bottom. The caves are a kind of "traps" and give a much greater chance of the preservation of sediments (and deposition processes records) during intense landform denudation on the surface. Close relation between karst surface landforms, karst drainage, cave morphology and river terraces controlled by erosion base makes it possible to study changes in valley morphology, including the determination of the stages of intensive or interrupted valley incision.

The evolution of cave system can be reconstructed from sedimentological characteristic of cave deposits and their dating. Speleothems represent the best kind of cave deposits for such a type of studies and, in general, their crystallization time can be linked with the vadose conditions. Thus their age gives a minimum age of dewatering of cave passage caused by the lowering of the erosion base.

The Demänová Caves (DC) are one of well-known multilevel cave systems in the allogenic mountain karst. The DC were described as a typical example of the relationship between the development of cave levels and the river terraces of the Váh River and Demänovka Stream in the Liptov Basin. Since the middle of the last century Droppa and following researches have distinguished 9 to 10 cave levels and have related them to stages of the interruption of valley incision and the formation of river terraces. The ages of cave levels were determined according to altitude correlation with terraces of the Demänovka Stream and Váh River from the Late Pliocene (uppermost levels) to Weichselian-Holocene (lowest-lying, active river passages).

Results of research conducted during last decades on the DC, including speleothem dating by U-series method, show that age of some passages with active Demänovka Stream (approximately at the same altitude or several meters below the surface river bed in the middle part of Demänová Valley) is significantly older than one estimated within the former scheme. Relation between cave morphology, speleothems and clastic deposits suggests long and complicated history of passage evolution with still active underground stream, i.e. several stages of partial or even complete infilling by clastic sediments and their subsequent erosion. The oldest period of cave fill, recorded as relicts of flowstone layers perching 2–2.5 m above active bed of the underground stream, is dated on Early Pleistocene (> 800 ka).

The study was supported by project funded by the National Science Centre, Poland (grant no. 2016/21/B/ST10/01483), by the bilateral mobility cooperation PAN-17-22 and by project VEGA 1/0146/19.

Late Pleistocene paleoclimate proxies from cave sediments and speleothems in the Estremadura region of central Portugal

Michael Benedetti¹, Jonathan Haws², Rhawn Denniston³, Brooks Ellwood⁴, Lukas Friedl⁵

¹University of North Carolina Wilmington, Wilmington, USA. ²University of Louisville, Louisville, USA. ³Cornell College, Mount Vernon, USA. ⁴Louisiana State University, Baton Rouge, USA. ⁵University of West Bohemia, Pilsen, Czech Republic

Abstract

The Estremadura region of west-central Portugal is home to a large limestone province (Maciço Calcário Estremenho) with many well-known caves and rockshelters, some of which contain important archaeological sites. Proxy records from the Portuguese margin indicate large environmental responses to Late Pleistocene climate fluctuations in this region, including rapid changes in sea surface temperature, upwelling intensity, and forest cover during transitions between mild/humid interstadials and cold/arid stadials. The most severe conditions occurred during Heinrich stadials (HS) associated with iceberg rafting events in the North Atlantic. This poster presents proxy records of weathering intensity and hydroclimate from two caves in the Estremadura region that illustrate the terrestrial impacts of these climate fluctuations.

The cave site of Lapa do Picareiro records Late Pleistocene variations in physical and chemical weathering intensity on the Serra de Aire massif. Excavations at the site have unearthed more than 10 m of sedimentary fill dating to approximately 9-75 ka, containing abundant faunal remains and Middle/Upper Paleolithic archaeological evidence. Bone preservation in the cave is good and disturbance by bioturbation, dissolution, or erosional processes is limited. Rhythmic bedding in the central part of the cave, where clast-supported coarse éboulis beds alternate with muddy finer éboulis, suggests a connection with Late Pleistocene climate. Several sedimentological parameters, especially clast size and magnetic susceptibility (MS), show good agreement with paleoclimate records. Cold/arid HS are represented by prominent coarse clast beds with little fine sediment and MS minima, while milder interstadials correspond with muddy beds and abrupt MS peaks. The MS record faithfully records Greenland stadials/interstadials and HS back to at least 45 ka, offering a valuable tool for interpreting archaeological evidence at the site.

Speleothem studies from nearby caves provide detailed records of effective soil moisture over the last two glacial stages. One stalagmite from Buraca Gloriosa overlaps with the period of record at Lapa do Picareiro (9-75 ka), and provides high-resolution proxies based on growth curves and isotope ratios ($\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^{234}\text{U}$). The speleothem record is consistent with the MS signal from Picareiro, and more broadly with paleoclimate proxies from offshore sediment cores and Greenland ice cores. The cold/arid HS intervals are marked either by hiatuses in stalagmite growth or by strong isotopic excursions interpreted to represent strongly reduced soil moisture conditions. Several notable paleoclimate features are evident in both the cave sediment and speleothem records, including the prolonged harsh climates during HS3, HS4, and HS6, the bipartite structure of HS2, a period of progressively more humid climate between H2 and H1, and the apparent severity of the Younger Dryas in this region.

Making sense of the faunal accumulation and palaeoecology at the Toll Cave through the multidisciplinary study of cave bear remains

Iván Ramirez-Pedraza^{1,2}, Miriam Andrés³, Carlos Tornero^{1,2}, Florent Rivals^{4,1,2}, Ruth Blasco⁵, Jordi Rosell^{2,1}

¹Institut Català de Paleoecologia Humana i Evolució Social (IPHES), Tarragona, Spain. ²Universitat Rovira i Virgili, Tarragona, Spain. ³Universidad Complutense de Madrid, Madrid, Spain. ⁴ICREA, Barcelona, Spain. ⁵Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain

Abstract

The inherent characteristics of caves make them good places that records, among others, the Quaternary fauna and flora, permitting the landscapes reconstruction. The Toll Cave is part of a karstic system located 50 km to the north of Barcelona (Spain) and one of the most interesting levels belongs to Upper Pleistocene (dated ca. 49,000 years BP). In this cave, different remains of carnivores and ungulates have been recovered but more than 90% corresponds to the cave bear (*Ursus spelaeus*). To shed some light on these accumulations, multidisciplinary work that combines a taphonomical and dental microwear analysis is being carried out. The objective is to elucidate the origin of the faunal accumulations and the role that the interaction between carnivores and humans could have played in the cave.

From a taphonomic perspective, we analyse mortality patterns, osteometry and taphonomic alterations in order to answer the questions of how the accumulation has been generated, what is the cause of the death of individuals, what is the demographic composition of the group by age and sex. Our data show that cave bear at Toll Cave died during hibernation. Additionally, a combined study of stable isotope analysis of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ in bulk-collagen and dental microwear analysis was applied to provide information about the cave bear diet at different timeframes (average diet of life vs. last days/weeks before death). As the cave bear individuals found at Toll Cave died during hibernation process, tooth microwear will inform about its diet at an important seasonal event in the life of these animals. Taking this into account, microwear analysis make it possible to establish the feeding habits of the cave bear before hibernation, which is more varied than during the rest of the year. We also considered what are the post-sedimentary processes that have modified the original sample after the death of the animals.

Contextualising the caves of South West England

Laura Basell¹, Chris Proctor², Philip Armitage³

¹Queen's University, Belfast, United Kingdom. ²Independent, Torquay, United Kingdom. ³Brixham Heritage Museum, Brixham, United Kingdom

Abstract

The caves of South West England have long been recognised as important archives of Quaternary landscape change including fauna and archaeology. Investigation of their archaeology and palaeontology was placed on a scientific footing by William Pengelly (1812–1894). He developed sophisticated recording techniques at his excavations in Brixham Cavern and Kent's Cavern, notably the adoption of a three dimensional grid system of recording. Continued excavations and research to the present day have permitted the application of modern dating techniques and reanalyses of fauna and archaeology from deposits spanning the last 500,000 years^{1,2}.

Alongside such endeavours, there have been significant advances in understanding the nature and timing of Quaternary landscape evolution in the south west peninsula over similar timescales. Of particular relevance are studies that elucidate the timing and extent of sea level change and now submerged landscapes, as well as improved chronological control on fluvial sequences. In open contexts, river terrace deposits are the most common locations for the discovery of Palaeolithic artefacts, although in the south west beyond the River Axe, these tend to be low density/single findspots^{3,4,5}.

This poster seeks to combine these different records of landscape change to present a summary overview for the region. Cave sequences will be situated in their landscape context and the record related to the current understanding of hominin occupation. A brief case study of ongoing research at Ash Hole Cave will be used to demonstrate the continued potential of cave sites in contributing to our understanding of the dynamic relationship between human- and landscape change; especially when a broad geoarchaeological approach is taken and new, multidisciplinary methods applied.

Constraining the chronology of dwarf elephant evolution using Quaternary deposits in coastal caves of the Mediterranean

David Richards¹, Victoria Herridge², Dan Nita^{1,3}, Jean-Luc Schwenninger⁴, Adrian Lister², Gabriella Mangano⁵, Laura Bonfiglio⁵

¹University of Bristol, Bristol, United Kingdom. ²Natural History Museum, London, United Kingdom. ³Babeş-Bolyai University, Cluj, Romania. ⁴University of Oxford, Oxford, United Kingdom. ⁵Università di Messina, Messina, Italy

Abstract

The mid-19th century to early-20th century saw the discovery of remarkable paleontological specimens in caves across the globe, among them dwarf elephants in Quaternary sediments of coastal caves of the Mediterranean (e.g. Spratt 1867; Falconer, 1868; Bate, 1907). However, this was followed by rather enthusiastic excavation that left very little material for future geochronologists to work with. We have visited previously-studied sites on Crete, Sicily and Malta and collected the minimum amount of material required to obtain MC-ICPMS U-Th and OSL age for a robust chronology of island evolution and body-size change in mammalian species. Without estimates of the timing of fossil emplacement in the sedimentary record, spatial patterns and rates of parallel evolution in island settings remain poorly constrained.

The coastal caves studied present challenging settings because of the complexity of their stratigraphy and inadequate excavation notes and archival documentation. As an example, we focus on a single site, Grotta Spinagallo, near Siracusa, Sicily, which, over the course of numerous excavations over 50 years ago, provided many specimens of the smallest elephant in the fossil record - *Palaeoloxodon falconeri* (shoulder height of female 0.9 m).

Attempts to obtain age estimates for bones and teeth from the middle Pleistocene by U-Th, ESR and amino-acid racemisation techniques are generally considered unreliable. We analysed >45 sub-samples (<100 mg) from calcite speleothem deposits that remain on the cave wall and, most importantly, exhibit unambiguous stratigraphical relationships with in-situ fossil remains. We illustrate improved methods for documenting the complex stratigraphy using an interactive cave survey with zoomable photo-mosaics and annotations. Diagnostic bones, now in museum collections, were found in 'reddish earth' that appears to have been emplaced between 350 and 230 ka based on U-Th ages of intercalated calcite flowstones. Three cave earth samples on this same material provide OSL ages > 200 ka. We have also sub-sampled calcite veneers (< 1mm depth) on a mandible and tibia of *Palaeoloxodon falconeri* from Spinagallo Cave that are stored in the Palaeontological Museum of the Catania University and obtain ages for the bone of $>220 \pm 4$ ka and $>300 \pm 20$ ka (2σ).

Do the cavities in non-karst rocks provide paleontological materials? A case study of granite grottos in the Middle Urals

Tatiana Strukova¹, Aleksandr Borodin^{1,2}, Evgenia Markova Markova¹

¹Institute of Plant and Animal Ecology UrB RAS, Ekaterinburg, Russian Federation. ²Ural Federal University, Ekaterinburg, Russian Federation

Abstract

In mountainous areas, cave deposits represent an important source of the Late Pleistocene and Holocene paleontological materials. This is particularly relevant to the Ural Mountains stretching submeridionally for more than 2000 km from the Arctic Ocean in the north to the steppes of Kazakhstan in the south. There are now more than 200 caves described in the region. Karst topography is highly developed on the western slopes of the Urals, with many caves, basins, and underground streams. The eastern slopes, on the other hand, have fewer karst formations; instead, rocky outliers and frequent outcrops of granite rise above the flattened surfaces. The areas of prevailing basalt and granite rocks have long been considered as unpromising sources of the paleontological materials. Outcrops of orogenic granitoids are confined to the East Uralian tectonic zone and form a chain of isolated massifs, which is known as the main granitic axis of the Ural Mountains. The granite island cliffs called Kamennye Palatki (stone chambers in Russian) create attractive features in the landscape and are extremely popular among local people. Ancient people used them as temporary shelters and sanctuaries. Archaeological studies at granite outcrops have a long history, but the only locality with the documented paleontological record is Shaytanoozersky Kamenniy Ostrov-1 (57°20' N, 60°13' E). The grotto is formed of granite blocks separated from the rock. About 10000 bone remains of mammals, birds, and fish are examined, and palynological analyses of the sediments is carried out. Types of fossilization and preservation characteristics of bone remains are described for both small and large mammals. Two complexes of mammalian bone remains, dated to the Late Pleistocene and Holocene, are identified. The Late Pleistocene complex is radiocarbon-dated (22460±340, IPAE-219, SOAN-3824; 23179± 1420, IPAE-220, SOAN-3825). Among small mammals, collared lemmings (*Dicrostonyx sp.*), narrow-skulled vole (*Microtus gregalis*), and steppe lemmings (*Lagurus lagurus*) prevail. *Rangifer tarandus* and *Equus uralensis* predominate among large mammals, along with numerous remains of *Marmota bobac*. In the Holocene complex, two stages are distinguished: an earlier one, including the Late-Pleistocene relic remains representing *Marmota bobac*, and the later one lacking marmot bones and containing only «forest» animals. The bird and fish remains, which could be identified to genus and to species, all show the Holocene type of fossilization; all these taxa inhabit the region until the present day. The results of the paleontological investigation of natural cavities in granite rocks, recently recognized as a specific type of paleo-archives in the Ural Mountains, provide some methodological clues for paleoecological studies in granite terrains.

Extinct sloth remains and their environmental context from an underwater cave in western Cuba

Matthew Peros¹, Joao Gabriel Martinez Lopez², Shawn Collins¹, Zachary Masson³, Geetanjali Deole⁴

¹Bishop's University, Sherbrooke, Canada. ²Cuban Museum of Natural History, Havana, Cuba. ³Concordia University, Montreal, Canada. ⁴Indian Institute of Technology, Dhanbad, India

Abstract

Underwater caves have been found to contain rich assemblages of paleontological and archaeological materials. Recent investigations at a subaquatic cave in western Cuba, Cueva Margarita 1 (CM1), have revealed the bone remains of at least three rare, extinct sloths. The bones include an individual of the species *Megalocnus rodens* and two individuals of the species *Neocnus gliriformis*. These animals were endemic to Cuba and are believed to have gone extinct 4000 years ago. A network of sediment cores were collected from CM1 to study the water level history of the cave, the environmental context of the paleontological materials, and landscape change outside the cave during the late Holocene. The sediment cores consist largely of sand-sized calcite particles along with organic matter, in addition to large quantities of seeds from *Cecropia* and *Ficus* trees. The main mechanism by which the seeds entered the cave is through droppings from frugivorous bats and birds, and their presence is likely indicative of times of low water level. In addition, fossil pollen analyzed in the cores closely tracks the seed data, although other tropical species, such as the tree *Didymopanax morototoni*, and the vine *Combretum fruticosum*, are also present in the pollen data. The seeds and pollen provide insight into the nature of the forest surrounding the cave, and the possible habitat in which the sloths lived. In the Neotropics today, two and three-toed sloths live predominantly in *Cecropia* and *Ficus* trees, which suggests the forest nearby CM1 was suitable sloth habitat. There is little information on the specific environments in which now-extinct mammals in the Caribbean lived, and this study illustrates how sediments from underwater caves can be used to provide context for paleontological research.

Abstract

Loess-paleosol sequences are in the focus of environmental research in Central-Eastern Europe because they offer presumably quasi-continuous terrestrial records of environmental change. As such, reliable dating approaches are crucial. Age models can be based on different methods, e.g. correlative approaches or absolute dating approaches. For the Urluia loess-paleosol sequence, which provides a high-resolution record covering the Last Glacial Cycle in the Lower Danube-Black Sea area, correlative and luminescence age models do not agree with each other (Böskén et al., 2018). While the performance of the luminescence data speaks for a reliable chronology, the radiometric ages for the samples presumably covering the MIS 4-5 interval do not fit the stratigraphic evidence. As ages in the lower half of the section do not increase with depth, field saturation has been suggested. To further explore the reasons behind this chronostratigraphic discrepancy, luminescence samples of the Vlasca loess-paleosol sequence, also in the Lower Danube area, were investigated. This contribution presents a detailed luminescence dating approach using OSL and pIRIR protocols for quartz, polymineral and feldspar samples. Furthermore, the question whether the observed discrepancy between the dating results and the stratigraphy represents a regional pattern or perhaps intrinsic luminescence properties are responsible will be discussed.

Böskén, J., Zeeden, C., Hambach, U., Veres, D., Klasen, N., Brill, D., Burow, C., Obreht, I. and Lehmkuhl, F. (2018). Consistency challenges between correlative and luminescence age models for the last ~150 ka in the Lower Danube Basin loess-paleosol sequences. Quantifying post-glacial landscape erosion on Calvert Island, western Canada using catchment-averaged and bedrock ^{10}Be erosion rates

Christopher Darvill¹, Brent Goehring², Brian Menounos³

¹The University of Manchester, Manchester, United Kingdom. ²Tulane University, New Orleans, USA. ³University of Northern British Columbia, Prince George, Canada

Abstract

Terrestrial cosmogenic ^{10}Be nuclide concentrations can be used to ascertain rates of landscape erosion, but may be influenced by changes in remnant glacial landforms and sediment supply. We present erosion rate estimates from 21 sites centred on Calvert Island on the western coast of British Columbia, Canada (51.6°N, 128.1°W). This region is notable for its general lack of glacial landforms and sediment cover, despite being covered by the western Cordilleran Ice Sheet until around 18–14 ka. Our data include thirteen erosion rates from exposed bedrock sites at altitudes of 9–679 metres above sea-level on Calvert Island and surrounding islands. We compare these with catchment-averaged erosion rates from seven watersheds on Calvert Island. Apparent catchment-averaged erosion rates are 118–263 mm ka⁻¹ (mean = 180 mm ka⁻¹), an order of magnitude higher than bedrock rates of 27–52 mm ka⁻¹ (mean = 43 mm ka⁻¹). When compared to ^{10}Be -derived erosion rates from northwestern USA and the European Alps, our rates are all within expected ranges for small, recently glaciated catchments. However, the significant difference between bedrock and catchment rates is intriguing given that both groups have experienced a similar exposure history since ice sheet retreat. A variety of controls are considered, but one possibility is that post-glacial stripping of sediments has occurred across this landscape, mobilising glacial sediments containing low ^{10}Be concentrations. If some of these sediments still reside in modern catchments, they could increase apparent erosion rates from catchments compared to bedrock sites. Consequently, erosion rate estimates in this region should consider mobilisation of glacial sediments within catchments following ice retreat.

Luminescence dating of loess in Armenia - Challenges towards a chronostratigraphy

Tilmann Wolpert¹, Daniel Wolf², Jonas Krus¹, Lilit Sahakyan³, Dominik Faust², Markus Fuchs¹

¹Justus-Liebig-University Giessen, Giessen, Germany. ²Technische Universität Dresden, Dresden, Germany. ³National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia

Abstract

Luminescence dating methods are key tools for establishing numerical chronostratigraphies in loess research. With the introduction of the post-IR IRSL (pIRIR) protocol in the recent past, it is now possible to determine more reliable ages from K-feldspar, using luminescence signals, which are only slightly affected by signal loss due to anomalous fading. Despite this methodological advance, difficulties in successfully applying luminescence dating to sedimentary archives still remain. These challenges include e. g. age underestimations in age ranges > 100 ka, as well as regional/site dependent mineralogical characteristics leading to poor luminescence properties. Therefore, it is not possible to generally apply standard luminescence approaches to loess archives.

In this respect, the southern Caucasus region is challenging for luminescence dating because of its major volcanic influence. Within the framework of a DFG-funded project (German Research Foundation) several Pleistocene loess-palaeosol sequences comprising at least three glacial/interglacial cycles are investigated in Armenia. The main goal of this study is to establish a chronostratigraphical record for these sequences.

Comprehensive pIRIR test measurements were applied to test parameters like stimulation temperatures, in combination with elemental and mineralogical characterizations of the sample material. These first investigations have revealed a number of obstacles for successful age determination: 1) The coarse-grained K-feldspar fraction cannot be used for dating due to poor luminescence properties, possibly resulting from very heterogeneous mineral phases within the single mineral grains. 2) The polymineral fine grain fraction shows unusual behavior due to decreasing equivalent doses with increasing stimulation temperatures above 250°C. 3) Despite good agreement of pIRIR ages with ages derived from fine grain quartz up to 60 ka, the pIRIR ages have a strong tendency to underestimate the expected ages above this range. This finding is confirmed by an Ar/Ar age of a distinctive tephra found within all investigated profiles.

In addition, two luminescence dating approaches were tested as a possible alternative to pIRIR: The red Thermoluminescence (TL) signal of quartz as well as pulsed IRSL measurements of the polymineral fraction.

This poster presents and critically discusses pIRIR results along with an evaluation of the potential of the tested alternative measurement procedures.

Bayesian age modelling of the last deglaciation in the southern sector of the Scandinavian Ice Sheet

Karol Tylmann¹, Vincent R. Rinterknecht², Andreas Börner³, Jan A. Piotrowski⁴

¹University of Gdańsk, Faculty of Oceanography and Geography, Gdynia, Poland. ²Université Paris 1 Panthéon-Sorbonne, Laboratoire de Géographie Physique, CNRS, Meudon, France. ³Landesamt für Umwelt, Naturschutz und Geologie Mecklenburg-Vorpommern (LUNG), Güstrow, Germany. ⁴Aarhus University, Department of Geoscience, Aarhus, Denmark

Abstract

Bayesian modelling offers a methodology for integrating various types of numerical dating and constructing consistent chronologies of geological sequences. Although it is routinely used for modelling radiocarbon chronology of lake sediments or archaeological deposits, it has been much less widely applied to model chronologies of palaeo-ice sheet retreat based on spatially distributed sites and multiple methods of numerical dating. Here, we present a Bayesian approach to model the timing of the last deglaciation of the southern sector of the Scandinavian Ice Sheet (SIS) in NW Poland and NE Germany. The study area covers ~850 km of the last SIS southern front, from the Vistula ice stream (B3) in the east, to the Odra ice stream (B2) in the west (Fig. 1).

We used published cosmogenic nuclide (CN), luminescence (OSL) and radiocarbon (¹⁴C) ages relevant to the last SIS retreat after the local Last Maximum Glaciation. Our modelling is based on: over 100 CN surface exposure ages of erratic boulders resting on glacial landforms; over 40 OSL ages of sand deposits; and more than 10 ¹⁴C ages of organic and calcareous deposits intercalating tills left by the last SIS. The dating sites are distributed along the ice sheet limits that correspond to the glacial phases of the Late Weichselian as identified in continental Europe (Fig. 1). The relative age of the ice margin fluctuations during the last SIS retreat was inferred from the morphostratigraphy of glacial landforms and the lithostratigraphy of glacial tills. These produced the relative order models used as prior information, which constrained the independent probability distribution of each age in a sequence. Based on this distribution, we modelled ages for three palaeoglaciologically different regions: the Vistula ice stream, the inter-stream area and the Odra ice stream, and obtained three sequences of the ice margin retreat. This allows to construct a consistent chronologies of the last SIS retreat and to model the rate of ice front recession along three, palaeoglaciologically diversified, longitudinal transects.

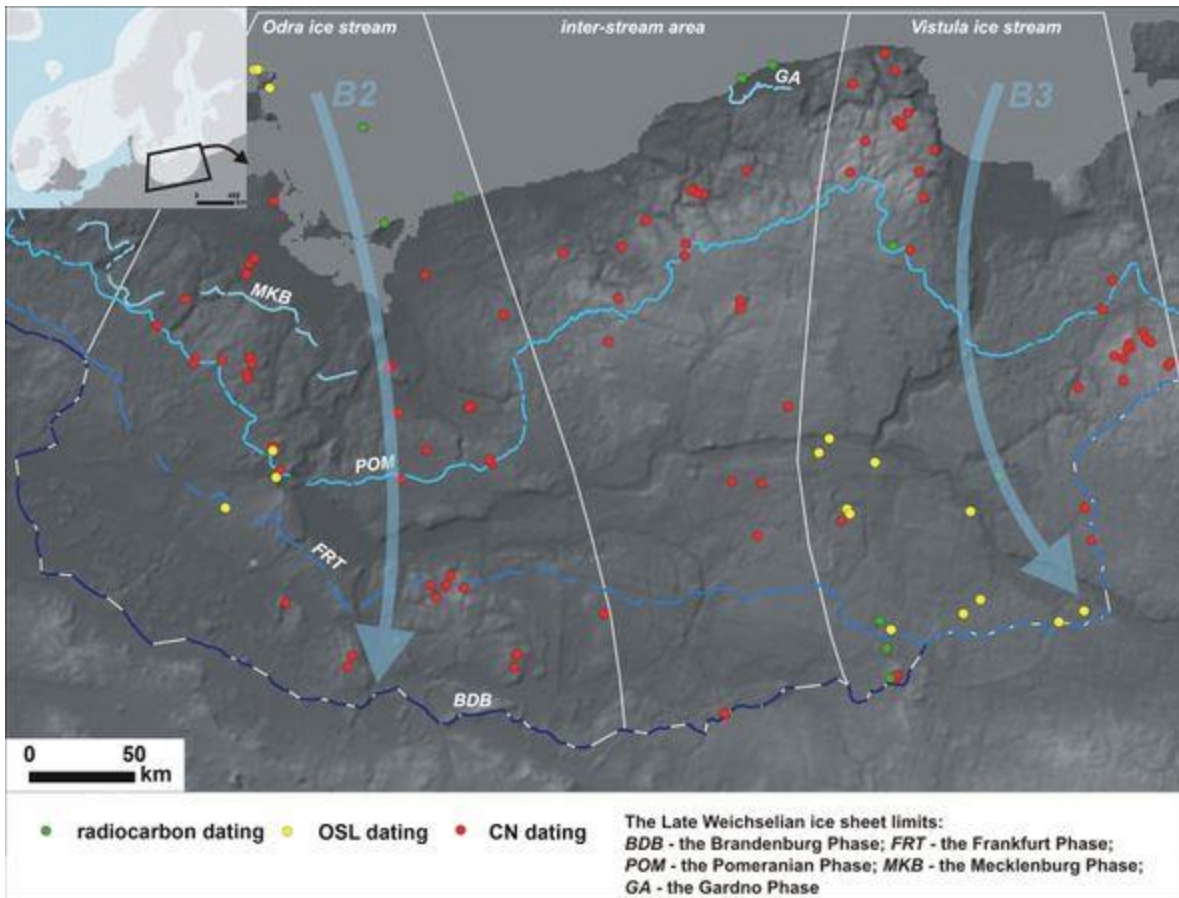

Fig. 1. Study area with the Late Weichselian ice sheet limits and sites of numerical dating used in the Bayesian modelling.

Geomorphic feedbacks on the climate control of the moraine record

Leif S. Anderson¹, Dirk Scherler^{1,2}

¹GFZ German Research Centre for Geosciences, Potsdam, Germany. ²Freie Universität Berlin, Berlin, Germany

Abstract

Length variations of glaciers are commonly attributed to climatic changes and their deposits are widely used to reconstruct past glacier extents and climates. In steep mountains, however, a layer of rocky debris on many glacier surfaces modulates their response to climate change and complicates paleoclimatic interpretations. Although the influence of debris cover on ice melt is well established, the coupling between temporally varying headwall erosion and glaciers has not been considered so far. Here, we study the response of glaciers using a numerical model that links feedbacks between mountain glaciers, climate change, hillslope erosion, and landscape evolution. We modulate hillslope erosion with temperature change by tracking frost cracking damage and permafrost in the headwall above the glacier. Our simulations use glaciological parameters meant to loosely represent glaciers in the Khumbu region of Nepal, though our conclusions are relevant for mountain glaciers in most ranges globally. We compare simulated glaciers with and without the effects of hillslope erosion. Because heavily debris-covered glaciers tend to have low surface velocities, changes in glacier length and moraine formation can lag debris supply changes by hundreds to thousands of years. We consider glacial-interglacial- and Holocene-scale temperature changes and periodicities. The relationship of the headwall elevations to the frost cracking and permafrost windows determines when in the climate cycle hillslope erosion feedbacks will take effect. The frequency-magnitude relationship for landslides onto the glacier surface is a strong control on any resulting moraine record. We develop a decision tree to determine which glaciers are likely to be influenced by debris and in which portion of a climate cycle. This decision tree considers modern climate, air temperature lapse rate, aspect, basin hypsometry, headwall area, and proximity to the modern permafrost and frost cracking windows.

Inter-comparison of karst denudation measurement methods (KADEME)

Kristina Krklec¹, David Domínguez-Villar¹, Sonja Lojen², Aleksandra Bensa¹, Régis Braucher³, Sanja Lozić⁴, Natalija Andačić⁵, Dražen Perica⁶

¹University of Zagreb, Faculty of Agriculture, Department of Soil Science, Zagreb, Croatia. ²Jožef Stefan Institute, Department of Environmental Sciences, Ljubljana, Slovenia. ³Centre de Recherche et d'Enseignement des Géosciences de l'Environnement (CEREGE), Aix-en-Provence, France. ⁴Independent researcher, Zagreb, Croatia. ⁵Independent researcher, Zadar, Croatia. ⁶University of Zadar, Department of Geography, Zadar, Croatia

Abstract

Denudation of Earth surface as a result of rock weathering is the fundamental process governing the landscape development. Weathering of rocks occurs by physical, chemical and biological processes. Ultimately, these processes transform rocks, and provide the material that forms soils. In karst regions, dissolution of carbonate rocks is a dominant process controlling denudation.

In order to quantify weathering and/or denudation rate of a certain carbonate area several different methodological approaches can be used. The most used methods are: [1] the exposure of rock tablets to the natural environment, [2] the use of micro-erosion meters on rock surfaces, [3] measuring the concentration of cosmogenic radionuclides on exposed rocks, [4] measuring water hydrochemistry to infer amount of carbonates being dissolved and [5] quantifying the differential erosion on bare-rock surfaces of known age. Every method has pros and cons and there is no consensus on which method provides the more reliable denudation rates. Not all methods quantify denudation over the same timescale and in all cases there are assumptions between acquired data (measurements) and the calculated denudation rates (interpretations). Since weathering is a slow geological process, the accuracy of denudation rate measurements is difficult to validate. Significant differences among methods have been reported by researchers that have used more than one method at the same location. Additionally, comparison of denudation results at regional scale suggests that different methods may have results differences exceeding one order of magnitude.

Although local factors can be important contributors to explain the scatter of reported denudation rates, the different methods never have been calibrated together using the same boundary conditions at one single location. As a consequence, at the moment there is no evaluation on the accuracy of available methods, and it is uncertain if any particular method provides results significantly biased compared to other methods.

Therefore, the aim of this study is to apply all possible methods that could be studied in a single location to evaluate if their results replicate within their uncertainties. Two study sites in Mediterranean climate region with different soil properties have been selected: Krnić (Croatia) and Ramacastañas (Spain). The different context will allow evaluating if the conclusions are extrapolated to different scenarios. The inter-comparison of denudation measuring methods will allow for the first time the unequivocal identification of strengths and flaws of the different methods. This is an important study to know the accuracy of available methods for the study of denudation and its important implications for the study of the Quaternary.

Denudation of dolostone karst, the case of Eagle Cave system (Spain)

Kristina Krklec¹, David Domínguez-Villar¹, Hai Cheng², Lawrence R. Edwards³

¹University of Zagreb, Faculty of Agriculture, Department of Soil Science, Zagreb, Croatia. ²Xian Jiaotong University, Institute of Global Environmental Changes, Xian, China. ³University of Minnesota, Department of Earth Sciences, Minneapolis, USA

Abstract

Evolution of cave systems is in great extent impacted by rock weathering. These processes include widening of cave passages and collapse of blocks from cave ceilings. Denudation of the surface above cave system additionally enhances thinning of bedrock above caves, favouring the cave ceiling collapses. These processes result in exposure of cave passages to the surface and formation of unroofed caves. In the area of Eagle Cave, in central Spain, collapse breccias and flowstone speleothems exposed at the surface indicate the existence of unroofed caves. The cave has a main hall where subsidence and ceiling collapses are ubiquitous, showing that collapses, whether they result in unroof caves or not are common.

To quantify the denudation rate on the region, we measured denudation rate using rock tablet method at this location. Depending on the lithology that composed the cave bedrock the denudation rate varied between 1.75 ± 0.66 and 2.48 ± 1.07 $\mu\text{m}/\text{yr}$. However, dating of speleothems exposed to the surface (outside the cave) in unroof caves around Eagle Cave, provides dates as young as 213 ka BP. This is surprising, since apart from existence of speleothems exposed at the surface, cave morphology of the unroof caves is completely lost, supporting a very dynamic process of destruction of cave galleries. The denudation rate calculated by the rock tablet method seems to be too small even to eliminate the collapse blocks of a thin ceiling over the studied speleothem. As previously highlighted in previous studies, different methods to estimate denudation rate provides results that differ in orders of magnitude. Our result supports such conclusions.

Therefore, the main goal of this ongoing research is to apply different methodologies to measure denudation rates, compare their results and estimate which are the benefits and problems that the different methods are providing. As well to improve our understanding of karst denudation rates and the accuracy of the methods used for their evaluation.

IRSL feldspars single-grain geochronology of glacial lakes and ice retreat in the northeastern Canadian shield

Laurence Forget Brisson¹, Tommy Tremblay², François Hardy¹, Michel Lamothe¹

¹Université du Québec à Montréal, Montréal, Canada. ²Canada-Nunavut Geoscience Office, Iqaluit, Canada

Abstract

In the cold-based glacial environments of numerous plateaus from the Canadian Arctic region, the timing of the retreat of the Laurentide ice sheet is of limited knowledge due to the scarcity of datable organic material, and abundance of inherited cosmogenic isotopes in available boulders. Here, we report the results of an extended infrared stimulated luminescence (IRSL) dating program conducted on feldspar single grains on plateaus of Boothia Peninsula, Southern Baffin Island Northwest Baffin Island and Barnes ice cap vicinity. We obtained 36 IRSL ages: 27 on glaciolacustrine deltaic sediments, 2 glaciomarine deltaic sediments, 2 glaciofluvial sediments, 3 littoral sediments, and 2 aeolian sediments. About 600 grains per samples were analyzed. Multiple samples were dated for each ice margin positions, allowing results cross-validation. An important relationship between the sedimentary setting and the importance of IRSL signal bleaching before deposition will be presented and discussed. Glaciolacustrine sediments are shown to be especially variable in the IRSL signal bleaching before deposition, reflected in important dispersion of the single grains ages. The method of age determination from the distribution of single-grain IRSL ages is also discussed. The results show a good correlation with a chronology based on ¹⁴C dating (converted to calendar years) on post-glacial marine littoral shells and inland peat (from various authors, reported in Dyke, 2003).

Abstract

The Altyn Tagh Fault (ATF) is a >1600 km long sinistral fault that marks the northern boundary of the Tibetan Plateau. Previous studies suggest that late Quaternary slip rates along the eastern edge of the ATF diminish towards the east, where the deformation is assumed to be accommodated by a set of thrust faults that splits from the ATF. Here, we examine the possibility that sinistral deformation near the eastern termination of the ATF may also be accommodated along the NE striking ~200-km-long Sanwei Shan fault (SSF) located ~60 km north of the ATF. To characterize the sense and magnitude of slip accommodated along the SSF, we mapped beheaded channels and alluvial fans, and measured indicators for slip orientation on outcrops. At a site located ~30 km east of the city Dunhuang, we found a well-preserved sub-vertical fault surface dipping 83 degrees to the SE with horizontal striations that indicate lateral shear. Fault zone of only several meters and core width of dozens of centimeters suggests that this fault may be fairly juvenile. A beheaded channel mapped ~400 m west of the active channel as well as ~100 m of left-lateral shift of the active channel both indicate left-lateral sense of slip. At another site located ~40 km east of the first site we found a sequence of laterally translocated Quaternary alluvial fans that record up to 600 m of sinistral offset along the SSF since their deposition. Luminescence dating of alluvial sediments from these two sites indicates 1-2 mm/yr of slip across the Sanwei Shan fault during the last ~100 ka. Our results provide new constraints on possible Quaternary slip partitioning at the eastern edge of the Altyn Tagh fault system.

Multiple-generation sandwich-like layers with soft-sediment deformation structures in glaciolacustrine succession of Dyburiai site, NW Lithuania

Szymon Belzyt¹, Małgorzata (Gosia) Pisarska-Jamroży¹, Barbara Woronko², Albertas Bitinas³

¹Institute of Geology, Adam Mickiewicz University, Poznan, Poland. ²Faculty of Geology, University of Warsaw, Warsaw, Poland. ³Nature Research Centre, Vilnius, Lithuania

Abstract

One of the most indicative factor, widely used during determining of seismic or non-seismic mechanisms triggering development of soft-sediment deformation structures (SSDS), is the sandwich-like vertical distribution of layers, i.e. repetitive sequence of deformed layers interbedded by non-deformed sediments. The sequence, comprised of up to nine deformed layers, varying in the following general characteristics: 1) thickness (5 to 50 centimetres); 2) grain size (sandy silt, silty sand, fine sand, silt); 3) bed continuity along with top and base boundary character; and 4) the overall general type of deformation, was observed within a glaciolacustrine succession in the Dyburiai (NW Lithuania), situated within the steeply, incised Miniija river valley. The succession is covered by Upper Weichselian glacial till of the Last Glaciation (MIS 2).

The layers with SSDS, traceable in horizontal extent along a 35-m wide section, exhibit an extraordinary variety of deformation styles. Layers that are coarser-grained (more sand) are dominated by complex load casts – often detached – and pseudonodules of differing scale that display either well-preserved primary intact or deformed sediment lamination.

In the former case, non-deformed internal laminations indicate that the liquefaction process was relatively rapid, and the degree of fluidization was modest due to gentle lithological diversity of sediments. The latter layer group includes finer-grained (more silt & clay) sediments with water and/or sediment-escape structures that inject into overlying sediments – in some cases cutting more than one layer. Their presence suggests an instantaneous increase of internal pressure.

Moreover, the brittle deformations observed in fine-grained deposits cut and intersect the then ductile SSDS, pliable structures that are interpreted to have been formed during preceding stage of plastic deformation. Thus, displacement and/or brecciation along faults had occurred subsequent to the SSDS genesis. This phenomenon clearly indicates an occurrence of a second distinct phase of the deformation process, most likely connected to the ice-sheet loading and glacial till deposition.

All the aforementioned deformed layers features – when taken in context with their described characteristics, along with separately examined interactions related to single SSDS dynamics –

suggest those SSDS are in-form artefacts of an abrupt external force that caused the rapid liquefaction of water-saturated sandy and silty sediment. Their genesis occurred shortly after the deposition of the primary prototypical SSDS form, but before the Last Glaciation ice-sheet advance.

The OSL dating results suggest that intra-morainic silty/sandy succession was deposited, and subsequently deformed, during the Marine Isotope Stage 5d or Early Weichselian.

Triggers for clastic dikes and indicative criteria of their earthquake origin: an overview

Oksana Lunina

Institute of the Earth's Crust, Siberian Branch of Russian Academy of Sciences, Irkutsk, Russian Federation

Abstract

Clastic dikes are often the only evidence of past disasters in poorly exposed areas and therefore their findings are extremely important for earthquake study. However, the variety of their origins greatly complicates the use of clastic dikes to assess the seismic hazards within the manifold environments. In addition to earthquakes, main triggers include desiccation of soft deposits, tectonic extension because of creep, flood, glacial loading, diagenesis in permafrost area, freeze-and-thaw action, tsunami, an inflow of fluid-generating clays in the region of high temperatures and overpressures and subsequent fracturing, storm waves, mass movement, and meteorite impact. Several triggers result in both Neptunian and injection dikes.

A review of differences between the non-seismic and seismic structures shows that characteristic features allow excluding some non-seismic forms from paleoseismological analysis with a high degree of reliability. Thus, all clastic injections except those of seismic genesis are geo-referenced to geological objects (channel banks, glaciers, mud volcanoes, landslides, tsunamigenic beds, and meteorite craters). Besides, most of them are common in the subsurface layer to a depth of 1 m and have a cylindrical shape. In contrast, the configuration of seismically induced injection dikes implies a length many times greater than the width and a height varied from a few centimeters to the first ten of meters at a width less than 1 m. The dikes up to 15 cm wide occur the most frequently and those greater than 1 m are generally associated with lateral spreading through the horizontal extension forces (Obermeier, 1996).

Neptunian dikes are often up to the first meters wide and have a laminated structure marking a stage-by-stage infilling of fractures. However, not all of them contain these characteristics and, therefore, for example, a permafrost wedge could be mistaken for liquefaction features. On the other hand, Neptunian dikes also form in seismic shaking, but identification of their earthquake origin without other residual deformation is challenging. In this regard, for paleoseismic tasks, it is better to rely on injection dikes and to take into account Neptunian ones only when additional evidence (surface ruptures, fractures with a displacement of at least 0.1 m, structural analysis, relation to active faults etc.) is available. Revision of all known features and specific descriptions of clastic dikes has defined 12 general and 12 individual geological and structural criteria (for study in sectional view), which make it possible to establish confidently the earthquake origin of the injection dikes caused by fluidization from seismic liquefaction. The author is going to present and discuss them on the special session of the 20th INQUA Congress.

Soft-sediment deformation structures caused by three trigger mechanisms. Case study from Slinkis, Central Lithuania

Małgorzata Pisarska-Jamroży¹, Szymon Belzyt¹, Barbara Woronko², Albertas Bitinas³

¹Institute of Geology, Adam Mickiewicz University, Poznań, Poland. ²Warsaw University, Faculty of Geology, Warsaw, Poland. ³Nature Research Centre, Vilnius, Lithuania

Abstract

Different geomorphic processes can result in similar looking deformation structures. When in search of a structure's provenance the identification of a trigger mechanism(s) is not inconsequential, especially when that trigger(s) has in evolution reworked an earlier generation of deformations. Two important points are here presented: 1) there are distinct lithological differences between deformation structures caused by differing trigger mechanisms, each having arisen in a singularly particular way so as to allow their classification; and 2) there are attendant temporal associations that further help to explain the developmental course of soft-sediment deformation structures (SSDS).

An extraordinary array of Pleistocene deformation-structure layers has been observed in a five-metre high riverbank section. The exposure is comprised of a succession of fine-grained meandering river terrace deposits in the Slinkis outcrop close to Serežius village, occurring along the Dubysa River valley at near its junction with the Nemunas River. We suggest three different site-specific trigger mechanisms are responsible for the development and/or reworking of a previously formed arrangement of SSDS.

The first group of deformation structures—ice-wedge casts and small-scale faults—are linked to periglacial processes that indicate a break in sedimentation had occurred. The second group of deformation structures—detached and undetached sandy load casts, silty flame structures, and injection structures like fluid-escape structures—are connected to occurring liquefaction (probably linked to earthquake activity). The fine-grained sediments were first deposited on the floodplain. Shortly after deposition the sediments were likely again deformed as an effect of glacio-isostatic adjustment—an artifact of shock-induced liquefaction of water-saturated sediments during consolidation. The Slinkis outcrop is positioned between two superregional W–E trending fault zones—Šilutė-Polock and Northern Prieglius-Birštonas—being a region classified as the most hazardous seismotectonic zone in Lithuania (Lazauskiene et al. 2012). The third group of deformation structures—brittle deformations like reverse faults—are linked to glaciotectonic processes. Faults cut and intersect load structures associated with the second group of deformation structures that had developed as an effect of a precedent liquefaction processes. The Last Glacial ice sheet had advanced resulting in the deposition of thick glacial diamictons at the uppermost part of succession, and is coeval with the development of reverse faults along the entire geologic column as described in the Slinkis outcrop.

Specific soft-sediment deformation structures of the Eastern Baltic Region: correlation with tectonic framework and seismic activity

Albertas Bitinas¹, Małgorzata Pisarska-Jamroży², Jurga Lazauskienė³

¹Nature Research Center, Vilnius, Lithuania. ²Institute of Geology, Adam Mickiewicz University, Poznań, Poland.

³Lithuanian Geological Survey, Vilnius, Lithuania

Abstract

For many years the entire eastern onshore of the Baltic Sea has been considered as a low seismic activity area. There were two main reasons that seismic activity has not been adequately assessed: 1) *a priori* prevailing opinion that the region, as a stable part on the Eastern European Craton, is of a very small seismic activity, and 2) lack of experience and skills to identify reliable traces of palaeo-earthquakes. But this opinion began to change essentially after a few earthquakes that occurred in 1976 in Estonian Osmussaare island (4.7M), in 2004 in the Kaliningrad Region of Russian Federation (5-5.2M).

The large amount of palaeoseismological data collected from different regions in recent years show that each earthquake trigger creates a signature on the geology and the geomorphology. Moreover, it was observed that in a number of earlier publications the all soft-sedimentary structures (SSDS) were attributed to the structures triggered by different geological processes – permafrost, slope processes, glaciotectonism, activity of living organisms, soil-forming processes, etc. But it was obvious that a part of the mentioned SSDS could have been caused by processes of sediment liquefaction what, possibly, was triggered by earthquakes caused by glacio-isostatic crustal rebound. There is a problem with the trigger mechanisms because liquefaction can be induced in many ways including, e.g. earth tremors, meteorite impact, tsunami and sediment loading. However, no criteria are known to distinguish liquefaction induced by different sources. Moreover, multi-triggering mechanisms can lead to multiple origins of SSDS, so it is difficult or even impossible to decide which one finally produced the SSDS in sediments. Finally, insight into the apparent discrepancy between the tectonic reaction of the earth crust during ice advance and ice retreat is necessary, and tracing faults in the bedrock which may have been reactivated during glaciation and deglaciation phases.

The seismo-tectonic framework of the Eastern Baltic Region has been outlined several times during the last decades, but not yet reliable tectonic framework was carried out – rather different tectonic and seismotectonic maps of the Eastern Baltic region exist. Moreover, correlation of SSDS with tectonic framework and seismic activity are still problematic due to number of reasons: it is impossible to associate single earthquake with some certain faults unambiguously due to significant errors of location of seismic events and faults location; the identification of the seismogenic faults is rather complicated due to the small scale of tectonic structures; not all the earthquakes in the Baltic Region are related to fault zones; etc.

Acknowledgements. The work has been financially supported by project GREBAL from the National Science Centre Poland No. 2015/19/B/ST10/00661.

Sand injectites in Quaternary sediments of the Central Yangsan Fault zone, SE Korea

Kyoungtae Ko, Yong Sik Ghim, Hoil Lee, Jin Cheul Kim

Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

Abstract

Since the 2016 Gyeongju Earthquake (Mw 5.8), the Quaternary fault research around the Yangsan Fault Zone is now under investigation in order to extract paleoseismological information for assessing earthquake hazard assessment. However, because of thick Quaternary cover as well as relatively low slip rates, it is difficult to recognize Quaternary fault on the surface, particularly in the central part of the Yangsan Fault Zone. Therefore, earthquake-induced, soft-sediment deformation structures (seismites) can give us useful paleoseismological information. Thus, we conducted a trench survey on the fluvial terrace in order to find the seismites and extract paleoseismological information from them. We have excavated the ground and acquired 4.6 m deep, 14 m long, and 4 m wide trench section. Based on grain size and stacking patterns, the Quaternary sediments on the trench section were divided into 8 units, mostly deposited by episodic river floods together with minor debris flows. We found vertical to horizontal aligned sand patch or dikes at a depth of ~ 3 m from the surface. They are composed of moderately to well sorted coarse to very coarse sand. This kind of structures can be formed by biological activities; however, we inferred them as sand injectite based on their occurrence and ichnological analysis. In addition, an undeformed overlying muds layer is inadequate to build up the pore pressure to underlying sediment layers. Therefore, we interpreted they are seismites. According to the C^{14} age dating from drilling core acquired from nearby areas, age of equivalent Quaternary sediments have been estimate at > 50,000 yrs BP. Therefore, this contribution shows that, at least, one moderate to strong earthquake (> Mw 5.0) occurred 50,000 yrs BP. around central part of the Yangsan Fault Zone.

Pleistocene lacustrine sediments with multiple, sandwich-like deformed layers (Baltic Sea bluff at Baltmuiža, western Latvia)

Piotr Paweł Woźniak¹, Szymon Belzyt², Małgorzata Pisarska-Jamroży², Māris Nartišs³, Kristaps Lamsters³, Barbara Woronko⁴, Albertas Bitinas⁵

¹University of Gdańsk, Gdańsk, Poland. ²Adam Mickiewicz University, Poznań, Poland. ³University of Latvia, Riga, Latvia. ⁴Warsaw University, Warszawa, Poland. ⁵Nature Research Centre, Vilnius, Lithuania

Abstract

The Baltmuiža site is located at the Baltic Sea bluff in the western Latvia. The study area was completely covered by Late Weichselian ice sheet, and at the end of glaciation experienced an additional, local ice-advance event of so called Apriki glacial tongue. As an effect of the advance, older sediments have underwent a heavy diapirization. Late Weichselian till is underlain by – up to 40-metres-thick – sands and silty sands. They were deposited at the margin of an extensive freshwater basin, in MIS 3 according to OSL dating results. Along the Baltic Sea bluff near Baltmuiža in these sediments occur layers with ‘trapped’, internal soft-sediment deformation structures (SSDS). Five layers with SSDS, sandwiched in generally not deformed sediments, were recognized there. The deformed layers are commonly rich in load casts and pseudonodules, injection structures and fluid-escape structures. Additionally, the thickest layer with SSDS is divided into sublayers characterized by different-scale (from millimetres up to 15 centimetres) load casts and pseudonodules, separated from each other by deformed clay laminae. Almost all layers with SSDS have an eroded top boundary.

Comparing the size of deformation, extent and structural features, the recognised layers with SSDS seem not to be directly connected with commonly observed in the vicinity of the Baltmuiža site glaciotectionic deformations (large-scale diapirs, folds, reverse faults). What is more, due to the basal ice sliding of Apriki glacial tongue, small-scale Late Weichselian subglacial deformations are limited to a thin layer of the topmost part of the studied sediments. The SSDS developed metadepositionally, in multiple stages, most probably just after the deposition of lacustrine sediments during MIS 3. Furthermore, Late Weichselian glaciotectionic processes caused that the layers with SSDS are deflected from the original horizontal position. The most probable trigger mechanisms responsible for the origin of the studied layers with SSDS include: (1) the glacioisostatic rebound affecting the crustal faults instability, (2) a local, seismic event (tremor) of moderate magnitude, caused e.g. by glaciotectionic processes. As a trigger that induced Late Weichselian modifications of previously developed SSDS cannot be excluded: (1) an ice loading at the final stage of glaciation, and (2) a local seismic event (tremor) of moderate magnitude caused e.g. by ice-blocks fall/collapse.

Soft-sediment deformation structures in diatomaceous mud related to a well-constrained historical earthquake record (Lago Riñihue and Lago Calafquén, Chile)

Ariana Molenaar¹, Jasper Moernaut¹, Maarten Van Daele², Marc De Batist², Gerald Degenhart³, Michael Strasser¹
¹University of Innsbruck, Innsbruck, Austria. ²Ghent University, Gent, Belgium. ³Medical University of Innsbruck, Innsbruck, Austria

Abstract

Previous studies proposed a link between earthquake magnitude or seismic intensity and the type and size of different soft-sediment deformation structures (SSDS). However, most of these studies were done on prehistorical records in outcrops inhibiting a direct comparison between recorded earthquake parameters and SSDS. Our study investigates SSDS in sediment cores of Chilean lakes and evaluates their occurrence and style by comparison with a well-constrained earthquake record based on historically documented seismic intensity and corresponding turbidites in depositional basins.

Sediment in the Chilean lakes consists of laminated diatomaceous mud intercalated with fine-sand tephra layers. We observe four different types of SSDS using X-ray computed tomography scanning: i) disturbed laminations, ii) folds, iii) faults and iv) mixed layers. Detailed core correlation using tephra and lahar marker layers allows for pairing of SSDS with individual events through the well-dated earthquake-induced turbidite record. The five recorded earthquakes had Modified Mercalli Intensities (MMI) of VII½ and VI½ at site. We observe more SSDS (i.e. at more coring sites) for the earthquakes causing higher intensities at site, suggesting a positive relation between seismic intensity and SSDS occurrence. Furthermore, disturbed lamination occurs most at MMI VI½, whereas folding is almost only observed for MMI VII½ events. These findings are in agreement with those obtained by studies in other settings (e.g. Lake Lisan). Nevertheless, we also observe SSDS that cannot be linked to any of the five large earthquakes. These could be related to smaller seismic events or other triggering mechanisms. Also, our data suggests a linear relationship between SSDS occurrence and slope gradient (ranging from 0.2°-4.3°) implying that gravitational downslope stress influences a slope's propensity to SSDS development. However, we suggest that SSDS occurrence at slope angles of 0.2° is solely influenced by seismic shaking as these slopes are considered stable. High-resolution peripheral quantitative computed tomography (HR-pQCT) scans of different SSDS types ranging over layers of both tephra and diatomaceous mud will help further investigate the mechanisms behind SSDS formation by studying their basal shear surface in very-high resolution.

Our study site allows for the investigation on the influence of different lithologies (i.e. diatomaceous mud and tephra layers) on SSDS development. Moreover, the correlation of individual SSDS with well-studied historical seismic events in two different lakes provides a unique opportunity to directly study the relation between seismic shaking, slope gradient and SSDS formation.

High-resolution seismic study as a tool for sequence stratigraphic evidence of latest Pleistocene-Holocene sea-level changes of the Korea Strait

Dong-Geun Yoo, Gwang-Soo Lee, Seok-Hwi Hong, Gil-Young Kim
Korea Institute of Geoscience and Mineral Resource, Daejeon, Korea, Republic of

Abstract

An extensive grid of high-resolution seismic profiles combined with sediment data give a good evidence for the high-frequency sequence stratigraphic reconstruction in this area. The results reveal that the shelf sequence forms a high-frequency sequence, which consists of a set of lowstand, transgressive, and highstand systems tracts formed during the latest Pleistocene-Holocene. Three systems tracts include eight depositional systems, each with different seismic facies and geometry. During the LGM, the sea level was about 120-130 m lower than present and the paleo-shoreline was located on the shelf margin near the Korea Trough. Most of the shelf was completely exposed, resulting in subaerial erosion associated with paleo-channel incision by the Nakdong and Sepojin Rivers. The paleo-river extended to the shelf margin, directly supplying large amounts of terrigenous sediments to shelf margin and trough region. These sediments were trapped within the trough and adjacent area, which form the lowstand prograding wedge (SU1) and the mass flow deposit (SU2), regarded as the lowstand systems tract.

The transgressive systems tract between the transgressive surface and maximum flooding surface includes five depositional systems, which show a succession of backstepping depositional arrangements: (1) ancient beach/shoreface deposit (SU3), (2) incised-channel fill (SU4), (3) thin sand sheet (SU5) (4) sand ridge system (SU6), (5) estuarine/deltaic complex (SU7). Five depositional systems can be grouped into two distinct groups (paralic and marine) bounded by a ravinement surface. Lower three depositional systems (SU3, SU4, SU7) belong to a paralic component that consists of the sediment preserved from shoreface erosion. The top of paralic unit is truncated by a ravinement surface and overlain by marine component. The marine component includes three depositional systems (SU5 and 6) consisting of the sediment produced through shoreface erosion during the Holocene transgression. The highstand systems tract above the maximum flooding surface is composed of a prodelta/shelf complex (SU8) consisting exclusively of recent muds. As the sea level reached the present position (6 ka), the sediment derived from Nakdong and Seomjin rivers are deposited in the inner shelf, forming the SU8 as a inner-shelf mud deposit.

P-2830

The first geological record of the historical earthquakes in the Korean Peninsula

Yongsik Gihm, Jin-Hyuk Choi, Sung-ja Choi, kyoungtae Ko
Korea institute of geoscience and mineral resources, Daejeon, Korea, Republic of

Abstract

Since the 2016 Gyeongju earthquakes ($< M_w 5.8$), SE Korea, paleoseismological information has been important to assess the seismic hazard assessment in those area. After detailed geomorphic analysis, we excavated the ground on the Quaternary segment of the Yangsan Fault, to gather its paleoseismological information. The trench site is composed of alternating layers of sand (or gravelly sand) and mud, inferred to have been deposited by episodic flooding on alluvial fan surface, and their ^{14}C age is younger than 1400 B.P. We also found a series of soft sediment deformation structures (SSDS; load and flame structures). Based on the detailed sedimentological analysis together with context-based evaluation, we interpreted the SSDS to have been formed by seismogenic liquefaction and associated fluidization. This interpretation is also well matched with historical liquefaction records of the 1643 Ulsan earthquake in SE Korea. Thus, this finding is the first geological records of the historical earthquakes in SE Korea and implies the minimum magnitude of the 1643 Ulsan Earthquake exceeding $M_w 5.0$.

Stone pavements: a promising archive for paleoenvironmental research!?

Markus Fuchs¹, Michael Dietze²

¹Department of Geography, Justus-Liebig-University Giessen, Giessen, Germany. ²GFZ German Research Centre for Geosciences, Section 5.1 Geomorphology, Potsdam, Germany

Abstract

Reconstructing the evolution of arid landscapes is vital but challenged by the limited availability of appropriate environmental archives. A widespread surface feature of arid landscapes – stone pavement – traps eolian fines and promotes formation of an accretionary archive, growing with time and thereby recording essential information about the conditions under which it evolves. Here, we give a state-of-the-art overview to stone pavement research and discuss constraints for reconstructing Quaternary environmental change. We present regional studies from Jordan, Israel, the Canary Islands and the western USA, and finally focus on the chronostratigraphic interpretation of stone pavements and their eolian fines, using OSL dating.

Late Quaternary paleoenvironmental evolution of the proximal area of the Atuel-Diamante distributive fluvial system, South America

Alfonsina Tripaldi¹, Adriana Mehl², Paul Hesse³, Florencia Lorenzo², Marcelo Zárate², Rory Williams³

¹IGBA-UBA-CONICET, Buenos Aires, Argentina. ²INCITAP-UNLPam-CONICET, Santa Rosa, Argentina. ³Department of Environmental Sciences, Macquarie University, Sydney, Australia

Abstract

Distributive fluvial systems (DFS) have been described worldwide under diverse climatic and tectonic setting. Studying the deposits of present DFS contributes to understanding Quaternary landscape evolution, doing paleoclimatic inferences, and improving facies models for interpreting sedimentary records. The eastern Andean piedmont, southern South America, shows several DFS, like the recently defined Atuel-Diamante DFS (Fig. 1). The Atuel and Diamante rivers carry seasonal meltwater from the Andes Cordillera and flow to the east. They are deeply entrenched in the San Rafael tectonic block where, at its eastern piedmont, they generate the DFS. This system has been barely studied in terms of its geomorphological, paleohydrological and landscape evolution. A doctoral thesis recently finished and associated investigations in progress have started to expose and interpret its morphology and late Quaternary history. In this presentation we characterize the deposits of the proximal area of the Atuel-Diamante DFS, with the aim of interpreting the late Quaternary paleoenvironmental evolution and to infer paleoclimatic variability. Methodology included geomorphologic mapping by remote sensing, field survey, stratigraphic section analysis of pedosedimentary facies, with AMS and luminescence chronology. We studied 5 localities along a SW-NE transect (Fig. 1a) where information was obtained at exposed deposits, pits and by augering. Present climate is temperate semiarid, influenced by the Andes rain shadow and the South Atlantic and South Pacific anticyclones. The fluvial drainage is, at present, a misfit system due to the current interglacial, the presence of agricultural irrigation networks and hydroelectric power dams on the Atuel and Diamante rivers. The proximal area, besides the gravel-sand Atuel and Diamante streams, shows many abandoned meandering channels and associated floodplains, with deposits dominated by silty fine sand and silt, together with minor gravelly sand-silt, forming fining-upward successions. Stabilized dune fields restrict, to the north and south, the studied DFS, where the aeolian medium to fine sand was also described and sampled to decipher the aeolian-fluvial relationship. Previously obtained chronology shows, in the Atuel River, a late Pleistocene-early Holocene record in an upper most, 8 m thick, fluvial terrace, suggesting important fluvial aggradation during the last glacial termination and a significant change in the system with extensive incision at early-mid Holocene. OSL ages in progress will provide detail about the mid-late Holocene evolution of the Atuel-Diamante DFS, and all together will offer data for paleoclimatic inferences.

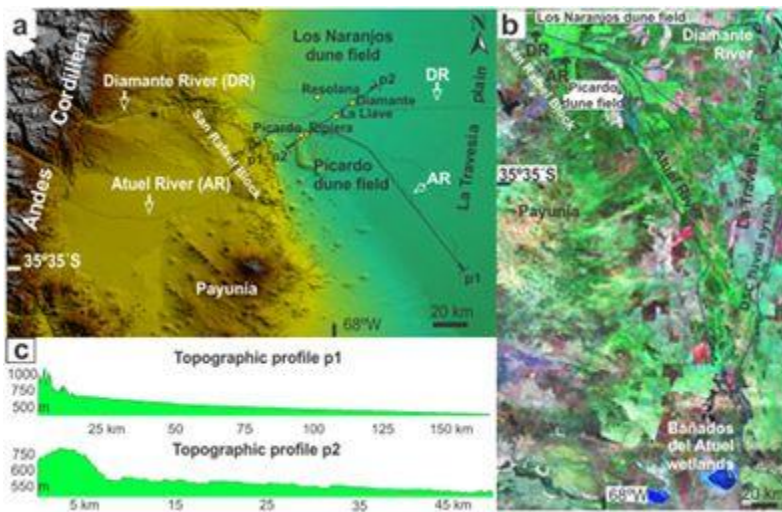

Figure 1: The Atuel-Diamante DFS, eastern piedmont of the San Rafael Block, and related tectonic structural and geomorphological elements in: a) SRTM digital elevation model, and b) Landsat ETM image; c) topographic profiles p1 and p2 along longitudinal and transverse transects, respectively. Diamante, La Resolana, La Llave, Ripiera and Picardo are study localities.

Grain size and their potential correlations to the dune stabilization along the Keriya River in the Taklamakan Desert, northwestern China

Ye Zhou, Xiaoping Yang
Zhejiang University, Hangzhou, China

Abstract

We studied the grain-size characteristics of the surface sediments from fixed, semi-fixed, mobile sand dunes and fluvial sand first and then discussed their possible link to the desertification process along the Keriya River, in the southern part of the Taklamakan Desert. Gaussian and Weibull function fitting techniques are used to quantitatively separate the poly-modal grain-size distribution system into independent individual components. We found out that the Gaussian distribution is better than Weibull function fitting in the case of Keriya River sediments. In addition, two to four sub-populations are identified by End Member Mixing Analysis. End Member 1 (EM1) with mode at $2\mu\text{m}$, correlates with well-sorted populations of finer-grained collected from the loess of Kunlun mountains above 3000 m. It should be transported by the westerlies, representing the atmospheric background value; EM2 with mode at $10\sim 13\mu\text{m}$, correlates with samples that contain moderately sorted populations and associated with vegetated interdunes, sandy loess and fluvial sand. This portion should be carried by East Asian winter monsoon (EAWM); EM3 with mode at $56\sim 90\mu\text{m}$, associated with samples of moderately to poorly sorted fine-grained collected from areas of vegetated interdunes, loess, sand loess and fluvial sand. This should be transported in the form of suspension by the EAWM; EM4 with mode larger than $250\mu\text{m}$, associated with moderately well sorted coarse and very coarse-grained sands collected from fluvial sand and mobile sand dunes, reflecting transportation in the form of saltation by the EAWM or fluvial processes. Finally, we compared the Landsat 8 image (2008) with Landsat 8 image (2018), and observed a decrease of NDVI, indicating that the desertification expanded along the Keriya River. The grain size result indicated that along with the increase of desertification level, the EM1 and EM2 populations decreased, while the EM3 and EM4 populations remarkably increased. These regional variations are probably associated with the reducing fixation degree of the dunes in the last decade.

P-2834

Wind induced changes in barchan-to-parabolic dune morphology and their sedimentological reorganization

Deguo Zhang¹, Peng Liang², Xiaoping Yang¹, Hongwei Li¹

¹Zhejiang University, Hangzhou, China. ²Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The development and transformation of barchan-to-parabolic dunes can be led by vegetation establishment, which may be induced by climate change and/or human intervention. However, little is known about the impact of wind strength change-induced vegetation restoration on dune morphology and the surface sedimentary features response to this process. Here we show that increased growing season NDVI related to the significant decrease in drift potential (DP) in the Mu Us Sandy Land during the entire study period (1982 to 2015). Further temporal analyses indicate that the increasing NDVI trends were largely contributed by decreased wind strength and temperature changes during the earlier study period (1982-2006). Furthermore, the increasing NDVI was consistent with the slightly increasing trend of precipitation from 2006 to 2015. Therefore, the initiation of dune transformation may have been caused by reduced wind strength favouring vegetation establishment and growth. Once dunes surfaces are covered by vegetation, the transformation processes are more sensitive to precipitation changes. To reveal the response of sedimentological reorganization during the dune transformation processes, grain-size characteristics along the longitudinal profile of three different types of dunes were examined. From barchan dune through transition dune to parabolic dune, with the increase of the fine sands (125-250 μm) proportions, the mean grain size (M_z) gradually decreased; in addition, as the very fine sands (<125 μm) class increases, the sorting (σ_1) of sand dunes gradually became worse. The decreasing wind strength lead to partly transport of fine sands on the upper part of dune windward slope, resulting in the progress coarsening and the reduction of dune height at the crest area. No distinct trend in sorting and mean grain size on the windward slope of transition dune, indicating that sand in transport had little influence on the particle size distributions. Conversely, the progressive of sorting and coarsening of sands towards the crest of parabolic dune, implying that vegetation limited the sands from upwind of dune, changed the effective source of dune into the underlying source deposits or reworking pre-existing aeolian deposits and trapped the sands on the crest area.

P-2835

Using post-IR IRSL luminescence methods to constrain the timing of alluvial “cut and fill” in the Great Karoo, South Africa

Christopher Oldknow¹, Andrew Carr², Janet Hooke³

¹Key Laboratory of Western China's Environmental Systems, Lanzhou University, Lanzhou, China. ²School of Geography Geology and the Environment, University of Leicester, Leicester, United Kingdom. ³Department of Geography and Planning, University of Liverpool, Liverpool, United Kingdom

Abstract

Headwater valleys in the Great Karoo, South Africa record past phases of incision, aggradation and wetland formation as alluvial “cut and fill” deposits. Until now, an understanding of their age structure has been confounded by: (i) a lack of organic material for ¹⁴C dating; and (ii) the frequent unsuitability of quartz for luminescence dating (in terms of both quartz performance and the relatively high environmental dose rates). To resolve this, we investigated the suitability of K-feldspar post-Infrared Infrared Stimulated Luminescence dating (pIRIR) methods at several outcrops exposed in a low-order tributary (Africanders River) of the Wilgerbosch catchment in the Sneeuwberg.

Single aliquot pIRIR protocols perform well, with consistently good recycling, good dose recovery and low recuperation. A critical concern, given the sedimentary context and use of the post-IR feldspar signal, is the issue of adequate bleaching prior to burial. This is considered via comparison with the more easily bleached (but fading) IR50 signal and with a limited number of rigorously screened quartz ages (Oldknow and Hooke, 2017). The latter approach demonstrates good overlap with the pIRIR₁₇₀ ages: (e.g. LV509: 8.2 ± 1.5 ka (quartz); 8.5 ± 0.8 ka (pIRIR₁₇₀)). pIRIR methods using the less fading prone, but also less bleachable high temperature post-IR stimulation temperatures (pIRIR₂₂₅ and pIRIR₂₉₀) are shown to result in significant age overestimates. However, measured fading rates for the pIRIR₁₇₀ signal are small (g values 0.1-1.6% per decade) allowing us to establish a new chronology comprising 23 pIRIR₁₇₀ ages.

The ages are all (given 1σ uncertainties) in the correct stratigraphic order. The chronology reveals four major phases of net aggradation: (i) 2.6 m of sediment accumulated from ~58-40 ka and was followed by a phase of soil formation; (ii) minor incision followed by a further 2 m of floodplain aggradation occurred ~39-37 ka; during which time an elevated water table resulted in the formation of wetlands; (iii) 1.6 m of sediment accumulated from 30-25 ka; and (iv) approximately 4 m of sediment accumulated ~14.6 ka. These phases of aggradation (with the exception of ii) were interrupted by at least two phases of incision at: (i) 37-30 ka (draining the wetland); and (ii) 25-17 ka. During the Holocene, infilled palaeogully architecture (e.g. LV627: 5.7 ka) attests to phases of incomplete incision with subsequent refilling. This study demonstrates the great potential of the pIRIR₁₇₀ protocol to constrain the timings of past geomorphic and hydrological changes in this semi-arid landscape, revealing major landscape adjustments throughout the late Pleistocene. The environmental drivers of such adjustments will be considered.

Abstract

The Taklimakan Desert, the largest sand sea in China, is one of the most important dust sources and of the extreme arid region in the world. The complex stratigraphy of eolian deposits in desert margin with multiple mechanism of transporting processes and lack of organic matter for dating have hindered the progress of studying paleoclimate changes in this setting. Here we investigated the loess and oasis deposits from the south margin of the desert by numerous AMS ¹⁴C and OSL dates and environmental proxies. We identified millennial-scale abrupt regional moisture changes during the late last Glacial and interpreted they appear to be influenced by the interplay of Asian summer monsoon circulation and mid-latitude Westerlies jet streams.

One striking sedimentation hiatus of regional dust deposition occurred during ca. 70-15 ka, while an episodic outbreak accumulation period (ca. 15-10) was observed at two loess sites on foothills where gully landform supports the eolian cannibalism hypothesis. We also observed the different mechanism of dust transporting processes at different altitudes of 2700 m and 3700 m asl in the same region. Based on a reasonably reliable chronology of the Holocene, the dust records clearly confirm an out-of-phase relationship between the low and high elevations in this region. We examined the concurrent locations and intensity of subtropical jet stream (SJS) and polar jet stream (PJS) to interplay with the low-level atmospheric circulations, e.g. East Asian winter monsoon. We found that lower level convergent and upper level divergent could explain this out-of-phase relationship for the sedimentation records at 27,00 and 3700 m asl. in the southern margin of the Taklimakan Desert.

Abstract

Reconstructing environmental change in dunefields, locations where aeolian dunes interact with fluvial systems and lake shorelines, requires wide spatial coverage and dense chronologies. This is extremely time-consuming and resource intensive if laboratory-based luminescence dating of samples is used in isolation. Portable luminescence readers (POSL) (Sanderson and Murphy, 2010) provide a useful means of generalising chronologies within simple systems, and of helping to understand more complex systems through a combination of *in situ* analyses and laboratory procedures. Here we explore datasets from: (i) 148 dune and 100 lake shoreline samples across southern Africa and (ii) dune damming sediments (DDS) within the Negev, Israel (Roskin et al., 2017), where insights into bleaching histories, sediment luminescence sensitivity and sample age can be gained through a combination of simple POSL profiling and laboratory calibration of luminescence-sensitivity, coupled with SEM analysis.

The southern African datasets show that POSL signals from bulk samples regressed against laboratory-based ages on quartz can be used to calibrate POSL signals into first-order age estimates, and that a regionally-specific approach is needed for different dunefields across the subcontinent (r^2 of 0.99, 0.93, 0.81 and 0.52) (Stone et al., 2018). Sample composition, such as quartz to feldspar ratios, account for the largest spatial contrasts, and sample luminescence-sensitivity may also influence signals. For the lake shoreline data, factors other than sample burial age are contributing to the POSL signals but with no clear single factor. The Negev case study shows an example of reflexive geomorphology in a more complex DDS setting using POSL alongside laboratory irradiation and SEM analysis. The different DDS could be identified from bulk samples at this vegetated linear dune (mostly stabilised since the Younger Dryas), after accounting for: (i) luminescence sensitivities through calibration, (ii) inherited luminescence signals based on depletion rates and (iii) stratigraphic position. Apparent ages for emplacement of both fluvial and aeolian units can be established providing a coherent basis for interpreting the environmental history of the DDS.

Overall the POSL approaches discussed here provide cost- and time-effective means of generalising chronostratigraphies over large areas in both simple and complex systems, in order to reconstruct Quaternary environmental changes.

Late Pleistocene and Holocene dune accumulation in the Shaybah area, eastern Saudi Arabia

Charlie Bristow¹, Khalid Abdulsamad Hasan Alramadan², Nicholas Lancaster³, Amanda Keen-Zebert³

¹Birkbeck University of London, London, United Kingdom. ²King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia. ³Desert Research Institute, Reno, USA

Abstract

Large compound crescentic megadunes characterize the northern Rub' Al-Khali sand sea in Saudi Arabia and the Liwa area of the United Arab Emirates, where they form a distinctive wet aeolian system with near surface groundwater levels. Studies in the Liwa area suggest a long (>150 ka) history of episodic aeolian accumulation influenced by fluctuating Pleistocene groundwater levels, as well as rapid Holocene accumulation (Bray and Stokes, 2003; Stokes and Bray, 2005). Little evidence exists for latest Pleistocene dune accumulation, unlike in areas of linear dunes to the north in the UAE.

Dune and interdune deposits were studied and sampled for OSL dating and mineralogical analysis in the Shaybah area of the Eastern Province of the Kingdom of Saudi Arabia. Dune samples were collected from sands exposed in a large sand quarry excavated in a large (167 m-high) mega-crescentic dune. Interdune sabkha samples were collected from aeolian sand deposits exposed in pits excavated for road building materials.

Field observations of fine grey laminae interbedded with the dune sand suggest that the sands were deposited at a time when there was more dust deposition. The presence of root casts suggests that there was some vegetation present when these sands were deposited.

We report the results of the OSL dating and compare them to the record from Liwa and elsewhere in the region. Preliminary and unpublished ages from Shaybah and Liwa suggest that latest Pleistocene dune accumulation occurred throughout the area, contrasting with previous models for the Liwa area (Stokes and Bray, 2005).

Holocene dune activity in the Thar Desert, India.

Aayush Srivastava, David Thomas, Julie Durcan
University of Oxford, Oxford, United Kingdom

Abstract

The sand dunes in the Thar, which are predominantly shaped by southwest Indian Summer Monsoon (ISM), provide an important archive of past climatic and geomorphological change. Whilst a small number of studies have undertaken geochronological investigations of dunes using luminescence dating, studies have been sporadic and have tended to rely on older dating protocols [1]. As a result, the temporal and spatial analyses of Thar dune accumulation histories and their comparison with growing multiproxy framework of past environmental dynamics become difficult. To address this, systematic sampling of dunefields was carried out in different regions in the desert. Sites were selected to form a transect across the modern precipitation gradient, and linear and parabolic dune forms, which have a high sediment preservation potential, were targeted. Optically stimulated luminescence (OSL) dating was used to provide a chronological framework, with the aim of inferring dune sensitivity to palaeoenvironmental change, and the time scales over which they register and preserve the palaeoenvironmental record.

Presented here is a new set of 60 OSL-dated dune accumulation chronologies from the Thar and their comparison with a range of proxies from both terrestrial and marine records. The chronology shows a near continuous record of dune accumulation throughout the Holocene. In contrast to previous studies, there are widespread records of dune accumulation between ~11.7 ka and ~8.5 ka coinciding with early Holocene monsoonal intensification, as well as during mid- to late Holocene when monsoons were weak. High accumulation rates are reported in the last century, suggesting that potential drivers of dune mobility in modern times include a strong anthropogenic dimension [2]. The comparison of Thar dune records with other terrestrial records demonstrates that there is no clear, consistent relationship between the timing of dune accumulation and periods of aridity as suggested earlier. The study concludes that a strategic approach to sampling coupled with robust dating protocols allow the scope for a more complex chronology to be identified and subsequently enhance our understanding of dunefield development and palaeoenvironments.

Pollen transport and deposition in semi-arid and arid lands from North Africa

Sahbi Jaouadi¹, Vincent Lebreton¹, Gonzalo Jiménez-Moreno², Christopher Hunt³

¹Département Homme et Environnement, Muséum National d'Histoire Naturelle, UMR 7194 CNRS, Paris, France.

²Departamento de Estratigrafía y Paleontología, Universidad de Granada, Granada, Spain. ³Liverpool John Moores University, School of Natural Sciences and Psychology, Liverpool L3 3AH, United Kingdom, Liverpool, United Kingdom

Abstract

The main objective of this study is to provide key information toward developing a comprehensive model of pollen transport and deposition in arid lands. Recently, Holocene sedimentary sequences have been retrieved in sebkha temporary lakes (playa-lake) from Tunisia (North Africa), and pollen analysis were undertaken (Lebreton et al., 2015; Jaouadi et al., 2016). However, pollen-based environmental reconstructions in semi-arid and arid lands are limited by a lack of knowledge regarding the processes controlling pollen transport and incorporation into the sediment, and the implications of such processes for the interpretation of fossil pollen records.

Water is the most important transport agent of pollen assemblages buried in sebkhas and other local humid sedimentary environments in arid lands. The pollen record is mainly controlled by inputs from the rivers catchment area by surface washes and sediments reworking during flood events. It is important that we characterise such processes and evaluate their implications for the interpretation of fossil pollen data. In this study, we present a dataset of sixty modern pollen spectra obtained from soil surface samples gathered in Central Tunisia in different steppe biomes located between the Mediterranean forest and the Sahara. Samples were collected in watersheds, watercourses, and on the surface of sebkhas in order to monitor pollen production, dispersal and sedimentation of the dominant plant taxa in the local and regional vegetation.

The results indicate a good overall correspondence between the pollen record on the surface of the temporary lakes and the vegetation associations of the watersheds. However, pollen records are less accurate 1) during extreme flooding events with clastic sediments reworking and 2) in some subdesert environments and small catchment area where pollen spectra reflect local halophytic vegetation.

Abstract

Continental-scale surface temperature reconstructions show, with high confidence, multi-decadal periods during the Medieval Climate Anomaly (950-1250 AD) that were in some regions as warm as the late 20th century. These regional warm periods did not occur as coherently across regions as the warming in the late 20th century, but they have been used to hypothesize that this warming forced the Pyrenean glaciers to disappear. Thus, the current ice that we observe in relict glaciers would have been formed during the Little Ice Age (1600-1850 AD). To test this hypothesis and confirm whether or not warming of the last 50 years exceeds the natural variability of the last millennia, we present the preliminary results obtained from an ice coring in Monte Perdido glacier in the Central Pyrenees, northern Spain, which is the first ice coring in this mountain range. Initially, to find the areas where we could expect the oldest ice, we developed a numerical model of glacier dynamics that tracks the ice particles from their deposition at the top of the glacier till their melt at the glacier front. This model requires, as input data, the ice-thickness distribution, which was determined by means of georadar field campaigns. Dating the ice has been approached by various techniques, including ²¹⁰Pb and ¹⁴C dates (on organic remains, pollen concentrates and water-insoluble organic carbon –WIOC– on ice). The study of ice samples taken along an elevation transect from the oldest ice to the most recent layers allowed us to date the glacier ice. Additionally, it provided a new record of past climate variability allowing to better understand the climate system, its natural variability in the past and the impacts of abrupt climate changes on the high mountain environment. This study includes stable isotopes analyses ($\delta^{18}\text{O}$) as potential paleothermometer, the interpretation of pollen content in terms of vegetation cover, the quantification of chemical content (e.g. eolian dust, heavy metals or black carbon) and the identification of microorganism associations (bacteria). The interpretation of all these proxies and dating outcomes as a whole provides evidences of the persistence of the glacier during the Medieval Climate Anomaly. It also suggests that other recent warm periods were not warmer (or drier) than late twentieth century, and proves that we are facing an unprecedented retreat of the Pyrenean glaciers.

Equilibrium Line Altitude reconstruction of the LGM paleoglaciers between the south-eastern Alps and the Northern Dinarides

Giovanni Monegato¹, Renato Roberto Colucci², Manja Žebre³

¹CNR - Institute of Geosciences and Earth Resources, Padova, Italy. ²CNR-ISMAR, Trieste, Italy. ³Department of Geography & Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom

Abstract

The south-eastern European Alps are characterized by a forealpine belt facing the foreland with relieves rarely exceeding 2000 m in elevation. During the Last Glacial Maximum (LGM), this area saw the growth of isolated glaciers around the highest peaks. Because they were disconnected from the major ice-streams, which flowed down the Alpine valleys towards the foreland, their reconstruction is an important tool for establishing paleoclimate conditions using the calculation of their Equilibrium Line Altitude (ELA). Through field and remote sensing analyses we reconstructed the paleoglaciers of the Mount Raut (2025 m a.s.l.) in the Carnian Forealps, the Mount Chiampon – Cuel di Lanis (1700 m a.s.l.) in the Julian Forealps and the Trnovski Gozd (1495 m a.s.l.) in the Northern Dinarides.

The Mount Raut is one of the highest mountains located close to the Friuli Piedmont plain, and its cirques hosted a glacier during the last glaciations. The frontal moraines are well preserved close to the Lake Ca' Selva at about 600 m a.s.l. According to the glacier reconstruction obtained with the tool GlaRe (Pellitero et al., 2015, 2016), the LGM ELA of the Raut paleoglacier was calculated at ~1340 m a.s.l. The Mount Chiampon – Cuel di Lanis is a 6-km long crest with several cirques in the northern side and well-preserved moraines at 600-800 m a.s.l. Five paleoglaciers were distinguished. They provide ELAs at ~1200 m a.s.l. (Monegato, 2012). The Trnovski Gozd karst plateau hosted small glaciers with an overall area of ~5 km². Glaciers covered the karstic relief on the north-facing slopes below the highest crest and their ELA was estimated at ~1240 m a.s.l. (Žebre et al., 2014).

In respect to other ELAs available in the Alps (Federici et al., 2016), these lower values may suggest a lowering of the mean annual air temperature towards the east. Low-elevated ELAs were calculated also for the Little Ice Age (LIA) glaciers of the Mount Canin (Colucci, 2016). Considering the present-day high mean annual precipitation of the Carnian and Julian sectors (about 2500 mm and 3200 mm w.e.), low values of ELAs both during the LGM and the LIA could be supported by the maintaining of these precipitation rates during the cold phases. This allowed the growth of many isolated glaciers in the forealps during the LGM and the spread of the Tagliamento glacier in the Friuli Piedmont plain despite its low-elevated accumulation area, not exceeding 2800 m in elevation.

A unique lacustrine record of the Alpine Lateglacial and the Lateglacial-Holocene transition from the centre of the Eastern Alps (Austria)

Ruth Drescher-Schneider¹, Jürgen M. Reitner²

¹Institute of Plant Sciences, Karl-Franzens University of Graz, Graz, Austria. ²Geological Survey of Austria, Vienna, Austria

Abstract

The reconstruction of the Alpine Lateglacial is in general based either on the succession of end moraines or on lacustrine and peat deposits. Palynologically investigated records consisting of lacustrine and glacial deposits from sites close to modern glaciers are missing so far.

The sediment sequence of Lake Stappitzer See in the Seebach Valley (Mallnitz, Carinthia) is filling this gap. It is located in the still glaciated Hohen Tauern mountain range surrounded by peaks of 3000 metres altitude. End moraines of the Little Ice Age and the Egesen stadial (Younger Dryas, 12.8-11.7 ka) are present in and close to the cirques. However, evidence of a valley glacier during the Gschnitz stadial (¹⁰Be exposure age 16.6±1.4 ka, Ivy-Ochs et al. 2006) is missing in this valley. This is in sharp contrast, to neighbouring valleys where Gschnitz end moraines are well developed. The deposits of the Auernig rock avalanche occur c. 6 km downstream of the drill site. Based on U/Th isochrones dating, the catastrophic slope failure happened at 17.5±1.4 ka. Terraces and delta deposits just upstream of the rock avalanche deposits indicate the formation of a large lake dammed by the landslide.

In 2001, Fritz & Ucik published a comprehensive study on the chronology of climatic and vegetation change of the Seebach Valley. Their interpretation of the lacustrine record of two drill cores is in some issues in contradiction to the scientific consensus. On occasion of a study on the erosion chronology of the Seebach Valley (Grischott et al. 2017), the cores were re-analysed regarding palynology and sedimentology (Drescher-Schneider & Reitner 2018). Taking in consideration also the reconstructed palaeoglaciation and the age of the Auernig rock avalanche, following results of the revision are notable: The basal sediments in 160–118 m depth were deposited by the Seebach Valley Glacier advancing in a proglacial lake dammed by the Auernig rock avalanche during the Gschnitz stadial. The sediments contain pollen derived from soils or deposits of older interstadials or interglacials. The record between 118 and 80 m shows glacio-lacustrine depositional conditions in contact to decaying ice. The following banded silt (80–48 m) is free of any indication for a lake in direct contact to glaciers. The corresponding pollen flora represents that of a grass tundra with first shrubs typical for the Oldest Dryas. The Bølling/Allerød-Interstadial (80–71 m) with a reforestation and the following massive climatic deterioration of the Younger Dryas (Egesen stadial, 71–61 m) are based on palynological evidence. The Holocene succession starting in 61 m depth with the early Preboreal is not continuous.

First steps towards a glacial chronology of the Verbano lobe, Italian Alps

Sarah Kamleitner¹, Susan Ivy-Ochs¹, Giovanni Monegato², Franco Gianotti³, Marcus Christl¹

¹Laboratory of Ion Beam Physics, ETH Zurich, Zurich, Switzerland. ²Institute of Geosciences and Earth Resources, CNR, Padua, Italy. ³Departement of Earth Sciences, Università degli Studi di Torino, Turin, Italy

Abstract

Reliable glacial chronologies for many of the major LGM piedmont glaciers on the southern side of the Alps have been recently established based on radiocarbon and cosmogenic nuclide dating. However, less is known on the timing of the Last Glacial Maximum in the central part of the southern Alps, where the Toce/Ticino and Adda glacier systems remain chronologically unconstrained. Scattered radiocarbon ages are available (Scapozza et al. 2014), but do not yield information on LGM maximum advance(s) or final glacier retreat from the forelands. This is particularly unfortunate as the glaciers of the central southern Alps were linked to the major Alpine ice domes.

The present study aims to overcome this gap of knowledge. Mapping and cosmogenic nuclide dating of the Verbano lobe will give insights into the timing and extent of the Last Glacial Maximum and possible (re)advances of the Toce/Ticino glacier system. So far, thirty rock samples from glacially deposited boulders have been collected for surface exposure dating on the western part of the piedmont lobe, both north and south of Verbania. First Beryllium-10 ages have been determined. Preliminary results show that one of the outermost lateral moraines, that was lately believed to have formed prior to LGM (Bini et al. 2009), is clearly of LGM age. The LGM extent of the Verbano lobe must have been significantly larger than proposed by Bini et al. (2009). The present data set together with field evidence further suggests a glacier re-advance following LGM that ceased with a rapid meltdown of the glacier.

Ice thickness and internal structure of two small glaciers in the Pirin Mountains (Bulgaria) assessed by geophysical investigations

Alexandru Onaca¹, Adrian Ardelean², Florina Ardelean¹, Emil Gachev³, Brigitte Magori¹, Flavius Sirbu¹

¹West University of Timisoara, Timisoara, Romania. ²National Museum of Banat, Timisoara, Romania. ³South-West University Neofit Rilski, Blagoevgrad, Bulgaria

Abstract

In the present study we examined the thickness and internal structure of two small glaciers in the Balkan Peninsula, using geophysical investigations. According to several recent findings the southernmost glaciers in Europe are located in the Pirin Mountains (Bulgaria) (Grunewald and Scheithauer, 2010). However, because their total area (between 0,5 and 1 ha) is very small, they are sometimes considered as perennial snow patches. Because a sufficiently strong electrical impedance contrast exists at the ice/snow and ice/ground interface, ground penetrating radar (GPR) is a useful tool for mapping the internal structure and the thickness of small ice bodies. Two small glaciers (Snezhnika and Banski Suhodol) (fig.1) and several snow patches were investigated using a MalåGeoSciences ProEx system with a 100 MHz unshielded rough terrain antenna. The measurements were performed in two different campaigns, in August 2017 and October 2018. All the radargrams revealed sharp reflections, indicating very well the contact between the snow/ice body and the bed topography. In the case of Snezhnika and Banski Suhodol glacierets, two different parallel and almost continuous reflections were identified. The upper reflections indicate the contact between snow/firn and ice and were identified at 3-5 m depth at Snezhnika and 6-8 m depth at Banski Suhodol. The lowermost reflections occur at 9-14 m at Snezhnika and between 14 and 17 m at Banski Suhodol, suggesting the contact between the ice body and the bed topography. The GPR measurements confirmed the presence of glacial ice bodies in the Pirin Mountains, with a maximum thickness of 10-12 m. In addition, electrical resistivity tomography surveys were conducted in the Banski Suhodol site, confirming the occurrence of permafrost in a talus slope below the glacier. The moraines around both glaciers do not host glacial ice or permafrost. High resolution digital elevation models for both sites were derived from aerial images taken by a cost-effective Unnamed Aerial Vehicle (UAV). In the following years the use of repeat UAV surveys and GPR measurements will allow us to evaluate more carefully the state of the southernmost glaciers in Europe.

Paired moraine-dammed lake assemblages in the Cordillera Blanca (Peru) and implications for paleoclimatic reconstructions

Lasafam Iturrizaga

University of Potsdam, Potsdam, Germany

Abstract

The tropical mountain range of the Cordillera Blanca is a key locality of proglacial lakes in high-mountain settings worldwide. A genetic classification of major lake types with their specific barriers and a generalized model for the distribution of the present lakes and paleolakes was set up. The origin of the lakes and their recurrent distribution patterns are linked to certain stages of the Pleistocene to modern glaciation and their corresponding geomorphological landforms. Characteristic repetitive moraine sequences are found in the upper parts of numerous valleys of the Cordillera Blanca associated with lake formations. In terms of the spatial arrangement of the lake types, combined lakes are classified as a distinct composite lake type, which occur also in other tropical mountain ranges, such as in the Bolivian Andes and Central Peruvian Andes. In the Cordillera Blanca, the lakes occur at nearly the same elevation or at successively lower elevations, and form characteristic lake sequences of two or more lakes. They may occur as multi-moraine-dammed lakes or mixed combined lakes such as moraine-rock-dammed lakes or multi-debris-dammed lakes. From special interest are in this study the paired moraine-dammed lakes with two individual lakes (e.g. Lagunas Qoyllurcochas, Lagunas Safuna Alta and Baja). They are dammed by the Great Endmoraine (GEM), primarily formed during the Little Ice Age and earlier, and the pre-GEM, formed during the Holocene. Both moraines are located in rather close vicinity to each other at a distance of 1–3 km. In contrast to the prominent sharp-crested GEM, the pre-GEM is a low-amplitude end-moraine complex, which usually does not exceed a few meters to tens of meters in height. The latter is often composed of several inserted moraine ridges or an irregular hummocky moraine landscape. It is argued here that the process of formation of these combined lakes is mainly controlled by a combination of distinct topographical and climatic factors. These have to be considered in regard to studies of the paleoclimatic reconstruction. Moreover, the occurrence of these lakes represents a special situation for the risk potential of glacier lake outbursts.

Landform composition and functioning within proglacial systems of the central European Alps

Jonathan Carrivick¹, Tobias Heckmann²

¹University of Leeds, Leeds, United Kingdom. ²Catholic University of Eichstaett-Ingolstadt, Eichstätt, Bayern, Germany

Abstract

Proglacial systems are enlarging as glacier masses decline. They are in a transitory state from glacier-dominated to hillslope and fluvially-dominated geomorphological processes. They are a very important meltwater, sediment and solute source. This study makes the first quantitative, systematic and regional assessment of landform composition and functioning within proglacial systems that have developed in the short term since the Little Ice Age (LIA). Proglacial system extent was thus defined as the area between the LIA moraine ridges and the contemporary glacier. We achieved this assessment via a series of topographic analyses of 10 m resolution digital elevation models (DEMs) covering the central European Alps, specifically of Austria and Switzerland. Across the 2812 proglacial systems that have a combined area of 933 km², the mean proportional area of each proglacial system that is directly affected by glacial meltwater is 37 %. However, there are examples where there is no glacial meltwater influence whatsoever due to complete disappearance of glaciers since the LIA, and there are examples where > 90% of the proglacial area is probably affected by glacial meltwater. In all of the major drainage basins; the Inn, Drava, Venetian Coast, Po, Rhine, Rhone and Danube, the proportions of the combined land area belonging to each landform class is remarkably similar, with > 10 % fluvial, ~35 % alluvial and debris fans, ~50 % moraine ridges and talus/scree, and ~ 10 % bedrock, which will be very helpful for considering estimates of regional sediment yield and denudation rates. We find groupings of the relationship between proglacial system hypsometric index and lithology, and of a slope threshold discriminating between hillslope and fluvial-dominated terrain, both of which we interpret to be due to grain size. We estimate of contemporary total volume loss from all of these proglacial systems of 44 M m³a⁻¹, which equates to a mean of 0.3 mm.a⁻¹ contemporary surface lowering. Overall, these first quantifications of proglacial landform and landscape evolution will be an important basis for inter- and intra-catchment considerations of climate change effects on proglacial systems such as land stability, and changing water, sediment and solute source fluxes.

Development of two small relict lakes located in NE Poland beyond the extent of the Last Glaciation

Danuta Drzymulska, Mirosława Kupryjanowicz, Magdalena Fiłoc
University of Białystok Institute of Biology Department of Palaeobotany, Białystok, Poland

Abstract

An occurrence of lowland lakes beyond the maximal extent of the Last Glaciation (Weichselian) is extremely rare. Currently, in NE Poland there are only two small natural water bodies: Lake Gorbacz and Lake Wiejki, both located in the Gródek-Michałowo Depression, the large, infilled by peat, form of terrain. They are relicts of much larger lakes (or one lake) that have been functioning here since the end of the Last Glaciation. At that time and at the beginning of the Holocene a number of lakes in this region of Poland was much higher. However, most of them became overgrown and transformed into peat bogs in different periods of the Holocene. The genesis of these Late Weichselian/Early Holocene water bodies has not yet been determined. Because in many of them, below a thin layer of sand, the lake and/or mire sediments accumulated during the Eemian Interglacial occur (also in the Gródek-Michałowo Depression), the so-called thermal karst is considered the most likely cause of their formation.

One core of sediments was collected from surrounding area of both existing lakes using the Instorf drill. The thickness of core from Lake Gorbacz (LG) vicinity was 5.8 m, and from near of Lake Wiejki (LWk) – 5.0 m. We investigated them by palynological method as well as by method of plant macrofossil remain analysis. The age of studied sediments was determined by radiocarbon method. In the LWk profile calcareous gyttja was recognized in the bottom. The first peat layer (4.55 m) was deposited in the first half of the Atlantic period (6029-5630 cal. BC; MKL-4187). This peat was described as Carici-Brayelti, what indicates that peat-forming process was initiated by sedge-brown moss community. After that, still in the Atlantic period (5638-5230 cal. BC; MKL-4186), mire surface was overgrown mainly by brown mosses what is confirmed by Bryaleti peat in the profile. The next succession sequence was formed by sedges. They were replaced by peat mosses in the Subatlantic period (201 cal. BC-244 cal. AD; MKL-4185).

P-2849

Simulating changing Holocene distributions of palsas and peat plateaus in North America

Richard Fewster, Paul Morris, Graeme Swindles
University of Leeds, Leeds, United Kingdom

Abstract

Permafrost peatlands represent a globally vast, organic carbon store which is particularly sensitive to climatic change. The distribution of permafrost within peatlands at coarse spatial scales is evidenced by the presence of palsas and peat plateaus, landforms which are closely controlled by climatic factors. Frozen temperatures render these ecosystems largely inert, but thaw and the development of saturated conditions significantly enhances carbon dioxide (CO₂) and methane (CH₄) emissions, presenting positive feedback mechanisms which threaten to accelerate future climate change. Although predictive models of permafrost degradation are well-developed for mineral soils, the thermal properties of organic soils complicate the response of peatland permafrost to climatic changes. As such, the extent and severity of future thawing has remained highly uncertain at hemispheric scales, as confident simulations of permafrost peatlands are only currently available for Fennoscandia. Bioclimate modelling of palsa distribution in Fennoscandia has shown that these features occur primarily in extremely cold, precipitation limited environments. Preliminary analysis indicated that bioclimate models of palsa distribution in Fennoscandia perform poorly in North America, suggesting that the climatic controls on permafrost development within peatlands may display interregional variability. This likely reflects the greater range of climate in North America along continental-to-maritime gradient. North American palsa lines are likely to have tracked north and south in response to Holocene climate shifts, but the lack of a generally applicable palsa distribution model means we are currently unable to simulate past or future changes.

We developed a catalogue of palsa and peat plateau distribution in North America (> 300 sites), and combined this with an existing catalogue from Fennoscandia. We used modern climate data to develop a bioclimate model that can be used to simulate past and future changes in the bioclimatic envelopes of palsas and peat plateaus. I will statistically relate this extensive dataset of permafrost peatland landforms to contemporary climate data to construct an advanced logistic regression model with which to predict the distribution of permafrost peatlands in North America. We will then incorporate into our model outputs from the HadCM3 Earth System model to hindcast permafrost peatland developments throughout the Holocene. Hindcasted distributions will provide new evidence with which to constrain the timing of permafrost aggradation and degradation in peatlands, enabling comparisons with estimates from traditional palaeoecological techniques. An improved understanding of permafrost peatland developments throughout the Holocene will also enhance the reliability of projected future permafrost peatland distributions under anthropogenic climate change. In this presentation I will briefly outline the project's aim and importance, talk through the model building process and present novel simulations of Holocene permafrost peatland developments.

Peatland development and possible responses to the Holocene environmental changes in Central European Russia

Elena Novenko^{1,2}, Dmitry Kupriyanov¹, Natalia Mazei¹, Maria Kusilman¹

¹Faculty of Geography, Lomonosov Moscow State University, Moscow, Russian Federation. ²Institute of Geography Russian Academy of Science, Moscow, Russian Federation

Abstract

The reconstruction of peatland developing processes is based on radiocarbon dating of lowermost peat horizons and plant macrofossil analysis of peat samples from 40 mires in the Meshchera lowlands (the central part of the East European Plain). The landscape of this region are formed on thick fluvio-glacial sands and characterized by flat relief, high level of ground water and large areas of pine forests and numerous mires. This area is belongs to so-called Polessye-type of landscapes. All studied peatlands are located on watersheds and high river terraces and formed by forest paludification. Phases of peatland initiation were compared with Holocene fire regime revealed from macro-charcoal data and climatic reconstructions available for this area.

The obtained results showed that the peatland developing process of these areas took place throughout the Holocene. The ages of basal peat samples showed that the majority of the studied peatlands formed between 9000 and 6000 cal yr BP, during the Holocene thermal maximum. The highest number of mires formed between 7600 and 6000 cal yr BP. The second period of active paludification ranged between 3700 and 3200 cal yr BP. According to climatic reconstruction this period was characterized by increased temperatures and driest conditions entire the Holocene and high fire frequencies. The last phase of peatland initiation occurred between 1500 and 1700 cal yr BP and was coincided with increase of human induced forest fires during human occupation of the area during the Early Iron Age. In the periods of the climatic cooling and increase of humidity in periods between 5000 and 4000 cal yr BP and 3000 and 2000 cal yr BP the lowest number initiated.

In contrast to the areas located in the taiga zone, where the active peatland growth correlated with wetter and cooler epochs, in the Meshchera lowlands the stages of paludification coincided with phases of dry and warm climatic conditions and the increase in the frequency and intensity of fires. Obviously, the peatland formation process in these areas was influenced by the fire regime of the territory. After severe forest fires, accompanied by the death of the forest stand, the water balance of the study area was changed by reducing evaporation and increasing surface runoff, which led to the waterlogging of the territory.

According to the plant macrofossil analysis of peat, all studied peatlands were in the eutrophic stage of development during the entire Holocene. The transition to mesotrophic conditions in different mires ranged from 1400 to 400 cal yr BP. It is possible that periodic fires and burning of peat deposits contributed to the supply of nutrients to the peatland ecosystems and provided eutrophic habitat conditions.

This study was supported by the Russian Science Foundation (Grant 16-17-10045).

Abstract

The geometric and genetic characterization of the Navamuño depression peatland system (ND) has been depicted using geophysical and geoprobes surveys. ND is a pseudo-endorheic system (~14 ha surface area) located in the Sierra de Béjar (Iberian Central System, ICS) and included in the Natura 2000 European protection network. The genesis and evolution of ND is associated to the neotectonic and glacial dynamics during the Quaternary times and is the first sedimentary basin with these features that has been surveyed until 20 m depth in these areas. The rest of ICS's peatlands do not reach this depth, staying around 8 m and belonging Holocene ages. Refraction seismic, magnetic resonance sounding (MRS) and electrical resistivity measurements were the geophysical techniques used. The stratigraphic of the peatbog was obtained and three main geophysical units (G1, G2, G3) were identified. These units had been grouped into two sedimentary bodies: an ancient sedimentary body (G3) of unknown age, and a shallower sedimentary body (<20 m depth) that embraces the Upper Pleistocene (G2) and the Holocene (G1). The geometry and facies distribution of units G1 and G2 was examined using the Sequence Stratigraphy principles. On the one hand sedimentary unconformities linked to the geometry of the geophysical units reveals that the depression was dammed, almost at the MIS2. On the other hand, geomorphological mapping reveals that the depression was under the influence of the former Cuerpo de Hombre glacier and was an ice-dammed lake synchronous to build-up of the lateral moraine during the MIS2. A general coarsening-upward trend was identified using a dynamic penetration probe and a direct-push borehole, revealing a MIS2/MIS1 shallowing upward sequence.

We conclude that the Navamuño's boundaries are forced by extensive faults leading the geometry of the basin and its high sedimentary rate (≈ 1 mm/yr). The depression is interpreted as a small tectonic basin filled with glaciolacustrine, glaciofluvial and post-glacial deposits of shallow pond/peat bog environment.

P-2852

Climate change and vegetation evolution during the last glacial period recorded by mountain peatbog in the western subtropical China

Yuanfu Yue¹, Zhuo Zheng², Kangyou Huang², Qiuchi Wan², Cong Chen², Yongjie Tang², Meiling Man Meiling Man², Ting Ma²

¹Guangxi Laboratory on the Study of Coral Reef in the South China Sea; Coral Reef Research Centre of China; School of Marine Sciences, Guangxi University, Nanning, China. ²School of Earth Sciences and Engineering, Sun Yat-sen University, Guangzhou, China

Abstract

The vegetation system in subtropical China was strongly affected by the decrease of temperature and the weakening of monsoon during the Last Glacial Maximum (LGM), and the regional vegetation changed significantly. However, there are still great differences in the understanding of vegetation types and distribution patterns in subtropical China. The knowledge of climate change and the process of vegetation evolution and migration during the LGM, and whether the expansion of grassland-meadow replaced the subtropical broad-leaved forest remain controversial.

Western Guizhou is located on the eastern slope of the Yunnan-Guizhou Plateau, which is the second step in China. It is in the semi-humid area of the western subtropical China. The vegetation types and distribution patterns are closely related to the southwest monsoon. In order to reveal the response of vegetation to climate during the LGM, better understand the mechanism of southwest monsoon change, regional environmental evolution and predict future climate change, AMS¹⁴C dating and pollen analysis were carried out on a peatbog collected in Western Guizhou mountainous area on the eastern slope of Yunnan-Guizhou Plateau. The preliminary results show that:

At the late stage of MIS3 (ca. 36-21 cal kyr BP), deciduous-evergreen broad-leaved forests were inferred from pollen data, which were mainly composed of *Quercus* (evergreen and deciduous), *Castanopsis/Lithocarpus*, *Fagus* and temperate species such as *Corylus*, *Carpinus* and *Betula*, with a small amount of pine and hemlock-based coniferous forests and shrubs which dominated by *Rhododendron*. While understory herbs were predominated by Poaceae and Cyperaceae. This stage indicated a cool climate, but the regional climate was still wet.

During LGM (ca. 21-16 cal kyr BP), the characteristics of pollen assemblage showed the constructive species which mainly represented by deciduous *Quercus*. D. and *Corylus*. It suggested that the vegetation was dominated by deciduous broad-leaved forest, reflecting the spatial shift of deciduous broad-leaved forest of northern subtropical zonal vegetation. Gramineae was still the dominant herbage, but there was no expansion of grassland vegetation, while Cyperaceae was almost disappears, indicating that the climate in the region was further drier and colder.

In the last deglacial period, the vegetation transitions from deciduous broad-leaved forest to deciduous-evergreen broad-leaved forest which dominated by *Quercus*.D, *Corylus* and *Castanopsis/Lithocarpus*, indicated that the evergreen broad-leaved forest expanded northward and the climate gradually rose and warmed up.

The vegetation succession and climate change in the LGM recorded by pollen from the mountain peatbog in Western Guizhou indicated that the vegetation succession in this area during the last glacial maximum. It was mainly characterized by the expansion and contraction of deciduous broad-leaved forests, and the climate experienced cool-wet-dry-cold-cool-wet, which generally corresponded well with the solar radiation in the northern hemisphere at low latitudes in summer.

Post Little Ice Age peat and carbon accumulation in northwestern Québec, Canada

Sanna Piilo¹, Hui Zhang¹, Michelle Garneau², Angela Gallego-Sala³, Matthew Amesbury^{3,1}, Minna Väliranta¹

¹University of Helsinki, Ecosystems and Environment Research Programme, Helsinki, Finland. ²Department of Geography, Université du Québec à Montréal, Montreal, Canada. ³Geography, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom

Abstract

It is expected, that ongoing climate change will alter high-latitude peatland vegetation dynamics and carbon cycling. Peatlands are globally important carbon sinks, even though they release carbon dioxide and methane to the atmosphere through plant respiration and peat decomposition. Peatlands act as environmental archives and can be used to reconstruct past changes and develop analogues for future projections. However, it is not yet fully understood how high-latitude peatlands will respond to ongoing climate change. We used plant macrofossils and peat property analyses as proxies to reconstruct recent changes in vegetation assemblages and carbon dynamics following the Little Ice Age period in high-boreal and low-subarctic regions in northwestern Québec, Canada. Our results from twelve surface peat monoliths, collected respectively from four peatlands located in two distinct ecoregions, suggest high peat and carbon accumulation rates from AD 1950s. Successional changes in plant macrofossils show heterogeneous responses, even though some consistent changes occur within the same region. The northernmost study region shows higher average apparent accumulation rates that could be linked to a larger increase in the growing season length (GDD > 0 °C) and changes in climatic conditions (temperature and precipitation). The average apparent recent carbon accumulation rates from both regions vary between 50.7 and 149.1 g C m⁻² yr⁻¹. Our results highlight the need to integrate multiple records from each studied peatland, but also from different peatlands within one region in order to disentangle the internal versus external variability of the signals recorded.

Indicator value of oribatid mites in determining past permafrost dynamics in northern European sub-Arctic peatlands

Inkeri Markkula¹, Pirita Oksanen², Peter Kuhry³

¹University of Turku, Turku, Finland, ²Independent scholar, Kaskinen, Finland, ³University of Stockholm, Stockholm, Sweden

Abstract

Indicator value of oribatid mites in determining past permafrost dynamics in northern European sub-Arctic peatlands

Permafrost dynamics play an important role in the surface hydrology and carbon balance of northern peatlands. Plant macrofossil analysis with radiocarbon dating has been widely used in detecting past permafrost dynamics in peatlands, however, there is a lack of permafrost-specific plant indicator species, which makes it challenging to determine the exact timing of historical permafrost aggradation. In this study, we investigated the indicator value of oribatid mites in determining past permafrost dynamics in sub-Arctic peatlands. Previous studies have shown that oribatid mites are suitable bioindicators of natural and anthropogenic changes in ecosystems, but their potential as indicators of permafrost occurrence and dynamics has not been investigated before. We carried out analyses of subfossil oribatid mite assemblages in Holocene peat profiles from two mires in northern Finland and Russia, and compared the results with earlier plant macrofossil analyses from the same profiles. For reference, present-day species compositions of oribatid mite communities in the same study areas were investigated in permafrost (palsa mire) and non-permafrost (aapa mire) peatlands and across five types of peatland vegetation: lichen, *Empetrum hermaphroditum*, *Rubus chamaemorus*, *Sphagnum* spp., hollow type and *Carex* spp.

In general, permafrost dynamics were well reflected in oribatid mite assemblages in our subfossil data. A change from a community of hydrophilous species to one consisting of taxa related to drier surface conditions was visible in the profiles at around the same time when first permafrost aggradation occurred. We found three promising oribatid mite indicator species. *Carabodes labyrinthicus* and *Chamobates borealis* were significantly more abundant in permafrost peatlands than in non-permafrost peatlands and in microhabitats of lichen and *Empetrum hermaphroditum* vegetation and low soil moisture content, and became the dominant species in peat profiles at the time permafrost was aggraded. Another Oribatida species, *Neoribates aurantiacus*, was found in low numbers, but was clearly associated to the presence of lichens and low humidity conditions across our present-day and subfossil datasets. This is particularly valuable since lichens are normally not preserved in peat deposits.

Our results indicate that Oribatid mites can contribute significantly to multi-proxy approaches that aim to reconstruct environmental conditions in permafrost peatlands as they include promising indicator species. The presence/abundance of the three identified indicator species, together with the general species composition of oribatid mite communities can give insights into dynamics and timing of local permafrost aggradation and humidity conditions.

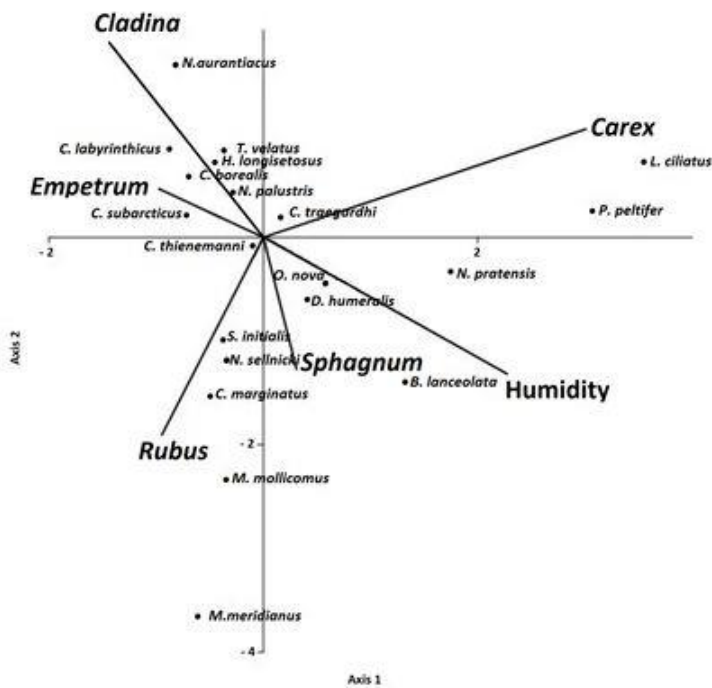

Fig. 1. Canonical correspondence analysis, abundance of oribatid mite species in relation to humidity and presence/absence of different vegetation types.

Fig 2. Oribatid fossil mites per 10 cm³ and selected plant macrofossil taxa as volume percentages in a peat profile, Vaisjeaggi palsa mire.

Changes in Late Quaternary circumarctic ground ice and soil organic carbon simulated by a simple model

Kazuyuki Saito¹, Hirokazu Machiya¹, Go Iwahana², Hiroshi Ohno³, Tokuta Yokohata⁴

¹JAMSTEC, Yokohama, Japan, ²University of Alaska Fairbanks, Fairbanks, USA, ³Kitami Institute of Technology, Kitami, Japan, ⁴NIES, Tsukuba, Japan

Abstract

Permafrost is a large reservoir of soil organic carbon (SOC), accounting about half of all the terrestrial storage, and almost equivalent to two times of the atmospheric carbon storage. Therefore, its degradation under global warming may lead to a substantial amount of additional greenhouse gas (GHG) release, and to further warming. In addition to gradual degradation through heat conduction, importance of abrupt thawing or erosion of ice-rich permafrost is recently recognized. Such ice-rich permafrost has been evolved on a long timescale (i.e., hundreds to tens of thousands of years).

Though important, knowledge on the “vulnerability distribution”, i.e., location of, and stored amount of ground ice and soil carbon in ice-rich permafrost is still limited largely due to scarcity of accessible in-situ data. Understanding of the processes, and geographical distribution of the vulnerability are necessary for enhancement of Earth system models as the permafrost-carbon process remains one of the large sources of uncertainty in climatic and biogeochemical assessment and projections of the Arctic.

In this study, conducted as a part of three-year research project (2-1605, ERTDF of ERCA, Japan), a simple two-box numerical model was developed to simulate the long-term evolution of ground ice and SOC in the circumarctic region. The model has two compartments, above-ground and ground. The former is driven by annual mean air temperature and total precipitation to calculate the carbon input to the ground (i.e., litter fall) and regulate subsurface thermal conditions, whereas the latter calculates carbon and water budget, including ice content, of the ground. The circum-Arctic domain (north of 50° N) is sectioned by 1 degree both in longitude and latitude. The distributed driving data and boundary conditions were prepared for the period from 125ka to the present, derived from ice sheets reconstruction data (ICE-6G_C dataset) and Greenland ice core data (the SeaRISE project), modified through the present-day reanalysis data (ERA-Interim and the University of Delaware products), as well as outputs from global climate models (CMIP5/PMIP3).

Fig: Schematic diagram of the two-box model

The circumarctic core data were compared to the simulation results at the corresponding locations for soil carbon dynamics to validate model process (e.g., decomposition, impacts of ground freezing), and for sensitivities on key parameters (e.g., time constant for carbon decomposition). The changes in geographical distribution in ground ice, soil moisture, and soil carbon content as well as frozen ground (i.e., permafrost and seasonally freezing ground) through the Late Quaternary demonstrated reasonable geo-characteristic differences, contrasting behavior between the glacial and non-glacial periods of the region, and the evolution of the vulnerable areas.

Identifying the key prerequisites of ecosystem resilience: a case of tropical peatland in Sumatra, Indonesia

k. [anggi hapsari](#)¹, siria biagioni¹, tim jenniferjahn², peter reimer³, asmadi saad⁴, supiandi sabiham⁵, hermann behling¹
¹university of goettingen, goettingen, Germany, ²Leibniz Centre for Tropical Marine Research (ZMT), bremen, Germany, ³goshen college, goshen, indiana, USA, ⁴university of jambi, jambi, Indonesia, ⁵bogor agriculture university (IPB), bogor, Indonesia

Abstract

The success of conservation nowadays relies on the support of local community that is often lacking due to the neglect to socioeconomic aspects. Thus, socioeconomic activities of local people, especially those whose livelihood depends entirely on the natural resources, needs to be accommodated. To ensure ecosystem sustainability, the socioeconomic activities certainly need to be compatible with conservation and should not undermine the ecosystem's resilience. An understanding of ecosystem resilience and its key prerequisites thus become crucial in incorporating socioeconomic aspects into conservation.

However, understanding ecosystem resilience (resistance and recovery) is challenging for it is a slow process that might take decades or centuries. Long-term ecological information is certainly required yet often lacking. Fortunately, this knowledge gap can be filled by palaeoecology.

Aiming to assess the ecosystem resilience and to identify its key prerequisites, particularly to human disturbance, a palaeoecological study, including the analyses of pollen and spore, charcoal and carbon (C) content, is conducted on the Sungai Buluh peatland in Sumatra, Indonesia. Its vicinity to the Muara Jambi temple complex, remains of the former Malayu Empire, provides a unique opportunity to understand ecosystem resilience to human disturbance.

The palaeoecological record from the Sungai Buluh suggests that the Malayu Empire people conducted activities on the peatland that altered vegetation composition of the peatland and slightly reduced the peatland's C sequestration capacity. Nevertheless, the peatland recovered in terms of its vegetation composition and its C sequestration capacity after the cessation of human disturbance following the site abandonment.

Here, two key prerequisite for peatland resilience are identified: (i) a maintained hydrological condition, and (ii) sufficient old vegetation remnant. Socioeconomic activities thus may be permitted to be conducted on the conserved peatland as long as those activities are considered "resilience-friendly" i.e. will not significantly impact the key prerequisites of peatland resilience.

Late Holocene peatland permafrost aggradation-driven greenhouse gas forcing to the atmosphere, in Seida, NE European Russia

Minna Väliranta¹, Maija Marushchak², Juha-Pekka Tuovinen³, Christina Biasi², Annalea Lohila³, Dmitry Kaverin⁴, Carolina Voigt², Hui Zhang¹, Sanna Piilo¹, Eeva-stiina Tuittila⁵, Pertti Martikainen²

¹University of Helsinki, Helsinki, Finland, ²University of eastern Finland, Kuopio, Finland, ³Meteorological Institute of Finland, Helsinki, Finland, ⁴Institute of Biology, Syktyvkar, Russian Federation, ⁵University of eastern Finland, Joensuu, Finland

Abstract

Impact of the permafrost development on greenhouse gas (GHG) dynamics and climate has been scarcely studied. We applied palaeoecological methods, plant macrofossils and radiocarbon dating, to study permafrost dynamics in Seida, NE European Russia. We combined palaeoecological data with on-site GHG measurements in order to model past radiative forcing (RF) during the late Holocene. The data suggest that the widespread late Holocene landscape change associated with the permafrost development resulted in a distinct increase in GHG emissions to the atmosphere. Hence, it appears that permafrost initiation triggered by a cooling climate generated a positive, i.e. warming RF impact driven by increase in CO₂ emissions. The results highlight the importance of Arctic peatlands for atmospheric GHG dynamics.

Testate amoebae from peatlands in the Alaskan continuous permafrost zone

Liam Taylor, Graeme Swindles, Paul Morris
University of Leeds, Leeds, United Kingdom

Abstract

Continuous permafrost peatlands represent a global carbon store of ~144 Pg C, yet little is known about how the vulnerability of this store will change with climate warming. Multiproxy palaeoenvironmental studies of peatlands have been conducted in the discontinuous permafrost zone, but there have been no investigations in continuous permafrost, despite the uncertainty of their future as a carbon sink or source. We present the first analysis of contemporary testate amoebae from the continuous permafrost zone, from a range of peatlands on the Alaskan North Slope and create two new transfer functions for reconstructing water-table depth and porewater electrical conductivity. We then use these transfer functions to perform palaeoenvironmental reconstructions from two peat cores at Toolik Lake, Alaska.

P-2859

From bog to fen - palaeoecological reconstruction of a calcareous spring fen on Saaremaa island, Estonia

Ansis Blaus, Triin Reitalu, Leeli Amon, Jüri Vassiljev, Tiiu Alliksaar, Siim Veski
Department of Geology, Tallinn University of Technology, Tallinn, Estonia

Abstract

This study of the Kanna calcareous spring fen on Saaremaa Island (Estonia) elucidates the history of fen development and vegetation diversity over the last ca. 9200 years. Pollen, including spores, non-pollen palynomorphs, macrofossils, loss-on-ignition and humification index analyses were carried out to reconstruct fen succession, vegetation development, environmental changes and human impact. Hierarchical clustering, ordination analysis and linear regression were applied to examine the vegetation composition and richness patterns through time and to identify the potential environmental drivers underlying these patterns. Our results suggest reverse mire development (bog to fen), a rare occurrence contrary to typical mire autogenic succession (groundwater-fed to rainwater-fed). Kanna developed as a small bog for the first 2000 years from 9200 to 7200 cal yr BP. Changes to the hydrological regime around 7200 cal yr BP — due to warmer and drier climate and land uplift — caused a shift from ombrotrophic to minerotrophic environment. Typical spring fen characteristics developed ca. 5000 cal yr BP and continued until ca. 400 cal yr BP, when the fen was fed by calcareous mineral-rich groundwater and harboured different calcareous and relict species contributing to very high diversity. We conclude that general shifts in Kanna fen succession, vegetation community and diversity are associated with climatic changes. The present high-diversity of the fen is a result of a long-term stable fen environment, which may have been even higher in the past. However, the pollen richness has decreased during the last 400 years, possibly due to anthropogenic or natural factors.

P-2860

Searching for drivers of the fen-bog transition

Paul Morris¹, Richard Fewster¹, Sean Astley¹, Olivia Byrne¹, Mariuz Galka²

¹University of Leeds, Leeds, United Kingdom, ²University of Lodz, Lodz, Poland

Abstract

During the course of their development, peatlands commonly transition from wet, nutrient-rich, methane-emitting fens; to drier, nutrient-poor, carbon dioxide-emitting bogs. These changes in wetness and trophic status represent decreasing hydrological connection between a peatland and local sources of surfacewater and shallow groundwater. Such hydrochemical changes also cause pronounced shifts in plant assemblage along a semi-predictable successional gradient, and are thus identifiable in plant macrofossil records from peat cores. It is currently unclear whether fen-bog transitions are an inevitable consequence of continued peat development raising the growing surface above local hydrological influences; or whether transitions are triggered by external drivers such as climate change. Spatial gradients in modern distributions of fens and bogs would appear to suggest a climatic control, meaning that future warming may cause changes in their distributions through altered peat accumulation rates and trophic status, with implications for greenhouse gas budgets and biodiversity. However, until now, no comprehensive database of fen-bog transitions has been available, and primary palaeoecological studies rarely consider more than a handful of sites, hindering the identification of general principles. We present interim results from an ongoing effort to develop a comprehensive database of published fen-bog transitions from around the world that will provide a basis to study the drivers of this phenomenon. Our secondary database mainly comprises study sites from North America and northern Europe, but also contains sites in Arctic Russia, Patagonia and southern Europe. In the majority of study sites, high quality plant macrofossil records reported in the primary literature allow us to identify a three-stage sequence of rich fen, poor fen, bog. In other cases, lower quality data allow us only to distinguish between herbaceous and bryophytic macrofossil zones. In all cases, we have estimated the ages of transitions by respecifying age-depth relationships using the original chronometric data reported alongside macrofossil records. Once completed, our database may become a valuable resource for peatland palaeoecologists. We plan to analyse the database using independent metrics of palaeoclimate change to identify any climatic triggers for fen-bog transitions.

P-2861

Multi-proxy approaches for the reconstruction of past palaeoenvironmental changes in Scotland: Piecing together Pictish social/environmental transitions from peat deposits

Samantha Jones

University of Aberdeen, Aberdeen, United Kingdom

This preliminary paper aims, through detailed environmental analysis (pollen, NPP, a strong chronology (eight ^{14}C ages) and XRF analysis) to expand our understanding of Pictish settlement, landscape and land-use during the early medieval period. A 1.86 m core was extracted from a valley fen adjacent to the Waters of Bogie, slightly south of the village of Rhynie in north-eastern Scotland, and within 270 m of a Pictish settlement and Crow stone dated to the 6th century. The bottom of the core produced a calibrated age of AD 260-415 and all but one of the radiocarbon dates are in good chronological order. Initial pollen counts have revealed relatively good preservation with a number of distinct changes in the vegetation record. Most of these changes appear to be associated with natural environmental transitions linked to a weakening in fluvial/stream energy after the 12th century and a gradual accumulation of peat, although some evidence also suggests agricultural activity.

In the archaeological record evidence, from the nearby Pictish settlement, highlights high status metalworking as well as a range of Continental imports (e.g. late Roman Amphora pottery and fragments of imported glass drinking vessels from western France), signifying that Rhynie was an important power centre during the early Medieval period. A series of radiocarbon dates and Bayesian modelling however indicate only a short phase of construction and use during the late fifth to mid-sixth centuries. What is particularly interesting about the palaeoecological results is that there is evidence of cereal pollen and a pronounced representation of herbivore dung fungi throughout the record, which suggests continuity of farming activities from AD 260-415 onwards, despite the 6th century abandonment of the Pictish settlement.

P-2862

Holocene alluvial peatland dynamics in Flanders, Belgium

Renske Hoeyers, Femke Augustijns, Nils Broothaerts, Ward Swinnen, Erika Vercammen, Laura Vervacke, Lijun Zhang, Gert Verstraeten
KU Leuven, Leuven, Belgium

Abstract

Rivers and alluvial floodplains are dynamic environments that experience natural and anthropogenic impacts. Sustainable management of these ecosystems requires a thorough understanding of the functioning of floodplains and their sensitivity to changes in internal and external driving forces. During the Early and Middle Holocene, most NW European floodplains were stable environments with limited floodplain aggradation resulting in the formation of peat. During these times, floodplains consisted mainly of large marshes where peat accumulated and river channels were absent or small. During the Late Holocene these environments changed completely towards single channel meander rivers with overbank deposits, and peat accumulation disappeared. Although this general framework of Holocene alluvial peatland evolution has been well established in previous research, it is still uncertain how these peatlands are controlled by internal and external drivers (such as topography, climate and human impact) and how the initiation date, growth rate and end date of peat growth are influenced by these drivers.

Four river catchments in Flanders were selected in this study, with varying soil properties, topography, and duration and intensity of human impact. The Dijle catchment (750 km²) is located in the central Belgian loess belt, the Mombeek catchment (90 km²) in the sandy loam region, and the Grote Nete (525 km²) and Zwarte Beek catchments (50 km²) in the sandy Campine region. A multi-proxy approach, including sedimentological proxies, pollen, macrobotanical remains and testate amoebae was chosen to reconstruct peatland characteristics and changes in external drivers. A database of 176 radiocarbon dates ranging over the different catchments was used to provide a chronostratigraphic framework.

Radiocarbon dating results show that alluvial peat growth started at the beginning of the Holocene. End dates are highly variable both within and between different catchments, varying from 6000 cal. BP to present-day. This variability can be explained by differences in floodplain connectivity and local differences in initiation and intensity of human impact in the catchment, as shown through the statistical analysis of regional pollen data. Peat accumulation rates are controlled by local variations though. The accumulated peat can be of different types, both *Carex* peat and *Sphagnum* peat can be found in alluvial peatlands, and a change of peat type can occur over time, mainly driven by local floodplain changes, as is shown by the comparison of macrobotanical data with pollen data. To assess the influence of differences in hydrology on peatland evolution, testate amoebae analysis was conducted, however poor preservation of these amoebae in alluvial peat hampered clear results. This in turn, leads to unreliable water table depth reconstructions for alluvial peatlands.

Overall, the study clearly indicates that a multi-site and multi-proxy approach is needed to fully grasp the Holocene evolution of alluvial peatlands and all driving factors involved.

A regime shift from erosion to carbon accumulation in a temperate northern peatland

Alice Milner¹, Andy Baird², Graeme Swindles², Mariusz Gałka³, Sophie Green⁴, Nicole Sanderson⁴, Madeleine Timmins¹, Dylan Young²

¹Royal Holloway University of London, London, United Kingdom, ²University of Leeds, Leeds, United Kingdom, ³Adam Mickiewicz University, Poznan, Poland, ⁴University of Exeter, Exeter, United Kingdom

Abstract

Peatlands are globally-important ecosystems but many are degraded. In blanket peatlands, degradation often occurs as erosion, which results in loss of carbon and important habitats over centennial timescales. It is often assumed that, once initiated, erosion will continue until all of the original peat mass has been removed. However, some peatlands are undergoing spontaneous recovery, with switches from erosion to renewed carbon accumulation, a type of ecological regime shift. It is not always clear why recovery occurs or the degree to which peatland ecosystem services are restored. We used palaeoecological techniques to chart the spontaneous recovery of an eroding blanket peatland in North Wales, UK and identify candidate mechanisms responsible for the regime shift. Key questions we address are: i) When did the spontaneous recovery start and what are the possible mechanisms? ii) What successional processes have occurred? iii) Have water levels changed or remained stable since the spontaneous recovery? iv) How much peat (and associated carbon) has accumulated since recovery started?

We present high-resolution plant macrofossil and testate amoebae data, alongside detailed analysis of peat characteristics and a chronology based on ¹⁴C and ²¹⁰Pb dating. There is evidence of rapid accumulation of peat after the initiation (e.g., 27 cm peat in 88.6 ± 4.02 years) with a range of successional pathways in peat-forming vegetation (e.g. *Sphagnum fallax* with *Juncus*, *S. fallax* with *Cyperaceae*, *Polytrichum*). Water-table depth reconstruction from testate amoebae indicate moderate-high water tables, with some evidence of standing water, typical of blanket peatlands. Possible causes of spontaneous recovery are linked to land use (e.g., reduction in grazing and burning), external factors (e.g. climate, air pollution), and internal changes to the system (e.g. active erosion causing changes in peatland meso-topography providing a setting for peat-forming vegetation such as *Sphagnum* to re-establish). Our findings contribute to understanding the future responses of peatlands under a changing climate and a wider understanding of ecological regime change.

Dynamic Holocene vegetation and North Pacific hydroclimate reconstructed from a mountain peatland, Molokai, Hawaii

David Beilman¹, Oliver Elison Timm², Charly Massa³, Jonathan Nichols⁴

¹University of Hawaii, Honolulu, USA, ²University at Albany, Albany, USA, ³Univeristy of Hawaii, Honolulu, USA, ⁴LDEO Columbia University, Palisades , USA

Abstract

An organic sediment core from the montane peatland Pepeopae on the Island of Molokai, Hawaii was studied for multi-proxy evidence of ecological and hydroclimatic change. Following a period of soil development, substantial carbon accumulation and the onset of organic matter stabilization began around 10 ka BP (thousands of years before present) under wet conditions. Continuous but variable peat formation was sustained throughout the Holocene, including maxima in carbon accumulation around 9 and 3 ka, that has resulted in a belowground carbon storage today of 144 kg C m⁻². Using sedimentary *n*-alkane chain length distributions, bog vegetation inputs to the peat was assessed in the context of 14 species of modern bog plant *n*-alkanes. Organic matter was not formed by litter inputs from a single plant type or types, but inputs shifted dynamically in their dominance in response to climate. We generated a new chronology for previously-published pollen data from the study site, which showed a similar tempo and response of vegetation change in the forests upwind of the peatland. Hydrogen stable isotope ratios of sedimentary C₂₉ *n*-alkanes show negative departures around 9ka and 3ka consistent with increases in storm-derived rainfall. Comparison of Holocene hydrogen isotope values from a contrasting mountaintop site on the Island of Oahu show a similar pattern, but differences in timing that relate to North Pacific atmospheric circulation.

Abstract

Over the last decades, historians have faced the necessity of reconstruction of land-use and settlement history not only through the study of the historical and archaeological sources but also by means of paleoenvironmental data. However, the deficiency of high-resolution multiproxy data hampers linking these approaches. This collaborative study creates new opportunities for combining palaeodata with historical sources. The aim of our study is to reconstruct the vegetation changes along with the progressing human impact accompanying the Polish state development. In this high-resolution multiproxy study, we focus on the Świąte fen, located in western Greater Poland (69 km south from Poznań) from which we retrieved 212-cm peat core that dates back to ca. AD 1100. We carried out pollen, plant macrofossil, charcoal, and selected non-pollen palynomorph (NPP) analyses continuously in a 1-cm resolution. Moreover, non-aquatic deposits were analyzed in terms of testate amoebae (TA) content in 2-cm intervals. The mire is characterized by relatively high peat accumulation rate along the entire length of the profile (average: 2.3 mm/yr). From ca. AD 1100 to 1380 the area possessed calcium-rich open water with the floating mosses, such as *Pseudocalliergon trifarium* and *Sphagnum cf. auriculatum*. At the same time, the share of herbs and Cyperaceae was the highest in the entire profile. In this period the occurrence of TA such as *Centropyxis aculeata* and *Arcella intermedia* could have confirmed telmatic habitat. This stage of the fen development was followed by an establishment of *Sphagnum magellanicum* (until AD 1970) and *S. angustifolium*, as well as *Eriophorum vaginatum*. This transition is simultaneous with changes in TA assemblages as reflected by an expansion of *Cryptodiffugia oviformis*, *Archerella flavum*, and *Hyalosphenia papilio*. From ca. AD 1620 up to 2015 *C. oviformis* dominated in TA communities which indicates stable but relatively low water table. From ca. AD 1785 the coring spot dominated by *Sphagnum fallax*, which points to the transition to lawn/carpet vegetation. These conditions were not appropriate for *Archerella flavum*. On the other hand, *Euglypha rotunda*, *E. compressa*, and *Physochila griseola* revealed the co-occurrence with the *S. fallax*. During the last 100 years, the forests were dominated by *Pinus sylvestris* and *Betula* which is an effect of the modern silvicultural activity. These data will be supplemented by historical sources in the future. Research financially supported from the funds of National Programme for the Development of Humanities (Project: NPH012; PI: Piotr Guzowski).

⁷Department of Hydrobiology, Adam Mickiewicz University in Poznań, Poznań, Poland

Abstract

High-quality studies of past environmental changes require complementary proxies and continuous sediment profiles. Raised bogs preserve well various subfossils in the oligotrophic peat. We focused on 3 peat cores from ombrotrophic bogs located in northern Poland, along the gradient of increasing continentality (Bagno Kusowo, Gązwa and Mechacz Wielki, respectively). The results of earlier analyses of pollen, testate amoebae (TA), and plant macrofossils were supplemented with non-pollen palynomorphs (NPPs) and additional AMS radiocarbon datings. To further facilitate the interpretation and discussion of results regarding bogs' development, hydrological and vegetation changes, we included data from 90 surface samples, collected in 2015 from the same bogs as cores. The samples represent different microhabitats such as hummocks, hollows, small pools, *Sphagnum* patches in forests, and overgrowing drainage ditches and they vary in regard to modern vegetation. During the collection of samples, additional information about pH, geochemistry, water level, canopy density and vegetation cover (within the frame 50 x 50 cm) was collected. The main aim of the research was to interpret the relationships between NPPs and environmental conditions, including modern samples and palaeorecord. The preliminary results of RDA from the modern pollen and NPP dataset revealed a positive correlation between *Assulina muscorum* (HdV-32A) and HdV-96A and DWT (depth to the water table), whereas a negative correlation was reflected by *Archerella flavum* (HdV-31A). The latter taxon together with a fungal type HdV-90 and *Sphagnum* spores also displayed a negative correlation with the canopy density. In data retrieved from peat cores, Bagno Kusowo and Mechacz Wielki recorded similar patterns of NPPs in relation to DWT, pH, and vegetation. In general, in both sites an increased abundance of humic substances was strongly correlated with the presence of macrofossils of *Eriophorum vaginatum*, *Sphagnum fuscum/capillifolium* and Ericaceae and fungal NPPs *Gelasinospora* sp. (HdV-1), *Chaetomium* (HdV-7A), and HdV-73. However, they were negatively correlated with DWT i.e. their occurrence was related to rather wet conditions. Fungal spores HdV-8B, HdV-123 and HdV-126 corresponded to herbal macroremains whereas HdV-18, HdV-19, and HdV-182 were correlated with more acidic conditions. Different patterns were reflected by the Gązwa bog. In this profile, a positive correlation between the presence of decomposed peat and *Eriophorum vaginatum*, *Sphagnum fuscum/capillifolium* and Ericaceae was not as prominent as in other peatlands. Moreover, DWT was also correlated with the presence of decomposed peat and Ericaceae macrofossils. Fungal NPPs HdV-13 and HdV-96A were linked with the occurrence of Ericaceae macrofossils, whereas *Assulina seminulum* (HdV-32B) and *Geoglossum sphagnophilum* (HdV-77A) were related to higher pH values. Our study reveals that individual history of *Sphagnum* peatland development may enrich interpretations explaining the distribution and ecology of NPPs. Research is financed by the National Science Centre, grant no. UMO-2014/13/B/ST10/02091.

⁵Department of Hydrobiology, Adam Mickiewicz University in Poznań, Poznań, Poland

Abstract

Most palaeoecological research applying testate amoebae (TA) as a proxy are conducted on ombrotrophic bogs, which are believed to be more suitable for palaeoclimatic studies. Only several studies regarded the entire oligotrophic-eutrophic gradient that provided novel data on the TA diversity and their habitat preferences in the past. In our study, we focus on a rich fen located in the vicinity of Lake Kazanie in Greater Poland. The exceptional diversity of testate amoebae (over 100 taxa recorded in a 92 cm long profile) gave us an opportunity to fully investigate the transformations of this fen in the last 300 years. The rich fen that developed in place of the terrestrialized lake was dominated in the past by brown mosses *Scorpidium cossoni* and *Pseudocalliergon trifarium*. Among TA, the most numerous were the representatives of *Centropyxis* sp. (with rare *C. delicatula*), *Diffflugia* sp., *Pyxidicula* sp., *Arcella discoides*, *Heleopera petricola*, *Hyalosphenia platystoma*, *Microchlamys patella*, *Paraquadrula irregularis*, and *Parmulina obtecta*. The transition to poor fen conditions in the coring spot took place about 30 years ago when *Sphagnum* mosses (mostly *S. fallax*) spread, contributing to the increase in the peat accumulation rate (from average of 0.15 mm/yr to 1.1 mm/yr). Simultaneously, as quantitative TA-based reconstructions reflected, the water level started to decrease gradually, which might have been connected with some drainage works, and a conductivity dropped, which suggests more acidic conditions. The expansion of *S. fallax* contributed to the appearance and/or spread of *Euglypha* ssp. and *Nebela* ssp., as well as of *Assulina muscorum*, *Corythion dubium*, *Heleopera rosea*, *Pseudodiffflugia* sp., and the regular presence of *Trinema lineare* and *T. enchelys*. In the period of *Pseudodiffflugia* sp. dominance, the prominent decline of TA diversity was recorded. Nowadays the Kazanie fen is mostly overgrown by *Phragmites australis* and *Sphagnum* mosses persist only in the margin areas, among them the coring spot. Hence, other strong shifts in TA taxonomic content and diversity are highly probable in near future on the entire fen surface. Our study provides a rare and intriguing reconstruction of extremely rich fen to poor fen transitions and illustrates well the differences between TA communities occupying acid bogs and alkaline fens. It also stresses the fact that fens appear much more complex and multidimensional habitats for TA. To explain the mechanisms driving TA diversity of fens, which are still poorly recognised, further studies are needed. Such studies are highly important for the predictions regarding the future of valuable but disappearing rich fens in Europe. Research financially supported from the funds of National Programme for the Development of Humanities (Project: NPH012; PI: Piotr Guzowski).

Holocene carbon storage of alluvial peatlands in contrasting river systems

Ward Swinnen^{1,2}, Nils Broothaerts¹, Renske Hoevers¹, Teun Daniëls¹, Eline Maurer¹, Gert Verstraeten¹
¹KU Leuven, Leuven, Belgium, ²Research Foundation Flanders, Brussels, Belgium

Abstract

Reconstructions of peatland carbon stocks and its variability over spatial and temporal timescales can provide important information on the factors governing local peatland dynamics and the carbon storage. Alluvial wetlands contain high amounts of carbon, mostly under the form of peat deposits, and constitute a common peatland type in temperate climates. Throughout the Holocene, most river systems in Europe have known phases of peat formation, but their long-term dynamics in relation to climatic and land cover changes remain poorly understood. In contrast to the high-latitude regions, which have been studied more intensively, human impact in temperate Europe through land cover changes has been much more intense and spread over a longer period of time and might prove to be an important factor in floodplain peatland formation. This study aims to study the Holocene evolution of floodplain peatlands in temperate river systems and to quantify the carbon storage.

In this study, four medium-sized river catchments (< 1000 km²) were studied, covering a range of climatic and environmental gradients and varying in degree and timing of human impact. Specifically, the sites were selected in Belgium, in the loess belt (Dijle catchment) and the sandy Campine region (Grote Nete and Zwarte Beek catchment) and in Scotland (upper Dee catchment). To make a detailed reconstruction of the floodplain architecture, soil corings were made along floodplain cross-sections. Combined with soil samples and radiocarbon dating, the Holocene geomorphic evolution could be reconstructed and the phases of active peat growth could be identified.

Overall, the results indicate that the long-term evolution of the fluvial system and the carbon storage is different for each of the regions. As the studied rivers respond differently to the complex interplay of climate, land cover and human impact, a variety of case studies is needed to study the long-term evolution of floodplain peatlands. The floodplains of the Dijle for example were covered by peat-forming alder forest during the Early Holocene. Later, hillslope erosion due to agricultural practices has led to a geomorphic transition towards meandering rivers and a reduction in the floodplain carbon storage. In contrast, floodplains in the Scottish Highlands have known more recent peatland formation, due to a reduction in fluvial geomorphic activity. Overall, the mean carbon storage ranges from 32 kg C m⁻² for the Dee to 66 kg C m⁻² for the Zwarte Beek, with a strong variability within each river system. In general, these case studies indicate that floodplain peatlands are difficult to model, since local peat growth models are insufficient to explain the observed dynamics. Additionally, upstream hydrology and geomorphological dynamics need to be accounted for.

P-2869

Peatland responses to repeated tephra deposition

Lauren Shotter¹, Anthony Newton¹, Andrew Dugmore¹, John Stevenson²

¹University of Edinburgh, Edinburgh, United Kingdom, ²British Geological Survey, Edinburgh, United Kingdom

Throughout the Holocene, Icelandic peatbogs have suffered repeated tephra fall events from volcanic eruptions. Large plinian eruptions have created key isochrones across Iceland, depositing metres of tephra on peatbogs proximal to the source volcano, thinning out over others across the island. This research has explored peatland response and resilience to this external driver from a number of sites across Iceland, using a palaeoenvironmental approach coupled with classical tephrochronology.

The frequent visible tephra layers found in Icelandic peatbogs, combined with radiocarbon dates, has provided robust chronological frameworks. These well support palaeoenvironmental investigation and allow sites hundreds of kilometres apart to be easily stratigraphically correlated. Data shows that the tephra events have been a driver for peatland dynamics and destruction, effecting peat initiation, accumulation, hydrology, and ecology. These results may be used to better understand the vulnerability of modern Icelandic peatbogs to volcanic eruptions and other external drivers such as human impacts and climate change.

Reconstructing Holocene carbon accumulation within two upland peat bogs in SW Wales: assessing the human and climatic impact

Kristy Holder¹, Siwan Davies¹, Alayne Street-Perrott¹, Isabel Macho²

¹Swansea University, Swansea, United Kingdom, ²Carmarthenshire County Council, Llandeilo, United Kingdom

Abstract

Peatlands represent an important component in the global carbon cycle, storing ~ 30% of belowground carbon, and in Wales (UK) peatlands are the largest terrestrial carbon store^[1]. However, centuries of persistent human interference have led to ~ 75% of Welsh peatlands becoming degraded^[1]. This degradation has destabilised peatland carbon stocks and resulted in Welsh peat becoming a source of anthropogenic CO₂ emissions, estimated to be producing ~ 400 Kt CO₂ equivalents per year^[1]. The impacts of recent human activity, alongside the threat of projected climatic changes, has brought peatland restoration to the forefront of the national environmental agenda. The Carmarthenshire peatlands, a series of six upland bogs in SW Wales, have frequently been subjected to burning and drainage, and their southerly, marginal position puts them at further risk under a warming climate. Using an innovative multi-proxy palaeoenvironmental approach, and in collaboration with Carmarthenshire County Council, this study is the first to reconstruct temporal carbon accumulation rates in response to human and climatic impacts, to inform appropriate conservation strategies. The work is focused on the two sites with the deepest peat depths, Pyllau Cochion and Figyn Common. At Pyllau Cochion, an age-depth model, constrained by 10 radiocarbon dates, is calculated against carbon content to provide a time weighted 'apparent' peat carbon accumulation rate (CAR)^[2]. This produces an average CAR value of ~ 21 (g C m⁻² yr⁻¹), comparable to other northern hemisphere Holocene rates. Carbon accumulation has varied substantially since peat initiation (*ca.* 9800 cal yrs. BP), with the highest rates observed during the Middle Holocene, succeeded by an overall declining trend towards lower values, with an especially pronounced reduction in recent times (*ca.* 700 cal yrs. BP – present). The lowest values in recent times are accompanied by an increase in burning activity and there is an indication that earlier fluctuations in carbon accumulation are associated with shifts in surface wetness. The results are compared to the nearby Figyn Common record. This research has contributed to a Heritage Lottery funded project that centred on implementing conservation measures and promoting public understanding of the sites. This includes a series of artistic impressions, from the Younger Dryas to the present day, that are underpinned by the proxy reconstructions.

Mid-late Holocene pollen records from the forest-steppe ecotone of the Mid-Russian Upland: Vegetation and fire history, human impact

Olga Rudenko¹, Elena Novenko^{2,3}, Lyudmila Shumilovskikh^{4,5}

¹Turgenev Oryol State University, Oryol, Russian Federation, ²Lomonosov Moscow State University, Moscow, Russian Federation, ³Institute of Geography, Russian Academy of Science, Moscow, Russian Federation, ⁴Department Palynology and Climate Dynamics, Georg-August-University Göttingen, Göttingen, Germany, ⁵Tomsk State University, Tomsk, Russian Federation

Abstract

Little is known about the history of the forest-steppe ecotone in Eastern Europe and here we report on its dynamics over the past ~7000 cal yr BP. A multiproxy research on peat deposits from several state nature reserves located within the Mid-Russian Upland, European Russia was carried out. Proxies used included pollen and non-pollen palynomorphs, plant macrofossils and micro charcoal particles in combination with radiocarbon datings and estimations of forest cover using the best modern analogue technique.

The data show that during the mid-Holocene (7000-4500 cal yr BP) the dominated landscape was wooded steppe and the boundary between forest and steppe biomes was disposed of 50-70 km further north-west in comparison to its present position. The boundary shifted to the south following climate cooling and an increase in precipitation during the period from 4800 to 2500 cal yr BP. Both birch-pine and mixed temperate deciduous forests of oak, elm, ash and lime with Scots pine and well-developed shrub understory of hazel and alder grew in the region. Over the past 4000 cal yr BP, the total woodland coverage has varied insignificantly, ranging from 30 to 50%, while the structure of the forests has changed radically. Intensive agricultural colonization of the territory accompanied by enhanced burning, soil erosion, felling of trees led to an irreversible reduction of deciduous forests and their replacement by secondary birch with total deforestation during the last 200-400 years.

Three main periods of frequent fires are identified: 3900-3200 cal yr BP, 2000-1600 cal yr BP (Early Iron Age), 1000-400 cal yr BP (Medieval period).

Nowadays the remnants of the primary forest-steppe vegetation are persisted in small locations only and under state protection.

Refining the calibration of oxygen stable isotopes as a proxy for the Southern Annular Mode in New Zealand restiad peatlands

Matthew Amesbury^{1,2}, Thomas Roland¹, Daniel Charman¹, Jessica Royles³, Howard Griffiths³, Rewi Newnham⁴, Andrew Rees⁴, Joshua Ratcliffe⁵, David Campbell⁵, Elizabeth Keller⁶, Troy Baisden⁵

¹University of Exeter, Exeter, United Kingdom, ²University of Helsinki, Helsinki, Finland, ³University of Cambridge, Cambridge, United Kingdom, ⁴Victoria University of Wellington, Wellington, New Zealand, ⁵University of Waikato, Hamilton, New Zealand, ⁶GNS Science, Lower Hutt, New Zealand

Abstract

The Southern Annular Mode (SAM) is a key control on Southern Hemisphere (SH) climate. It has had a positive trend since the 1950s, but its long-term behaviour is poorly understood. Developing reliable SAM reconstructions is critical to understanding SH climate but there are few appropriate land areas from which reconstructions can be derived. New Zealand (NZ) is a sensitive location for detecting past changes in the SAM due to the competing influences of temperate (dominated by the SAM) and sub-tropical climates. Developing a robust insight into past SAM behaviour requires proxies for both temperature and precipitation in order to elucidate regional variations in climate drivers and responses. Stable isotope ratios of carbon and oxygen have the potential to provide such a dual approach, however it is imperative that proxy development is grounded in a mechanistic understanding of the contemporary processes that result in isotopic fractionation and underpin palaeo interpretation.

We previously tested relationships between carbon and oxygen stable isotope ratios in restiad plant cellulose with climate and hydrological variables in NZ to investigate their potential as palaeoclimate proxies in Holocene age peat deposits formed predominantly of *Empodisma* spp. root remains. Here, we refine the calibration and interpretation of the oxygen isotope proxy for precipitation moisture source. We have expanded the spatial and temporal extent of our calibration dataset and, following cryogenic vacuum distillation, additionally analyse the isotopic composition of internal plant waters to better determine and understand plant physiological and isotope fractionation processes. We found precipitation, peatland water and internal plant water to be clearly linked, meaning that source waters for cellulose synthesis are well-defined. Mechanistic modelling using source waters to predict root cellulose isotope values is effective, and correlations between source waters and root cellulose isotope values are significant, but only when an average of internal root and shoot water inputs is used, suggesting that *Empodisma* mobilises sucrose from both roots and shoots to form root cellulose. These results improve our understanding of the physiological and isotopic processes governing cellulose synthesis, providing a more robust foundation for interpretation of the oxygen stable isotope proxy in a palaeo context.

The colour of Draftinge Mosse peatland, Sweden

Olalla López-Costas^{1,2,3}, Malin Kylander^{4,5}, Jenny Sjöström⁴, Noemí Silva-Sánchez¹, Sophia V. Hansson⁶, Antonio Martínez Cortizas¹

¹Earth System Science, Universidade de Santiago de Compostela, Santiago de Compostela, Spain, ²Archaeological Research Laboratory, Stockholm University, Wallenberglaboratoriet, Stockholm, Sweden, ³Laboratory of Physical Anthropology, Universidad de Granada, Granada, Spain, ⁴Department of Geological Sciences, Stockholm University, Stockholm, Sweden, ⁵The Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden, ⁶Department of Bioscience – Arctic Environment Section, Aarhus University, Roskilde, Denmark

Abstract

Colour is a physical property of light as seen by the human eye. It has been traditionally used to approach, for example, the degree of humification (DPH) and plant remains in peat. To avoid the subjectivity inherent to an individual's perception, parameters defined according to colour spaces, such as CIE Lab, are used. The colour-metric of peat provides an alternative non-destructive and rapid method to study its physical characteristics and obtain information on peat/peatland evolution and environmental drivers.

Freeze-dried and milled peat samples (n=160) from a core collected from Draftinge Mosse (Southern Sweden), spanning the last ca. 8,300 years were measured for colour. Usual CIE Lab parameters: L* (luminosity), a* (green to red), b* (blue to yellow), C* (chroma) and h* (hue), were obtained with a Konica-Minolta CR-5 colorimeter. Other analyses available for this core (n=76) include total C and N, C/N ratios, isotopic composition ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$), and a FTIR degradation index (Cb/Lp, carbohydrates/lipids), which allow us to assess the colour results. The studied core can be divided into two main sections according to peat composition, a fen phase and a bog phase.

CIE Lab coordinates, L a* b*, and C* are highly correlated between them (0.73 to 0.99). Hue is only correlated negatively with a* (-0.63). In general, the colour of the peat varies from very dark brown to dark brown (from 46.8 to 22.38) and chromaticity is low (C* from 8 to 21). The peat composition seems to have an influence in the colour, the fen showing lower L*, a*, b* and C* and higher h* than the bog.

The colour parameters, except for h*, were negatively correlated (-0.50 to -0.76) to C, N and $\delta^{15}\text{N}$ and positively correlated (0.68 to 0.78) to the Cb/Lp index and $\delta^{13}\text{C}$: the colour gets darker and less chromatic as C, N and $\delta^{15}\text{N}$ increase, and Cb/Lp and $\delta^{13}\text{C}$ decrease (i.e. as peat decomposes). The hue (h*) is moderately correlated to N (0.58) and age (0.64), which means the peat became brownish with time. The a* parameter is also inversely related to age. We interpret the obtained results as indicative of 1) a long-term control by decomposition (mainly a* and h*), and 2) a climatic-controlled decomposition that occurred under decreased or increased wetness, when the peat section was at, or near, the surface of the bog. This shows that quantified colour studies are viable tools for studying decomposition in peatlands.

Geochemical indication of paleoenvironmental changes during the formation ombrotrophic bogs of the South of West Siberia (Russia) in the Holocene

Natalia Larina¹, Sergei Larin², Ksenya Belozerova¹, Svetlana Volkova¹

¹Tyumen State University, Tyumen, Russian Federation, ²Cryosphere Earth Institute SD RAS, Tyumen, Russian Federation

Abstract

A characteristic feature of Western Siberia is a lot of eutrophic marshes with inclusion some ombrotrophic bogs, alkaline meadows, solontchaks, as well as lakes, different in size, shape, origin and extent of salinity. According to the research (Larina et al., 2013, 2014) ombrotrophic bogs began to form in Subboreal-Subatlantic periods of Holocene in this area. Beginning of formation water meadow dates from the early to mid subboreal period. Low-power peat deposits were formed at the beginning of Subatlantic period of the Holocene. In regard to the stratigraphic thickness of peat are relatively uniform. Lake sediments often are placed at the basis, and then a layer of lowland peat goes, which is replaced by high peat, sharply or gradually, through a horizon transitional peat. Capacity of the individual horizons may differ due to local factors that determine the rate of peat accumulation. The average rate of vertical growth of peat in Subboreal Subatlantic-Holocene period, calculated from the radiocarbon dates obtained from peat bogs and water meadow Tobol-Ishim forest-steppe, is 0.8 mm / year. The rate of growth of peat is not constant and can change considerably in the separate time intervals.

Geochemical characteristics some of peat bogs were investigated to assess the biogeochemical conditions in the different periods of the Holocene, to identify local, regional and global signal of anthropogenic environmental impact. They reflect the different temporal features organo-accumulation of soil formation, biogeochemical migration of the elements, climate change and vegetation during the Holocene, as well as the specifics of the modern stage of formation of peat.

Geochemical analysis of peat deposits is a source of information on the rate of accumulation and decomposition of organic matter, which are determined by various factors, including climatic and environmental. Indicator of dynamic and direction of these processes can serve as a study finding forms of organic matter in the peat. Fractionation was carried out for some purpose samples of peat, selected from different depths and with different genesis. In selected fractions of humic and fulvic acid were identified stability constants for carboxyl, carboxyl -phenolic and amine-phenolic groups with using potentiometric method. The presence of these groups was confirmed by IR spectroscopy.

Another important indicator of environmental and climatic changes is the concentration of heavy metals that flow into peat deposit mainly from rainfall and long-range Eolian dust. Form finding of metals in peat is also important. This determines the migration ability of metals in peat deposits and sources of metals.

Combination of methods allows reconstructing the conditions, when the peat layers formed.

ACKNOWLEDGEMENT

The work was carried out with the financial support of the Russian Foundation for basic research (Contract No. №18-44-860010) and the government of the Khanty-Mansiysk Autonomous Okrug–Yugra.

Hawaiian paleohydrology: insights from testate amoebae and Cladocera in peatland deposits

Kevin Barrett

University of Wisconsin-Madison, Madison, Wisconsin, USA

Abstract

Few high-resolution paleoclimate records exist for the Hawaiian Islands and available records are primarily derived from proxies of vegetation, which are challenging to untangle from human activity in recent centuries. It is critical to develop independent proxies of ecohydrological dynamics to give context to ongoing changes in biodiversity and climate on the islands. Fossil remains of testate amoebae (Protozoa: Rhizopoda) and Cladocera (water fleas) have been used as environmental indicators in paleohydrological studies of temperate and boreal peatlands, especially those dominated by *Sphagnum*. We present the first use of this proxy in tropical montane peatlands in Kohala, Hawaii Island and apply it to a case study of peatlands in Kohala recently dominated by *Sphagnum* moss. Peatland surface soils were collected from a variety of ecohydrological habitats (from water pools to hummocks) and analyzed for modern testate amoebae and Cladocera. We identified 51 taxa from 21 genera of testate amoebae and 4 taxa and genera of Cladocera. Multivariate analysis indicates that the presence and abundance of testate amoebae and Cladocera taxa are significantly controlled by water table depth. A transfer function based on weighted averaging was developed to predict water table depths from species relative abundance data: RMSEP = 9.87 cm, $r^2 = 0.58$. We applied the transfer function to a series of peatland cores from Kohala to reconstruct a thousand year history of water table depth fluctuations and to examine the recent (~150 years ago) expansion of *Sphagnum palustre*. Testate amoebae and Cladocera inferred paleohydrological reconstructions show that arid conditions between 1840-1860 and following the 1977-76 winter Pacific Decadal Oscillation shift preceded expansion and establishment of *Sphagnum* moss in Kohala peat. The peat-based paleohydrology is supported by a five-century reconstruction of Hawaiian winter rainfall derived from ENSO teleconnections. The results highlight the potential of utilizing testate amoebae and Cladocera to estimate paleohydrology from peatland deposits in tropical montane ecosystems.

Holocene climate and permafrost history for the western Kenai lowlands, Alaska, from stable isotopes and plant macrofossils

Lesleigh Anderson¹, Miriam Jones², Ben Jones³, Virginia Littell⁴

¹U.S. Geological Survey, Geosciences and Environmental Change Science Center, Denver, CO, USA, ²U.S. Geological Survey, Florence Bascom Geoscience Center, Reston VA, USA, ³University of Alaska Water and Environmental Research Center, Fairbanks, AK, USA, ⁴University of Washington Earth and Space Sciences Department, Seattle, WA, USA

Abstract

The current state of permafrost in Alaska and meaningful expectations for its future evolution are informed by long-term perspectives on previous permafrost degradation. South-central Alaska currently has a mean annual temperature of $\sim 2^{\circ}\text{C}$ and is typically mapped as permafrost free. However, residual permafrost is known to persist in wetlands with spruce protected permafrost plateaus. In the Browns wetland complex of the western Kenai lowlands, two ~ 600 cm cores were obtained within a permafrost plateau in 2014 and the ice-rich peat record was found to span the past 12,000 years. The oxygen and hydrogen isotope ratios of the frozen pore water reflects freeze/thaw and paleoclimatic history that can be integrated with lithology, cryostructural analyses, and macrofossil assemblages. Results indicate rapid peat accumulation and syngentic permafrost development in an early fen system by 12,000 cal yr BP that became a bog by $\sim 11,500$ cal yr BP. By $\sim 9,000$ cal yr BP an abrupt shift in lithology to ice-poor silt reflects some combination of a decline in peat accumulation, increase in peat decomposition, and/or hiatus. Pore-water isotope compositions indicate thaw unconformity and/or stagnant multi-annual active layer depths. Resumption of peat accumulation by $\sim 3,700$ cal yr BP includes brief shifts in fen and bog macrofossil assemblages that could indicate periods of thaw. They co-occur with epigenetic cryogenic textures and steady declines in pore water isotope ratios that reflect an overall cooling trend along with a shifts in atmospheric circulation indicated by other regional records. Similar isotopic trends are evident from the bulk peat cellulose isotope record from nearby Horse Trail Fen and broader geographic comparisons are also made with newly developed lake sediment isotope records from Upper Cook Inlet. As the first continuous post-glacial record of water isotopes from an Alaskan peatland permafrost that links the evolution of ground ice with climate trends, this study provides a framework for future investigations of paleoclimatic signals from similar wetland systems that characterize large regions of Alaska and Siberia.

Climatic controls on peat swamp formation and evolution since 1300yr BP as recorded by phytoliths in the Xishan Mountains, China

Zhang Xinrong^{1,2}, Du Yu^{1,2}, Ma Chunmei³, Ping Shuaifei^{1,2}, Feng Chong⁰

¹College of Earth Sciences, Jilin University, Changchun 130061, China, ²Key-Lab for Evolution of Past Life and Environment in Northeast Asia, Ministry of Education, China, ³School of Geography and Ocean Science, Nanjing University, Nanjing 210023, China, ⁴Faculty of Geographical Science, Beijing Normal University, Beijing 100875, China

Abstract

Over the past millennium, there have been several precipitation–temperature cycles characterized by instabilities in the eastern monsoon region in China, but the processes, factors, and anthropogenic activities potentially responsible remain poorly understood. In this study, we present an analysis of phytoliths from borehole core drilled through an ombrotrophic peat mire in Jiangxi Province, China. Our results records three climatic episodes over the past 1300 yr: a warmer interval, c. 800–1305 A.D., similar to the Medieval Warm Period (MWP); a cooler interval, c. 1305–1860 A.D., similar to the Little Ice Age (LIA); and another warmer interval, as the climate entered the Present Warm Period (PWP) after c. 1860 A.D. Quantitative analysis of phytolith assemblages demonstrate that the MWP comprised two intervals: the early MWP, c. 800–1140 A.D., was progressively wetter in a warm–dry setting and late MWP, c. 1140–1305 A.D., was warm and humid. The LIA also comprised two intervals: the early LIA, c. 1305–1610 A.D., was cool and dry, and the late LIA, c. 1610–1860 A.D. was cool and humid. Some abrupt climate events occurred at: (1) c. 1050, 1110–1130, and 1780–1845 A.D. (wet events); (2) c. 1980–1990 A.D. (dry events); (3) c. 920 and 1770 A.D. (warm events); (4) c. 980 and 1050 A.D. (cold events). The transition from the MWP to the LIA, as indicated by phytoliths, was a gradual process that took c. 100 yrs, and exhibited frequent temperature fluctuations. Correlations between the phytolith assemblages and the solar activity, East Asia Summer Monsoon, El Niño, and La Niña are evident. Solar maxima and La Niña-like conditions are related to warmer and humid conditions that led to clay–sand accumulation during the MWP. Solar minima and El Niño-like conditions were associated with a cold and wet climate that led to peat accumulation during the LIA. These observations provide important insights into paleoclimatic change in the eastern monsoonal region of China. It provides reliable information to analyze the response of the Xishan Mountains in SE China to the MWP and LIA, which is helpful to explore the 100-year-scale climate fluctuations and potential mechanism in the scenario of global changing.

Quaternary evolution of the Upper Yellow River: progressive drainage of formerly endorheic Tibetan Plateau basins

David Bridgland¹, Zhenbo Hu², Robert Westaway³

¹Durham University, Durham, United Kingdom, ²Lanzhou University, Lanzhou, China, ³University of Glasgow, Glasgow, United Kingdom

Abstract

The existence of endorheic drainage basin systems high on the NE Tibetan Plateau, while surprising, can be explained in relation to the 'basin-and-range' structure imposed upon the upland block by the nature of the tectonism that created it, there being a series of elongate basins of various sizes separated by mountain ranges formed from resistant rocks. Many of the basins on the NE Tibetan Plateau, although endorheic earlier in the Quaternary, have been 'captured' by drainage to the ocean, in particular by the Yellow River (Huang He). This has led to 'inversion' of these basins, with a striking change from sediment accumulation to incision by the river and its tributaries into the basin-fill deposits. The progress and timing of the incision is recorded by the disparate terrace sequences in the various basins. The Yellow River drains a succession of basins from its upper reaches to its lower course across the North China Plain: the Yueguzonglie, Zaling, Eling, Zoige, Xinghai-Tongde, Gonghe, Gui-de, Xunhua, Longzhong, Zhongwei-Zhongning, Yinchuan, Hetao, and Fenwei basins, generally connected by gorge-reaches through the intervening hard-rock mountain ridges. The fact that different basins are at different stages of dissection is perhaps key to understanding the evolution of the Yellow River drainage system, a topic that has been debated for many years. There is continuing uncertainty about whether basins have become linked to the oceanic drainage as a result of headward erosion ('capture') or because the fluvio-lacustrine basins have overflowed, either because they have become filled or as a result of tilting caused by lateral variations in uplift of the Tibetan Plateau.

P-2879

HOLOCENE CLIMATE PULSES AND MARINE REGRESSIONS TRIGGERING FLUVIAL ADJUSTMENTS IN THE NORTHERN LITTORAL OF THE RIO DE JANEIRO STATE, BRAZIL

André Souza, Archimedes Perez Filho
UNICAMP, Campinas, Brazil

Abstract

In this work, we seek to investigate the connections between the low terraces genesis and marine regressions events induced by Holocene climate pulses. We used absolute dating by optically stimulated luminescence and grain-size analyses in 10 samples collected on low fluvial, marine and marine terraces located on the left (4 samples) and right banks (6 samples) of the Paraíba do Sul river. The low fluvial-marine terraces present sandy fraction decrease up to top (160 cm: 98%; 100 cm: 17%; 50 cm: 5%). Meanwhile, in the low fluvial terraces are predominantly clayey fractions (ranging from 93.8% to 65.8%) and the marine terrace, predominance of the sandy fractions (99%). In general, the low terraces are topographically staggered towards the sea, ranging from 13 to 2 meters above the RSL. Thus, the low fluvial terraces are located about 13 meters, the fluvial-marine and marine terraces around 4 and 2 meters above the current RSL. In the right bank, the low fluvial terraces are distributed into two levels from the water surface of the Paraíba do Sul river (3 m (T1) and 2 m (T2), respectively). The absolute ages were 0.340 ± 0.025 ka (T1) and 0.25 ± 0.020 ka (T2). In the left bank, it is located 12 m from the RSL and the absolute ages were less than 100 years. The fluvial-marine are positioned at 4 and 3 meters from the RSL (left and right margin, respectively). On the left bank, the ages were 0.45 ± 50 ka (160 cm deep), 0.385 ± 0.17 ka (100 cm deep) and less than 100 years (50 cm deep). On the other hand, the ages were 0.250 ± 0.035 ka (150 cm deep), 0.125 ± 0.030 ka (120 cm deep) and less than 50 years (70 cm deep) to the left bank terraces. Finally, the low marine terrace had ages less than 100 years (70 cm deep). The results showed that the geochronology of T1 (right margin) is correlated to the beginning of a marine regression, whereas the T2 is likely related to the second regressive pulse. Likewise, the left bank low fluvial terraces are geochronologically match with the most clayey tops coverings of the low fluvial-marine and marine terraces, suggesting connections with the coastline establishment around 100 years B.P. The ages of the events are correlated to the Little Ice Age and severe droughts recorded in Central America. In this sense, it is possible that a rainfall increase occurred due to Intertropical Convergence Zone (ITCZ) persistence over the Southern Hemisphere along of the late Holocene. Therefore, the increase of fluvial discharge driven by climate pulses triggered marine regressions, coastline displacements, base level lowering and channel entrenchments. We are thankful to FAPESP (grant 2016/00382-9) and CNPq (grant 304414/2014-0) by financial support.

P-2880

First ESR chronology of the Duero River terrace system in Northern Spain

Davinia Moreno, Alfonso Benito-Calvo

Centro Nacional de Investigación sobre la Evolución Humana (CENIEH), Burgos, Spain

Abstract

Intraplate basins potentially preserve the most complete record of tectonic, geomorphic and climatic evolution within the interior of continents. In the Iberian Peninsula most of the largest Cenozoic sedimentary basins show a change from aggradation to degradation. Determining the cause of the transition from aggradation to degradation and how this was linked to tectonic, climatic, and geomorphic events hinges on the chronology of the fluvial network incision and excavation of the basins fills. Fluvial terrace staircases, as a product of river incision, provide a direct record of incision and are known to be the result of the combination of climatic changes and tectonic uplift.

The incision of most of the Iberian Peninsula basins appears to have initiated in the Quaternary but the precise timing of its initiation is actually poorly known and constrained. In order to overcome the lack of chronologies for these basins, in the following study we started by studying the Duero basin and its terrace system. It is a major intracratonic basin bounded by Cenozoic structures and is characterized by a maximum of 16 terrace levels from +141-144 m to +8-10 m, with the present alluvial plain at +4-5 m (Pérez-González *et al.*, 1994; Santisteban and Schulte, 2007). The only published ages for the Duero basin are by Moreno *et al.* (2012) who confirmed the potential of the Electron Spin Resonance (ESR) dating method applied on bleached quartz extracted from terrace fluvial deposits on the Arlanzón valley, a main tributary of the Duero River located in the NE area of the basin. In this work, ESR was systematically applied to the main river, the Duero River, dating 4 different terraces spanning from the high to the medium levels: T2 (+135m), T3 (+114m), T5 (+90m) and T10 (+41m).

ESR dates are coherent with the analyzed terrace system and allow defining the onset and development of the Duero valley in the center of the basin. Additionally, these results also allow to reconstruct the incision response of the tributary system, comparing these ESR results with those published about the Arlanzón river in NE sector of the basin.

Holocene dynamic and meander undersizing of an alluvial sector of the Jacaré-Guaçu river, state of São Paulo, Brazil

Éverton Vinícius Valezio, Archimedes Perez Filho
Universidade Estadual de Campinas, Campinas, Brazil

Abstract

Fluvial dynamic is directly linked to the physical constraints of the landscape. Allogenic and autogenic changes impact on the channel's morphology and condition its associated forms. Throughout the Upper Pleistocene and Holocene, the Jacaré-Guaçu river migrated vertically and laterally, developed terraces and a wide floodplain, maintaining the meandering configuration. The relation of the fluvial forms mapped with the fluvial evolution of a specific alluvial segment in the mid-section of the Jacaré-Guaçu river indicates that the presence of a planimetric oversized meander bend, currently placed at a lower terrace level, corresponds to distinct hydrological characteristics from those of now. The mapping, identification and evolutionary interpretation of the selected section were carried out using Rapideye and CBERS-HRC orbital imagery; elevation data from the Shuttle Radar Topography Mission (SRTM) and aerial photographs (1:25,000), along with fieldwork and Optically Stimulated Luminescence (OSL) dating. The abandoned meander located 4 meters above and 600 meters away from the current channel has greater width and length measurements than the ones found on the current Jacaré-Guaçu river, as well as semi-rounded to rounded gravel with up to 30 centimeters at the base of the terraces, which contrasts to the pebbles currently carried by the river. The identified fluvial terrace, widely located at the left bank, shows the preferential displacement of the river towards the right bank, with sand deposits dating from ~ 7.6 kyr to ~ 7.9 kyr (samples collected at 90 and 135 centimeters deep, at different points of the terrace). The remaining and established forms of the floodplain and its respective measurements and dating suggest changes in the precipitation and drainage dynamics, resulting in the undersizing of the Jacaré-Guaçu river in response to climatic implications over the Holocene. Our thanks to FAPESP (São Paulo Research Foundation) for financially enabling this research (Process n. 2016/24390-0).

Landscape evolution of the Gangkou River in the southern Taiwan in respond to sea-level changes and tectonics since late Pleistocene

Jia-Hong Chen¹, Shyh-Jeng Chyi¹, Lih-Der Ho¹, Jiun-Yee Yen², Christopher Lüthgens³

¹Dept. of Geography, National Kaohsiung Normal University, Kaohsiung, Taiwan, ²Dept. of Natural Resources and Environmental Studies, National Dong Hwa University, Hualien, Taiwan, ³Institute of Applied Geology, University of Natural Resources and Life Sciences, Vienna, Austria

Abstract

Gangkou River is the largest drainage basin in the eastern Hengchun Peninsula of the southern Taiwan. The geomorphic features of the river basin are remarkably wide valley plain with flights of fill terraces and relatively narrow active channel. Such underfit river feature is unusual in a tectonically active area like Taiwan, where rapid river incision usually creates gorges and a flight of bedrock terraces.

Results from field survey, radiocarbon dates and X-ray fluorescence indicate that large-scale aggradation took place between 16ka and 6ka BP and formed fill terraces with relative height of 14m to 20m to the modern channel bed. The fill terraces are consist of floodplain facies sediment. Furthermore, we took a 30-meter long drill on a higher fill terrace near the estuary. The X-ray fluorescence data reveals chemical signals of marine transgression event between 8.5ka and 7.5ka BP at the depths of 5m to 12m from the top of the drilling core, and the accumulation rate of 2.8-3.0 mm/yr is estimated from the core. However, fluvial archive is absent basinwide between 6 ka and 0.5 ka, and only marine terrace (4.9-4.8ka), beach rock (4.5-4.2ka) and sand dune (around 3.4-3.2ka) developed in the same period can be found in the estuary area, yielding a tectonic uplift rate of 0.9 mm/yr. Meanwhile, the beach rock layer covered unconformably the estuary deposit of 8ka. The unconformity indicates a period of river erosion, which could be induced by the tectonic uplifting and gradual sea-level falling since the middle Holocene. Finally, lower terraces with relative height of 2m to 5m were formed around 0.5ka, and the alluvial deposit also covered unconformably the floodplain facies sediment of about 9ka.

In summary, we propose the landscape evolutionary history of the Gangkou River basin, demonstrating that sea-level could be the primary control factor of a coastal drainage basin in an orogenic setting. Our findings point out that rapid sea-level rise and low uplift rate cause significant river aggradation and wide valley in the estuary of Gangkou River during the late Pleistocene to the early Holocene. The aggradation event probably would not stop until 6ka, and the height of sea-level at that moment is about 9 meters higher than the modern one. Afterward, relative sea-level falling induced a long term river incision basinwide.

Facultad de Ciencias. Universidad Nacional de Educación a Distancia, Madrid, Spain

Abstract

In western Iberia, mechanisms that explain the transition from endorheic to exorheic continental-scale drainage reorganisation are foreland basin overspill, headwards erosion and capture by an Atlantic river, or a combination of both. To explore these controls we have investigated the Portuguese sector of the Douro River, the site of drainage re-organisation. The Douro River routes downstream through weak sedimentary infill of the Douro Cenozoic Basin (Spain), after which the river cuts down through granitic and metamorphic rocks cut by active fault zones (NE Portugal), before reaching the Atlantic coast. We investigated the drainage reorganisation using an integrated remote sensing, field survey and geochronological approach applied to Pliocene-Quaternary fluvial sediments and landforms. The older drainage record is documented by a series of high and intermediate landform levels comprising 1) a high level (1000-600 m) faulted regional fluvial erosion surface, the North Iberian Meseta Planation Surface (NIMPS); 2) an inset level (650-600 m altitude) comprising a broad fluvial surface formed onto a large ENE-WSW depression that overlies resistant Proterozoic and Paleozoic bedrock and 3) an inset (500-450 m) fluvial surface. The younger drainage record comprises an entrenched fluvial strath terrace sequence of up to 9 levels (T9 = oldest positioned at 246-242 m above the modern river base (a.r.b.); T1 = youngest positioned at 17-13 m a.r.b.). Levels T1 and T3 display fault offsets where the cross active NNE-SSW fault zones.

The three lowest terrace levels (T1-T3) were dated using optically stimulated luminescence (OSL) techniques using Quartz-OSL and post infra-red stimulated luminescence (pIRIR). Results ranged from 39-12ka (T1), 57ka (T2) and >360ka (minimum) (T3). Fluvial incision rates of the younger (terrace) drainage record were quantified and temporally extrapolated to model the ages of the high to intermediate elevation levels of the early drainage record. Integration of incision data with fault zone derived crustal uplift values informs on the timing of the endorheic to exorheic drainage reorganization.

We interpret the NIMPS to be part of the endorheic Douro Cenozoic Basin drainage divide erosion. The inset wide fluvial surface at 650-600 m altitude represents the overspill level in the area of the Mesão Frio ridges (drainage divide with the Atlantic drainage). Development of the exorheic ancestral Douro valley is documented in the 500-450 m fluvial surface with our age and uplift modelling suggesting this became established during the upper Pleistocene (3.6 Ma) through to the Early Pleistocene (1.8 Ma). The entrenched river terrace sequence spans the Pleistocene, developing via spatial and temporal variations in rock strength, uplift and cyclic cool climate variability as the river adjusts to the Atlantic base level.

Dating Swiss Deckenschotter with isochron-burial dating

Catharina Dieleman¹, Marcus Christl², Christof Vockenhuber², Naki Akçar¹

¹University of Bern, Bern, Switzerland, ²ETH Zurich, Zurich, Switzerland

Abstract

Swiss Deckenschotter (*Cover Gravels in German*) are the oldest Quaternary deposits in the Northern Alpine Foreland and document the landscape changes during the Early and Middle Pleistocene. They are characterised by a succession of glacio-fluvial sediments intercalated with glacial and/or overbank deposits. A significant phase of incision divided this succession into two units: Höhere Deckenschotter (HDS; Higher Cover Gravels) and Tiefere Deckenschotter (TDS; Lower Cover Gravels). The Northern Alpine Foreland in Switzerland was overridden at least 13 times by the glaciers during the Quaternary, of which eight glacier advances can be tracked in the HDS and TDS sequences. For a long time, HDS and TDS were correlated with the Günz and Mindel glaciations after Penck and Brückner. HDS were correlated with the Günz glaciation and TDS with the Mindel. The timing of the Deckenschotter deposits is still poorly understood and absolute ages are scarce. Recently, a new chronology has been established in several HDS and TDS outcrops by depth-profile and isochron-burial dating techniques. The new chronology suggests that HDS and TDS are ca. 2 Ma and ca. 1 Ma old, respectively. However, it is challenging the existing chronology based on mammal fossils at Irchel, since 2 Ma old deposits are located at the same morphostratigraphical position as 1 Ma old ones. Therefore, how far does the chronology explain the approach “*same elevation means same age*”? The aim of this study is to explore Swiss Deckenschotter deposits at Irchel, the area around Mandach and Lake Constance in detail, to reconstruct the timing of the Early and Middle Pleistocene glaciations with isochron-burial dating, and to implement these results into a more complex landscape evolution model than thought so far.

To achieve these goals, we selected eleven new Deckenschotter sites: three HDS sites at Irchel, three HDS and three TDS sites in the area around Mandach, as well as one HDS and one TDS sites in the region of Lake Constance. One sediment sample consisting of quartz pebbles and at least nine clasts of various lithologies, shapes and sizes were collected per site. After the physical quartz separation, ¹⁰Be and ²⁶Al were extracted from five clast samples and the sediment sample for the accelerator mass spectrometry (AMS) measurements at ETH Zurich. In addition, sediment analyses were conducted to reveal the sediment source, paleoflow regime, transportation mechanisms and depositional environment. First results will be presented.

P-2885

Global and local climatic variations during the last interglacial-glacial cycle recorded in loess on the terraces of Dnister River (Ukraine)

Maria Łanczont¹, Przemysław Mroczek¹, Maryna Komar², Andryi Bogucki³

¹Maria Curie-Skłodowska University, Lublin, Poland, ²National Academy of Sciences of Ukraine, Kyiv, Ukraine, ³Ivan Franko National University, Lviv, Ukraine

Abstract

On the slopes of the upper Dnister River a set of Pleistocene terraces (II-V) of various age is developed, all with loess cover. Two lower terraces are located at a similar height, and the loess superstructure in the common fragment represents the last interglacial-glacial cycle. These terraces are represented respectively by sites in Yezupil and Mariampil, situated on both sides of the river valley. The aim of the studies is to assess the impact of local factors on the nature of environmental changes and microclimate features.

After the Eemian pedogenic stage in both sites remained luvisol developed into loess (Yezupil) or on the river sediments (Mariampil). Starting from the Early Weichselian, the rate of loess sedimentation and the soil processes environment in both sites were different. The early glacial is represented by one chernozem horizon (Yezupil), and three such soils separated by loess (Mariampil). Soils formed during MIS-3 are cambisols, in the first case weakly developed, in the second – much better.

Yezupil's success begins with Eemian, but already during the dominance of loose forests. The optimum was dominated by thermophilic multi-species deciduous forests with rich undergrowth, meadow vegetation occurred in depression reliefs, and steppe on hills. In the period of early glaciation, a mosaic of forest patches and open places with steppe vegetation characterized the landscape. During MIS-3 there were steppe, meadow and pioneer communities as well as small pine and birch thickets.

In Mariampil, quite complete stages of the Eemian forest development (warm and temperate deciduous forests in optimum) have been documented. Interstadials was characterized by the continuous presence of pine and oak forests later pine, with a decreasing admixture of other deciduous trees, and forestless areas and forestry enclaves covered by steppe-meadow vegetation. During MIS-4, the landscape was open with groups of pine-birch forest. In the middle part of the MIS-3, there were comfortable conditions for tree vegetation, which occupied the depressions while the slopes and watersheds were occupied by meadow steppe vegetation. During MIS-2, a mosaic landscape with tundra and steppe vegetation with coniferous trees prevailed.

Differences in the vegetation composition indicate the dependence of the local vegetation variation on the site surrounding morphology and their location within the river valley. The Yezupil's surrounding were relatively cooler due to NE exposure, the position in the straight-line NW-SE section of the valley with the probability of the tunnel wind effect. In turn, the vicinity of Mariampil was characterized by a certain quietness. This place was more sheltered, better sunlit and warmer, which caused: SW exposure, covering from the north by a high ridge, location at the break point of the river valley, which could have a detrimental effect on the wind capacity causing increased aeolian sedimentation.

Morphological and geochronological investigations (OSL) in the Miaoli Tablelands (NW Taiwan)

Shih-Hung Liu¹, Chia-Han Tseng², Yan Li³, Robert Hebenstreit¹, Margot Böse¹, Manfred Frechen⁴

¹Institute of Geographical Sciences, Department of Earth Sciences, Freie Universität Berlin, Berlin, Germany,

²Graduate Institute of Applied Geology, National Central University, Taoyuan, Taiwan, ³School of Ocean Sciences, China University of Geosciences, Beijing, China, ⁴Department of Geochronology, Leibniz Institute for Applied Geophysics, Hannover, Germany

Abstract

In northwestern Taiwan depositional terraces are located in the foreland of the Neogene high mountain ranges. The terrace evolution has so far been outlined in general but detailed studies are missing. They are considered to be of Quaternary age. Geomorphological mapping, open-source borehole data interpretation and luminescence dating (coarse-grain quartz-OSL) approaches have been applied to determine the morphology and chronology of the relevant terrace evolution.

Three sub-categories of terraces are classified by their elevation and morphology: 1) *sedimentary highland "SH"* (> 250 m asl., mainly in the eastern part), 2) *sedimentary terraces "ST"* (250 – 50 m asl., in the central part) and 3) *alluvial terraces at the riverbanks, and coastal plain "AL"* (< 50 m asl.). The complete sedimentary sequence of the terraces is > 50m thick. This sequence represents the depositional environmental change that has started from shallow marine, to tidal-flat and beach, subsequently to fluvial environment and then is overlain by aeolian dust. We identified three sub-types of sedimentary successions. Type-I contains the complete sedimentary succession, which represents the terraces in *SH* and *ST*. Type-II contains most parts of the sedimentary succession except the gravel and cobble bed(s), which are indicative of the fluvial environments. This type represents remnants of the terraces in *ST*. Type-III shows very thin (< 2 m) gravel and cobble bed(s) on the top, representing fluvial channel deposits and terraces near the coastal area. We suggest that the different sedimentary successions have a clear relationship to the landform.

Luminescence dating shows that the samples from the beach sediment layers are beyond the range for quartz-OSL signals. The fluvial gravel and cobble bed in the "*ST*" gave OSL ages of ca. 22ka, while the fluvial gravel and cobble bed on the "*AL*" gave OSL ages of ca. 10ka. The different depositional ages indicate the cyclical deposition-erosion-transportation processes have reworked the gravel and cobbles from the "*ST*" to the "*AL*".

The underlying marine and coastal sediments in the studied stratigraphy indicate that the mountain foreland was once a shallow marine environment during a sea-level high stand. Sediment yields from the high mountain ranges are documented as fluvial deposits by the complete sedimentary sequence of the terraces. The regression triggered the fluvial response and the subsequent linear erosion. Once the gravel and cobbles were eroded by denudation and fluvial incision, terraces called tableland today, become a clear morphological feature after uplift. Finally, the elevated erosional base during the early Holocene triggered the latest deposition of the gravel and cobbles in the coastal area. We assume that the combination of tectonic processes, eustatic sea-level changes and surface processes is responsible for the landform development in the study area.

Diachronism of river terrace formation? – Lessons to learn from luminescence dating results

Thomas Kolb¹, Markus Fuchs¹, Ludwig Zöller²

¹Justus-Liebig-University, Giessen, Germany, ²University of Bayreuth, Bayreuth, Germany

Abstract

Revealing an amazing diversity of forms, river systems must always be interpreted as products of their specific landscapes. Extremely sensitive to external and internal forcing, they reflect the particular characteristics of climatological and geological conditions as well as the changes of these conditions. These changes are regularly preserved in depositional series whose varying sedimentary characteristics can be attributed either to palaeoclimatic variations or to tectonic activities and their corresponding changes in fluvial discharge and sediment load. What applies to fluvial sediments in general, is particularly true for river terraces. The importance of fluvial terraces in geomorphology, archaeology and modern river engineering is well documented by a huge and still growing number of studies spanning a wide range of climatic and regional settings.

However, the information gained from fluvial terraces and their significance for palaeoenvironmental research strongly depend on an accurate dating of the terrace formation. Numerical ages are of fundamental importance for the interpretation of sedimentological, morphological and stratigraphical findings. They are essential for assessing the influence of various driving forces and for providing insights into the mechanisms and dynamics of river adjustments over differing timeframes. Without a reliable chronological framework, reconstructing past fluvial environments would not be possible.

In this poster, we present luminescence ages of fluvial deposits originating from an Upper Pleistocene river terrace in a small valley located in the headwaters of the Main River, Germany. For this study, several samples from various locations throughout the river longitudinal course have been analysed. Surprisingly, the determined luminescence ages for material from the lowermost part of the valley are significantly older than those from the middle section, which in turn are older than those from the valley's upper reaches. Based on the evaluation of a high-resolution digital terrain model (DTM) and on intensive fieldwork, we can be sure that all samples originate from the very same morphological unit, a well-preserved late Pleistocene fluvial terrace.

Our results suggest a diachronic alignment of sedimentation ages for fluvial deposits, starting with old ages close the mouth of a river and getting progressively younger for locations approaching the upper reaches. Whether these results only represent a local feature or a general pattern of fluvial response to external or internal forcing, cannot be answered at this point. If these findings were confirmed in other fluvial systems and were not only the result of very specific local conditions, they would be of great relevance for geomorphological research in fluvial landscapes and generally emphasize the particular importance of careful interpretations of ages derived for fluvial deposits.

P-2888

Neotectonic control on Solani river basin in the western part of the Himalayan foothills, India

Narendra K. Patel, Pitambar Pati

Department of Earth Sciences, Indian Institute of Technology Roorkee, Haridwar, India

Abstract

The foothill-fed Solani river is flowing through a longitudinal fault. It forms a river basin of 1933 km² area in the western Himalayan foothills of the Ganga foreland basin before meeting the Ganga river. This paper aims to study neotectonic control on the Solani river basin using morphotectonic indices such as longitudinal river profile, channel sinuosity, basin asymmetry, bifurcation ratio, stream gradient index, drainage density, mountain front sinuosity and field studies. Though the Solani river is flowing on a sloping surface (1.7% slope), it shows meandering channel characteristics along with its tributaries. Local convexity in the longitudinal river profile indicates differential uplift or local disequilibrium state of channels due to tectonic perturbation of the faults. The calculated sinuosity index (SI) values depending on the window size are found to be representative of neotectonic influence along the river course. The SI value along the river varies from 1.27 to 1.96. The drainage basin asymmetry factor (AF) 17.41 indicates the main channel has shifted towards the downstream right side of the drainage basin. Bifurcation ratio (Rb) varies from 2 to 3.3, the mean Rb of the entire basin is 2.67. The drainage basin has moderate drainage density of 2.33 indicates low to moderate infiltration of the region. Stream gradient index (SL) of Solani river ranges from 15.9 to 116.8. SL values against river length shows consistent anomalies across active fault zones. Mountain front sinuosity (S_{mf}) adjacent to the river basin varies from 1.04 to 1.13 indicating active nature of the region with pronounced uplift. S_{mf} and the channel sinuosity show a good correlation and suggest neotectonic control. Uplift rate along the Himalaya in the region shows a strong correlation with the morphotectonic signatures of faulting. There are three unpaired terraces in the right bank of the river course indicating temporal activity of the Solani fault in Quaternary.

Arqueología, Paleontología y Recursos culturales AUDEMA S.A., Madrid, Spain, ⁶Aarhus University, Risø DTU, Aarhus, Denmark, ⁷- Centre for Nuclear Technologies, Technical University of Denmark, Risø Campus, Denmark

Abstract

This study presents new geochronological and paleoclimatic data from the lower terraces of the Tagus River in the environs of Toledo city (central Spain). Within the Upper Tagus basin, a maximum of 22 terrace levels developed from +180 m to +3-5 m (above present river thalwegs). The research is focused on Middle to Late Pleistocene terraces with palaeontological and Palaeolithic (Acheulean and Mousterian) sites preceding the Last Glacial period. Includes new OSL datings on Quartz (Qz-OSL) and k-Feldspar (pIRIR) grains for the terrace levels up to +25 m. Because the Qz-OSL is in saturation for the samples collected from terrace deposits, all measurements were made with the pIRIR protocol. The ages obtained indicate that the terrace at +9-8 m (Lower Valdelobos site) was developed during MIS 3 (56 ± 3 ky), the terrace at +14-16 m (Salchicha site) during the last interglacial (MIS 5; 100 ± 5 ky) and the one at +20-18 m (Monterrey site) around the MIS7-MIS6 transit (180 ± 15). The +20-18 m terrace is about 4.4 m thick, buried by 1.5-2 m thick fine sands of probable aeolian origin. Beneath this sandy cover, the terrace top deposits displays a well-developed soil profile, corresponding to a typic Haploxeralf, which consists of a dark brown (7.5YR 4/4 m) to strong brown (7.5YR 4/6 m), about 80 cm, thick prismatic argillic horizon with some vertic features. Particle size distribution data show an increase in clay content with depth, ranging from 28.5% to a maximum of 43% from clay illuviation process, occurred after end of deposition of the terrace. Carbonate leaching of overlying sandy materials gave place to development of carbonate nodules (2-3 cm in diameter) and even calcified roots about 4 cm length, preferentially in the lower part of argillic horizon. This process represent a period of increasing aridification, which occurred after the deposition of the aeolian cover with ages of 15.3 ± 1.2 ky (Qz) to 12.7 ± 0.8 ky (Kf). These sand deposits penetrate within the underlying argillic horizon across significant cm-scale sand wedges interpreted as an initial vertic origin enhanced by frost action (ice wedges), during cold periods after terrace deposition. Similar sands of supposed aeolian origin cover the younger terraces and even some older ones (Pinedo Terrace, at +25-30 m), with ages of 11.8 ± 1.3 ky (Qz) to 11.0 ± 0.9 ky (Kf). These data suggest that deglaciation and onset of the Holocene featured enhanced aridification, indicated by carbonate accumulation in soils and occurrence of a generalized aeolian mantling of younger fluvial terraces.

Evolution of Quaternary fluvial terraces and their placer gold deposits in the Klondike Goldfields, Yukon Territory

Jeffrey Bond, Sydney van Loon
Yukon Geological Survey, Whitehorse, Canada

The genesis of Quaternary fluvial deposits and their placer gold content, particularly in mature landscapes, is often linked to pre-Quaternary eluvial and fluvial history. The unglaciated Klondike region of central Yukon Territory contains some of the richest placer gold-bearing streams in the world. These deposits formed through a long process of Pliocene weathering, fluvial sedimentation and reworking, and earliest Quaternary drainage capture that triggered terrace formation. The Pliocene White Channel gravel terraces contain an anomalous abundance of quartz clasts and detrital gold particles, signifying previous environmental refinement. Previous studies suggested that chemical weathering of regolith was the primary process of altering the Klondike schist to clay, contributing to a build-up of vein quartz and gold in the surficial environment. While this is undoubtedly true, recent stratigraphic studies indicate a more complex process of chemical alteration within the fluvial environment. In recent mining exposures, a pre-White Channel gravel deposit (informally termed the Paradise gravel), has been identified stratigraphically below, and adjacent to, the White Channel gravel. Non-quartz clasts within the Paradise gravel were clay-altered at the time of reworking by the White Channel gravel, approximately 4 million years ago. Clay-altered metamorphic and igneous clasts disintegrated into fine particles in the fluvial environment and were transported out of the drainage leading to a higher concentration of quartz within the White Channel gravel. Importantly, placer gold reworked from the Paradise gravel was concentrated at the base of the White Channel gravel forming a rich pay streak.

Terrace formation began at the onset of the Quaternary period 2.84 million years ago when the first continental glaciation diverted the Yukon River into central Alaska causing a lowering of base level. Thick deposits of White Channel gravel were reworked into relatively thin Quaternary fluvial deposits. Placer gold reworked from the Pliocene sediments accumulated into anomalously rich deposits in Quaternary terraces and modern streambeds. The most spectacular placer gold concentrations were recorded in Eldorado Creek where each 500 foot-long claim contained on average 30,000 oz of gold. While most of the valley-bottom deposits have been mined out, modern miners still discover buried intermediate-level Quaternary terraces containing economic gold concentrations. These

terraces are often found on the inside bends of valley curvatures, preserved as a result of lateral channel migration

during incision.

Aerial view of a tributary to Quartz Creek in the Klondike Goldfields. The Quaternary fluvial terrace, inset into the Pliocene terrace is a subtle landform feature often masked by colluviated loess. The exploration trench was excavated in 2018 and discovered economic gold concentrations within the landform.

P-2891

Plio-Quaternary evolution of the central Apennines: the case of the Medium-Upper Aniene River Valley (Latium, central Italy)

Paola Molin, David Scaccia, Andrea Sembroni, Michele Soligo, Paola Tuccimei Dipartimento di Scienze, Università Roma Tre, Rome, Italy

The Apennines Chain has been affected by a regional uplift since the Upper Pliocene, with an increase in uplift rate since the end of Lower Pleistocene. In the last decades, many attempts have been made to estimate the timing and magnitude of the topographic growth affecting the chain. Estimations of past surface uplift in orogen interiors are difficult for the lack of geomorphic markers with known original elevation such as marine terraces. For this reason it is crucial to exploit continental indicators of past base levels such as fluvial terraces and planation surfaces. In particular fluvial terraces record changes in fluvial dynamics (aggradation and incision) depending on the interaction between climate and tectonics. Moreover, when carbonate aquifers are present, climate influences the formation of fresh-water travertines which, for this reason, are widely studied to investigate Quaternary climate changes. In this framework the Medium-Upper Aniene River Valley (Central Italy) represents a good testing site to investigate the interaction between surface processes, climate, and tectonics in the context of the Apennines topographic growth. Indeed this portion of the Aniene River Valley is characterized by widespread well-exposed Quaternary deposits consisting in wide fluvial terraces and fresh-water travertines alternated in places with lacustrine and volcanic deposits. Despite the well exposure of outcrops and the dateability of travertines and volcanic deposits, poor efforts have been done in order to correlate the Quaternary deposits along the Aniene River Valley nor to investigate the interaction between deposition, tectonics, and climate. In order to tackle this problem we perform a multidisciplinary approach comprising a topography and river network GIS investigation, a field survey campaign to map the Quaternary deposits along the valley, a geochemical and geochronological analysis of travertine deposits, and a paleontological analysis of lacustrine deposits outcropping in the study area. The results allow to reconstruct the Plio-Quaternary evolution of the Medium-Upper Aniene River Valley in the framework of the uplifting and extending Apennines chain.

P-2892

Pleistocene terraced travertines and fluvial deposits, incision and uplift in Acquasanta Terme area (central Apennines, Italy)

Erlisiana Anzalone¹, Paola Molin², Andrea Sembroni², Michele Soligo², Paola Tuccimei²

¹CNR Isafom, Ercolano, Italy, ²Dipartimento di Scienze, Università Roma Tre, Rome, Italy

The Acquasanta Terme area is located in the Marche region (central Italy), on the eastern side of the central Apennine Chain. The Apennine Chain is a Neogene E-verging thrust-and-fold belt formed from the convergence of the Eurasia and Adria-Africa plates and the successive Tyrrhenian Sea opening in Miocene time. The Apennines are affected by a strong regional uplift since the end of the Lower Pleistocene. The interaction between this upheaval and the climate changes generates alternating phases of incision and aggradation in the Apennines valleys. In particular, in the Acquasanta Terme area, four levels of fluvial terraces formed: the first three levels are covered by bodies of travertines. These are thermal water deposits of Middle-Upper Pleistocene, developed exclusively on the SE side of the Tronto River Valley. The travertines bodies, consisting mainly in low Mg calcite, have different lithofacies, represented either by in situ carbonate incrustations on vegetable supports or by deposits showing a "clastic" textures. This lithofacies association define depositional settings varying from pool gradin to waterfall environment and showing progradational and aggradational patterns. Travertine deposition is still active in correspondence of several hot springs in the Acquasanta Terme area. We dated the three carbonate bodies by U-series method, obtaining the time span of deposition: more than 350 ka to about 54 ka (first level), 113 to 53 ka (second level), 79 to 26 ka (third level). Using the age relative to the samples collected close to the base of the travertine bodies (sometimes very close to the underlying fluvial deposits) and measuring the elevation of the river terraces with respect the elevation of the present Tronto River channel, we calculated an incision rate of 0.6 mm/yr for all the three terraces. This result is comparable with the uplift rate estimated for the central Apennines chain.

P-2893

A study of late Quaternary sedimentary archives of upper Indus valley, Ladakh: Implications on paleoclimate, provenance and drainage reorganization

Ravish Lal¹, Naresh Chandra Pant¹, Hari Singh Saini², Abul Amir Khan¹

¹University of Delhi, NEW DELHI, India, ²Geological Survey of India, Faridabad, India

Abstract

Ladakh, a tectonically active highest plateau of the planet earth, is uniquely located in low latitudes, to study and understand the climate-tectonic interaction during Quaternary, a period of major climate changes. Representing the elevated trans-Himalayan domain, it is bound by the southern Indus-Tsangpo Suture Zone (ITSZ) and the northern Shyok Suture zone. The other remarkable tectonic element present is a crustal scale strike slip fault known as Karakoram fault. The major geological units present in the upper Indus basin include Ladakh granite of the Island arc affinity, the ophiolites and subordinate metapelites. Quaternary deposits in a ~250 km long stretch of Indus were examined to infer the late Quaternary geological history of this valley. The Quaternary deposits in this stretch occur as isolated and incomplete sedimentary sequences of river terrace deposits, moraines derived tills and other glacial deposits and fan deposits at hill slopes, debris flow and alluvial fans and paleo-lacustrine deposits.

On account of the climate cum geographic position of the Ladakh it is worthwhile to evaluate the influence of global and regional climate forces. To facilitate this evaluation, the fluvial and lake deposits are chosen to represent glacial (cold) and interglacial (warm) periods respectively during the Quaternary time.

Based on the morphology of the river valley and other geomorphological considerations and the nature of associated deposits, the study area has been divided in four sectors : (Sector I to Sector IV). Sections at Tsaka La (river terrace deposit in Sector I), Nyoma (Lacustrine sequence in Sector I), Upshi (Composite glaciofluvial deposit in Sector II), Shey, Spituk and Palam (Lacustrine and fan deposits in Sector III) and Zinchan (Lacustrine deposit in Sector IV) were logged, granulometrically analysed, age constrained and studied for provenance signatures using heavy mineral assemblages.

Thus OSL ages obtained represents aggradational activities under fluctuating climatic condition from MIS 5e – MIS 3. Data generated in the present work has been used to provide an event stratigraphy during late Quaternary in the upper Indus valley and accordingly, the glacial stratigraphy of the region has been modified. Lastly terrestrial record of Ladakh was compared with respect to the global climate record (MIS) to see the Synchronicity of Quaternary climate of Ladakh and the present study shows that from MIS5 to MIS4 the influence of regional climate forces in Ladakh waned and the local climate conditions were similar to the global ones.

P-2894

Might the East Asian Summer Monsoon Control the Formations of the Qingyijiang Terraces in Northern Piedmont of Mt.Huangshan, Southeast China?

Chunsheng Hu

Anhui Normal University, Wuhu, Anhui Province, China

The Qingyijiang River, which is an important tributary of the lower Yangtze River, drains the northern flank of Mt. Huangshan in southeast China. Field investigation focuses on the natural outcrops along the Qingyijiang River in the Jingxian Basin, where a well-preserved sequence of four terrace gravel layers is present. These Quaternary terraces of the Qingyijiang River offer a valuable archive for palaeoenvironmental changes in a subtropical climate region. Using electron spin resonance (ESR), optical stimulated luminescence (OSL), and palaeomagnetic dating and pollen and grain size analyses, the objective of this study is to reveal the essential controlling factor of Qingyijiang terrace formations. The results indicate that (1) the formation ages of four Qingyijiang terraces were estimated to be ~1300, ~900, ~600, and ~1.5 ka based on ESR, OSL, and palaeomagnetic dating; (2) the Qingyijiang terraces were generated under warm and wet paleoclimatic conditions which were inferred from the pollen and grain size analyses that resulted in four significant wet periods (~1300, ~900, ~600, and ~1.5 ka); (3) the significant wet periods in the study area were mainly influenced by a significant weakening of the East Asian summer monsoon, which occurred at ~1300, ~900, ~600, and ~1.5 ka; and (4) the terrace formations of the Qingyijiang River might be directly controlled by the weakening of the East Asian summer monsoon. This study suggests that terrace generation might not always be controlled by climatic cycles in different climatic regions, and the mechanism behind terrace formations might be regionally unique.

Chronology of the establishment of Sarthe's alluvial system

lale SERIN--TUIKALEPA^{1,2}, Yoann CHANTREAU³, H el ene TISSOUX¹, Pierre VOINCHET²

¹BRGM, Orl ans, France, ²UMR 7194, Paris, France, ³DRAC Grand-Est, Ch alons-en-Champagne, France

Abstract

In terms of geomorphology, Quaternary period is characterized in Northern France by the entrenchment of the main alluvial systems. The glacial/interglacial Quaternary climatic cycles of this period induce a variability in the competence of the rivers, and then a balance between erosion and deposition phases. In active uplift tectonic context, it usually results in the establishment of stepped terraces systems. Indeed, each climatic cycle seems allowing the establishment of a terrace deposit that can be protected from the erosion during the next glacial cycle through tectonic reasons (uplift, change of the course...). In parallel to geological and climatic events, Quaternary is also marked by the appearance of the genus Homo. During the Middle Pleistocene, prehistoric men are already present in Western Europe and in the Northern part of France. In sedimentary basin context, evidences of past human occupations have been recognized mainly at the bottom or at the top the fluvial terraces deposits.

The Sarthe river is located in the western France and flows on the edge of both geological formations of the sedimentary Paris basin and the Armorican Massif. This precursory work intended to establish the first chronological framework of the alluvial system of the Middle Sarthe's drainage basin and, by extension, to constraint the ages of the prehistoric human artifacts found on the surface of the terraces. In that aim, the Electron Spin Resonance (ESR) dating method was applied to optically bleached quartz extracted from Quaternary alluvial deposits. Results indicate that the Sarthe hydrographic network is aged of about 1.2 Ma, and that the incision of the valley by the river continued throughout the whole Middle and Late Pleistocene. Most of the fluvial terraces were deposited during the Middle Pleistocene.

Lower Palaeolithic archaeological artifacts of were found on terraces dated between 650 ka and 400 ka, while Middle Palaeolithic ones were recovered at the surface of formations dated between 320 and 200 ka, and Upper Palaeolithic ones on the most recent terrace.

Tributary stream long profile analysis of the Douro River (Portugal): insights into long-term drainage evolution in Western Iberia

António Martins¹, Alberto Gomes², Pedro P. Cunha³, Martin Stokes⁴

¹Institute of Earth Sciences; Department of Geosciences, University of Évora, Évora, Portugal, ²CEGOT, Department of Geography, University of Porto, Porto, Portugal, ³MARE, Department of Earth Sciences, University of Coimbra, Coimbra, Portugal, ⁴School of Geography, Earth and Environmental Sciences, University of Plymouth, Plymouth, United Kingdom

Abstract

We investigate the projection of the concave-up longitudinal profiles of the upstream sections of Douro River tributaries. This allows quantification of fluvial incision patterns as the trunk river passes through different tectonic blocks. The tributary profiles show two distinct configurations: 1) an upstream relict reach, almost in “equilibrium”, and 2) a lower rejuvenated reach, with an irregular form that relates to adjustment by the Douro River to the Atlantic base level. The relict profile is an almost steady state form, developed under a prolonged period of base level stability when the Douro Cenozoic Basin (DCB) changed from endorheic to exorheic (to the Atlantic). This basin encompassed a significant area of the northern Iberian continental landmass (mainly in Spain) with its western boundary (in Portugal) controlled by the high relief Western Mountains. The switch from sedimentation to erosion of the DCB implies a significant continental scale drainage rearrangement. The subsequent incision stage is recorded in strath terrace staircases with up to 9 levels configured within enlarged meanders and tectonic depressions.

In this work we used unpublished geomorphological maps and related information produced by Ferreira (1978), combined with new DTM model analysis and field surveys along the Douro watershed. These analyses have allowed identification of erosion surfaces and terrace levels, with quantification of their heights above the modern river bed. Regression analysis of gradient vs length and log slope vs log length enabled relict and rejuvenated profiles to be constructed. Projection of the relict profile to the tributary junction with the Douro River used the equilibrium longitudinal profile equation of Goldrick and Bishop (2007).

Results suggest that the tributary profiles contain an ancestral morphology of the Douro River that differs from the current convex morphology. In the “Arribas do Douro” knickzone, incision exceeds 500m, with some ~440m in the vicinity of the Vilarica Fault and > 600m in the downstream areas of the Plateaus and Mountains of Northern Portugal. Older knickpoints are clearly represented in the longitudinal profiles. These correspond to the upper limit incision wave migration from the Atlantic Ocean, reflecting the establishment of connection between the ancestral Douro and the Atlantic coast.

Determination of the rock uplift in Central Menderes Massif (Aydın Block), Western Turkey; inferences from OSL dating of fluvial terraces

Emrah Özpolat¹, Cengiz Yıldırım¹, Tolga Görüm¹, Eren Şahiner², Orkan Özcan¹

¹Eurasia Institute of Earth Sciences, Istanbul Technical University, Istanbul, Turkey, ²Institute of Nuclear Sciences, Ankara University, Ankara, Turkey

Abstract

Western Anatolia is one of the rapidly extending areas on the earth. Menderes Massif in Western Anatolia has been experiencing uplift above the South Aegean arc since the Neogene. However, quantitative dating studies on determine the rock uplift or surface uplift of the Central Menderes Massif has not yet been perform. The primary goal of this study is to determine the rock uplift rate of Aydın Block (central part of the Menderes Massif) by incision rates derived from key river terraces controlled by normal faults through the southern flank of Aydın Block using the OSL dating method. OSL ages of river terraces will help us to understanding the the influence of climate and tectonics on landscape evolution of study area.

Firstly, geomorphic units in southern mountain-front of Aydın Block were in detail mapped using a combination the Red Relief Image Mapping (RRIM) technique, unmanned aerial vehicle, TanDEM-X (12.5 m spatial resolution), D-GPS, and field observation. Firstly, we extracted the river terraces deformed by active normal faults from the three different locations through southern flank of Aydın Block using the with high-resolution (10 cm) DEM. From West to east, these locations are Tabakhane, Kabaklık and Esnek river, respectively. We determined at least the 5 terrace staircase with terrace elevations of 90 ± 0.2 m, 82 ± 0.2 m, 35 ± 0.2 m, 25 ± 0.2 m and 3 ± 0.2 m above the Tabakhane River, the 3 terrace staircase with terrace elevations of 45 ± 0.2 m, 22 ± 0.2 m, 8 ± 0.2 m above the Kabaklık River and the 6 terrace staircase with terrace elevations of 92 ± 0.2 m, 70 ± 0.2 m, 46 ± 0.2 m, 33 ± 0.2 m, 25 ± 0.2 m and 16 ± 0.2 above the Esnek River.

To determine the deposition time from the river terraces using the OSL dating, we chosen the three samples strategy from per river terrace level. We collected the six samples from terrace elevations of 90 ± 0.2 m and 25 ± 0.2 m for Tabakhane river, the six samples from terrace elevations of 22 ± 0.2 m and 3 ± 0.2 m for Kabaklık river and the twelve samples from terrace elevations of 92 ± 0.2 m, 46 ± 0.2 m, 25 ± 0.2 m and 15 ± 0.2 m for Esnek river. Thus, totally 24 OSL samples were collected from fluvial sediments. The preparation of samples for equivalent dose was performed under red light conditions. The luminescence measurements are currently under progress. We aim to present the first results during the congress. This study is supported by TÜBİTAK #116Y077 project and by the Turkish Academy of Sciences within the framework of the Distinguished Young Scientist Award Program (TÜBA-GEBIP-2016)

Quaternary river terrace-climate relationships on the NW Sahara Desert margin (Morocco)

Martin Stokes¹, Jesse Zondervan¹, Anne Mather¹, Sarah Boulton¹, Matt Telfer¹, Alaeddine Belfoul²

¹University of Plymouth, Plymouth, United Kingdom, ²Ibn Zohr University, Agadir, Morocco

Abstract

In this study we explore the role of cyclic Quaternary climate change as a driver for controlling temporal patterns of river terrace development from the south-central High Atlas Mountains of Morocco. This is a low-mid latitude, up to 4km high, dryland mountain setting along the north western margin of the Sahara Desert. We illustrate the cyclic climate relationship using the adjacent Dades and M'Goun Rivers, key non-glaciated catchments (areas = 1500-1200km²) that document along-strike variations in orogenic system lithology (strong carbonates vs weak mudrocks) and tectonic configuration (route across the fold-thrust belt, wedge-top basin, thrust front regions). Terraces occur primarily as straths, with erosional bases located at regular 10m altitudinal intervals from ~+2-3m to +80m above the valley floor, and a rare occurrence at 140m (Dades). Terraces are variably distributed along the Dades and M'Goun trunk drainages, being well preserved in the Thrust Front region, but variably preserved within the Wedge-Top Basin and Fold-Thrust Belt regions related to rock strength variations. Individual terrace levels are generally <7m thick, comprising key stratigraphic levels of a basal bedrock erosion surface, overlain by up to 5m of fluvial conglomerate (imbricated rounded cobbles) and variably capped by ~2-5m of fluvial slack water sand-silt or slope conglomerates (angular, poorly sorted gravels). To assess the timing of terrace formation we targeted the one of the most continuous strath terrace levels (~10m above the modern river) from a range of different trunk drainage locations across key orogenic system regions (Thrust Front etc). Results (published and preliminary) reveal that the 10m terrace aggraded between 164-127ka (fluvial conglomerate) and incised between 110-77ka (fluvial sands-silts). This suggests aggradation during the (MIS6) glacial followed by valley floor incision and terrace inundation during the (MIS5) interglacial through to the (MIS4) glacial, implying that terrace formation is potentially tuned to 100ka climate cycles. We compare this chronology and climate relationship to other African Quaternary archives, noting that this emerging chronology is one of the first meaningful insights into climate-related river behaviour on the north western margins of the Sahara Desert. The study illustrates that dryland mountain river terraces possess potential for informing on climate-related landscape development patterns. This is especially significant since most terrace-climate studies with meaningful chronologies and robust climate-fluvial landscape relationships come from moderate-large mid latitude river systems with direct hydrological linkages to the waxing and waning of northern hemisphere glacier / ice sheet systems. As knowledge of terrace formation is primarily based on numerical modelling studies, field examples such as this are essential to test and verify such approaches more robustly.

Lower Paleolithic artifacts preserved on the lower fluvial terraces of Minho River near Melgaço, NW of Iberia: diversity and chronology

João Pedro Cunha-Ribeiro¹, Sérgio Monteiro Rodrigues², Alberto Gomes³, Eduardo Méndez-Quintas⁴, José Meireles⁵, Pedro Xavier⁵, Manuel Santonja⁴, Alfredo Pérez-González⁴, Andrea Serodio Domínguez⁶, Martina Demuro⁷, Lee Arnold⁷

¹UNIARQ, Archaeology Center, University of Lisbon, Lisboa, Portugal, ²CITECEM; Department of Archaeology, University of Porto, Porto, Portugal, ³CEGOT, Department of Geography, University of Porto, Porto, Portugal, ⁴CENIEH, Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain, ⁵Lab2PT, University of Minho, Braga, Portugal, ⁶Data Gestión Cultural S.L, Vigo, Spain, ⁷School of Physical Sciences, Environment Institute, University of Adelaide, Adelaide, Australia

Abstract

Lower Palaeolithic industries are known in the Lower Minho River, Northwest of Iberia, for about 100 years. The first findings of Acheulean age were collected scattered along the river valley. Since the 1960s, attention was paid to an important Acheulean site of the right bank – Gándaras de Budiño, Galicia, Spain – with controversial chronology. New research has connected such site to the Middle Pleistocene and more recently new important Acheulean sites were discovered in the same river bank.

In the last three years, archaeological work carried out in the left bank of the Minho River (Portugal) has also allowed to (ACHO QUE LEVA UM "TO") the identification of new Palaeolithic sites, generally associated to ancient river deposits, also dating from the Middle Pleistocene. Its characteristic large cutting stone tools include different types of bifaces, most of them made from quartzite pebbles or wide flakes removed from large cores, and cleavers, as well as other artefacts such as cores and flakes, sometimes retouched.

In 2016, 2017 and 2018 multidisciplinary research was carried out at Carvalhas (municipality of Melgaço, Portugal), an archaeological site located in the surface of a river terrace, with the top 20 m above the current river bed. Such research involved the excavation of three different geoarchaeological contexts, the analysis of the local geomorphology and the sedimentary architecture of the terrace, and OSL dating.

Preliminary results suggest that the Acheulean assemblages are connect to an ancient river channel or meander, and to a colluvium/slope deposit, and were produced between c. 255 Ky and c. 335 Ky. Another assemblage, with a significant amount of flakes and associated to a deposit with different features, may date from a later period and be related eventually to the Middle Palaeolithic (no dates available for this context).

In conclusion, the abundance and diversity of the lithic stone tools from Carvalhas attest to the human presence at the NW of Iberian Peninsula during the Middle Pleistocene.

Late Quaternary evolution of fluvial terraces along Tista River in Darjeeling Sikkim Himalayas: Implications to climate and tectonics

Atul Kumar Singh, Manoj Kumar Jaiswal

Indian Institute of Science Education and Research, Kolkata, India

Abstract

Fluvial terraces are important geomorphic archive preserving information about past fluctuations in climate and tectonics. In tectonically active regions such as Himalayas which are also the drivers of Indian Summer Monsoon (ISM) and were influenced by the past climatic changes. To understand the impact of two processes, different sections of fluvial terraces were studied along the Tista River in the Darjeeling Sikkim Himalayas over a stretch of ~65 km.

An attempt has been made to reconstruct the geomorphic history of the region using Optically Stimulated Luminescence (OSL) dating and geochemistry. Four level of terraces were identified in the region as T4, T3, T2 and T1, in decreasing order of their ages. T3 terrace is nested into T4 and could only be differentiated on the basis of chronology. The upper age limit of T4 is ~72 ka and this period was followed by a glaciation phase. We do not get any deposits during this phase showing that this was a period of no active sedimentation. The T3 has an age range of ~50-30 ka and is regional in nature, whereas all other terraces are fragmentary in space. This time period was also an interglacial phase with similar precipitation conditions as of today. However, the Chemical Index of Alteration (CIA) values indicate that the weathering was not intense during this period indicative of relatively dry condition. The T2 formed during ~24-11 ka which was period of Last Glacial Maxima (LGM) followed by interglacial period and Younger Dryas event. The striking difference between T4, T3 and T2, T1 is its terrace material. The T4 and T3 are composed of laminated sand with few intercalations of cobble-pebble layers whereas, the T2, T1 and present day channel are composed of pebble, cobble and boulder beds with few thin sand units. The river dynamics during formation of T4 and T3 was such that it could only transport sand sized particles while during formation of T2 and T1 it changed drastically. It is important to understand that this change was either induced due to climatic fluctuations or due to the tectonics. We observed in two of the studied sections the T3 terrace was deformed indicating that this deformation event took place after its formation, i.e. 30 ka. This was followed by the formation of T2 terrace, pointing towards a tectonic activity between 30 ka and 24 ka which drastically changed the dynamics of the Tista River. Even the younger terraces viz. T2 and T1, also show warping indicating that the region is tectonically active in present day scenario, posing a serious problem for the local inhabitants. The climate and tectonics are working hand in hand in shaping the geomorphology of the region.

Holocene river terraces and alluvial fans in the Republican River valley: Implications for geoarchaeology in the central Great Plains, USA.

Anthony Layzell, Rolfe Mandel
Kansas Geological Survey, Lawrence, USA

Geomorphic and stratigraphic investigations during the late 20th century in the Republican River valley proposed a sequence of two distinct Holocene terraces. This differentiation, however, was based on limited age control and is problematic. Here, we present results from a systematic study of different alluvial landforms at 22 localities in the Republican River valley. A suite of over 50 radiocarbon ages determined on soil organic matter provide age control for periods of landscape stability and soil formation.

Holocene alluvial landforms in the river valley include a broad floodplain complex (T-0a, T-0b, T-0c), a single alluvial terrace (T-1), and alluvial fans that mostly grade to the T-1 and T-0c surfaces. Remnants of a late Pleistocene terrace (T-2), mantled by Holocene (Bignell) loess, are also preserved. Holocene alluvial fans also grade to the T-2 surface, indicating that higher geomorphic surfaces have provided local base level control during the Holocene.

Radiocarbon ages from the upper A horizons of buried soils, indicating approximate burial ages, cluster at ca. 10,050-9200, 6800-5800, 4500-4100, 3600-3100, 2200-1700, 1300-900 yr. B.P. The correspondence between these age groups and particular landforms provides important information on the evolution of the Republican River valley and, subsequently, on the temporal and spatial pattern of buried cultural deposits. In particular, age groups 6800-5800, 4500-4100, and 3600-3100 are exclusive to buried soils in the T-1 fill and associated alluvial fans. In contrast, age groups 2200-1700 and 1300-900 yr. B.P. are associated with buried soils in almost all landform types, including the T-1 and T-0c fills as well as fans that grade to the T-2, T-1, and T-0c surfaces.

Stable carbon isotope ($\delta^{13}\text{C}$) analysis of soil organic matter indicates a shift from ~40% C_4 biomass at ca. 6000 to ~85% at ca. 4500 yr B.P. This increase in C_4 biomass is interpreted as reflecting a shift to warmer and likely drier conditions during the Altithermal (Holocene Climate Optimum). We propose a scenario where (1) a reduction in C_3 vegetation after 6000 yr B.P. destabilized the uplands, resulting in an increase in sediment supply and aggradation of the T-1 fill and associated alluvial fans and (2) the establishment of C_4 vegetation by ca. 4500 yr B.P. stabilized the uplands, resulting in a reduction in sediment supply and subsequent incision and abandonment of the T-1 surface. The proposed timing and nature of landscape change is consistent with regional records from the Central Plains and provides an important model for identifying where specific cultural deposits are likely to be preserved in buried contexts.

P-2902

Characteristics and geochronology of the Severance Formation: a new mid-through late Wisconsinan lithostratigraphic unit in the Eastern Plains, USA

Rolfe Mandel¹, Arthur Bettis², Paul Hanson³

¹University of Kansas, Lawrence, USA, ²University of Iowa, Iowa City, USA, ³University of Nebraska-Lincoln, Lincoln, USA

Abstract

Studies of late Quaternary landscape evolution in river valleys of eastern Kansas and Nebraska have identified thick packages of mid- through late-Wisconsinan alluvium beneath terraces and thin to moderately thick accumulations of late-Wisconsinan colluvium preserved along margins of valley floors. Previously, these alluvial and colluvial deposits were referred to as the valley facies of the Gilman Canyon Formation (Mandel and Bettis, 2001), a unit of late-Wisconsinan loess on the adjacent uplands, but subsequently have been defined as a new lithostratigraphic unit, the Severance Formation. Recent investigations have revealed that the Severance Formation consists of two members: an early member that sometimes occurs immediately beneath the Gilman Canyon Formation, and a late member that is beneath a terrace surface or a thin veneer of Peoria Loess. Preliminary OSL ages suggest that the early member aggraded between ca. 50 and 30 ka. Hence, the early member records Marine Isotope Stage 3 (MIS 3) alluvial activity that predates the oldest Gilman Canyon Formation deposits and has potential to provide a window into a virtually unknown period on the Eastern Plains. OSL and radiocarbon ages suggest that the late member aggraded between ca. 30 and 14 ka (MIS 3 and 2); hence, it records valley activity just prior to and during cool and dry conditions that coincide with the accumulation of the Peoria Loess and related eolian sand on upland and high-terrace landscapes. The shift from the relatively warm moist conditions of MIS 3 to relatively cool, dry MIS 2 was accompanied by incision, perhaps mimicking the response of the drainage system across the MIS 4 (relatively cool/moist)/MIS 3 boundary.

Both members of the Severance Formation are oxidized, and the late member typically has two or more paleosols forming a pedocomplex similar to the one developed in the Gillman Canyon Formation. The paleosols tend to have thick, well-expressed Bt horizons with strong brown to yellowish brown matrix colors; prismatic to subangular-blocky structure; iron and manganese oxide stains and nodules; discontinuous clay films and silans; and many to common macropores. Radiocarbon ages determined on total decalcified organic carbon from the paleosols in the Severance comprise two separate clusters: 28-25 ka and 17-15 ka.

P-2903

Geologic influence on subglacial hydrology and glacier basal motion

Neil Glasser¹, Manja Žebre¹, David Egholm²

¹Aberystwyth University, Aberystwyth, United Kingdom, ²Aarhus University, Aarhus, Denmark

Abstract

Understanding subglacial systems is essential for making predictions of glacier motion and the contribution of glacier melt to stream runoff in the context of overall glacier response to climate change. Several studies have shown that subglacial hydrology is one of the key controls on basal sliding, but how the ice bed geology influences the subglacial drainage system and therefore the basal sliding, is still poorly understood. The drainage system at the base of a glacier usually consists of two main components with complex interactions: 1) a distributed system of linked cavities and 2) a channelized system that depends on the development of Röthlisberger channels into the basal ice. Both systems are expected to evolve during the melt season in response to variable water flux, effective pressure, and sliding speed. In this study, we use a two-dimensional finite element model to simulate the seasonal evolution of a hydrological system at the base of a glacier. The sliding velocity of the ice is allowed to vary as a function of the contact area between the ice and its bed.

Our computational experiments consider a range of groundwater transmissivities in order to explore the effect of groundwater flow on the seasonal variability of sliding velocity. Using low groundwater transmissivities ($< 10^{-5} \text{ m}^2 \text{ s}^{-1}$), typical of non-carbonate rocks, a subglacial drainage system evolves from an inefficient drainage system in winter with relatively slow sliding, a high contact area, and moderate effective pressure, followed by the spring event with enhanced sliding as the capability of the drainage system is exceeded by the increasing surface melt. In summer, channels gradually develop as the subglacial system adapts to the increased water flux. The development of channels cause cavities to shrink and sliding consequently slows towards the winter level. On the other hand, by applying groundwater transmissivities typical of carbonate rocks ($> 10^{-5} \text{ m}^2 \text{ s}^{-1}$), the water discharge through bedrock prevails over the entire year, leaving the channelized system largely undeveloped. As a result, the sliding velocity remains low and stable throughout a year.

Warm-based glaciers typically exhibit a distinct seasonal variation in sliding velocity, with spring-summer sliding velocities sometimes two or three times faster than winter averages. However, glaciers resting on carbonate rocks, where the meltwater discharge through bedrock accounts for more than 90% of the total meltwater flux, are, at least in some cases known to show reduced seasonality. Our results demonstrate how groundwater flow can effectively remove the seasonal variation of glaciers flowing on carbonate rocks such as well-karstified limestone.

P-2904

Subglacial seasonal meltwater deposits from a thick Weichselian till sequence, Dösebacka, Sweden

Mark Johnson, Olof Johansson Ström
Gothenburg University, Gothenburg, Sweden

Seasonal changes in subglacial hydrology, which affect ice-flow rates, have been inferred from the Greenland ice sheet. The sediment record of this type of event is not known because of the inaccessibility of the bed. Here, we report on a serendipitous sequence of diamicton and sorted sediments at Dösebacka, Sweden, which we interpret as being produced by seasonal development of subglacial meltwater delivered from the surface of the Scandinavian ice sheet during the last glaciation. The sequence consists of 30 m of diamicton with interbeds of sorted material. Though there is some variation, sorted sequences are 5-30 cm thick and are coarsening upward starting with 1-3 cm of clay, followed by silt, sand and pebbly sand. Deformation in the sorted sediment is rare. Five to seven sorted layers are identified and can be correlated across the outcrop. Diamicton beds are 1-5 m thick between the sorted layers. The diamicton is massive and contains a strong fabric, and we interpret the diamicton as subglacial traction till. We interpret the sorted sediment as a sequence deposited by subglacial meltwater and created during increased water pressure at the bed. Initially, increased water pressure produces patches of bed separation that are not connected laterally. In this standing water, clays are deposited. With time, these pockets become better connected, and water velocity increases as indicated by the increase in grain size. We hypothesize that these sequences represent seasonal delivery of meltwater from the surface. Thus, each sorted bed represents a summer and indicates seasonal subglacial drainage evolution. The coarsening upward indicates the evolution of bed-hydrology integration from standing pools to connected systems.

P-2905

The ability of glaciers to erode limestone beds

Olivia Steinemann¹, Susan Ivy-Ochs¹, Sandra Grazioli¹, Marc Luetscher², Urs H. Fischer³, Christof Vockenhuber¹, Hans-Arno Synal¹

¹ETH Zürich, Zürich, Switzerland, ²ISSKA, La Chaux-de-Fonds, Switzerland, ³NAGRA, Wettingen, Switzerland

Abstract

Despite numerous studies and the use of various techniques, quantifying glacial erosion is still challenging. This is due to difficulties accessing the ice-bedrock interface for direct measurements. In addition, the question of representivity of using sediment load of meltwater remains as the detangling of contributions from glacially eroded material from other sediment sources e.g. from gravitational processes is difficult. Furthermore, glacial erosion is dependent many factors like ice thickness, bedrock slope, glacier type (cold based/warm based, plateau glacier/valley glacier) or lithology to mention only a few. Therefore it is not surprising that reported erosion rate values range over many orders of magnitude (10^{-3} – 10 mm/a). Studies so far focused mainly on glaciers eroding crystalline bedrock. Therefore, this study aims to quantify glacial erosion on a limestone bed to ascertain the influence of lithology. To do so a combined approach of detailed geomorphological mapping of the only recently ice-free glacier forefield combined with cosmogenic nuclide analysis which enables calculating erosion rates, is used. In order to calculate subglacial erosion rates we implement the MECED cosmogenic nuclide MATLAB model developed by Wirsig et al. (2017). The model includes periods of glacier coverage, snow shielding and karst weathering. The study area is the Lapiez de Tsanfleuron (CH). It is with around 10 km² one of the biggest karst fields in Switzerland and the highest part of the area is still covered by the Tsanfleuron Glacier. The glacier forefield has a pronounced glacial polish, many different karst features, and a prominent Little Ice Age (LIA) moraine crossing the entire forefield. Samples for erosion rate determination were distributed over the forefield, as well inside and outside of the LIA extent, to detect possible spatial variations of erosion rate values eventually linked to karst features.

Investigation of large-scale glaciotectonic deformations at the paleo-ice stream bed using multiple geophysical methods, a case study from western Latvia.

Kristaps Lamsters, Jānis Karušs, Jurijs Ješkis, Amanda Stūrmane, Pēteris Džeriņš
University of Latvia, Riga, Latvia

Abstract

Subglacial processes are usually interpreted from sedimentary sequences exposed in subglacial bedforms that frequently shape paleo-ice stream beds. In Western Latvia, subglacial structures are hidden under almost flat ground surface mainly due to postglacial erosion processes of the Baltic Ice Lake. Along the bluffs of the Baltic seashore in Strante-Ulmale site, outstanding glaciotectonic structures are described (Saks et al., 2012) showing that relatively flat ice stream bed holds unique features characterizing active and passive subglacial glaciotectonic deformations formed beneath a local Apriķi ice tongue. Research comprises the study of the distribution and morphology of glaciotectonic structures, as well as disintegrated Late Pleistocene sedimentary sequence using ground penetrating radar (GPR) and electrical resistivity sounding (ERS).

The thickness of Pleistocene deposits in the coastal area of Western Latvia reaches 70 m. The upper dozens of meters consist of shallow basin clayey, silty and sandy sediments overlain by a defragmented cover of the several-metres-thick Late Weichselian till and topmost marine and aeolian gravels and sands. The sandy sediments are protruded by clayey silt diapirs in places.

To study the diapirs and complicated sedimentary sequence we used GPR Zond 12-e with 300 MHz antenna and the electrical resistivity sounding (ERS) system SYSCAL Pro Switch 72. GPR profiles (32) with a total length of 9 km were recorded. With ERS two profiles with the two-meter spacing between electrodes (72 electrodes in total) and seven profiles with five-meter spacing (54 electrodes) were recorded.

The GPR data show strong reflections from disturbed layering and diapir structures. It is possible to detect the surface of the upper till unit or clayey silt diapirs, as well as sandy sediment sequence up to 10 m below ground surface. The maximum penetration depth of GPR signal is used to visualise the possible distribution of defragmented Pleistocene sandy, silty and till sediments. Combining GPR results with results of geological drilling we show that it is possible to distinguish the areas covered by upper till from diapir structures. Results from ERS greatly coincide with GPR results. Unlike GPR, ERS method allow to detect the thickness of upper till unit and provides deeper look on possible under-till structures up to the depth of 25 m from the ground surface.

This work was financially supported by the specific support objective activity 1.1.1.2. "Post-doctoral Research Aid" (Project id. First extensive glaciations of the northern Alpine foreland: Sedimentology of diamicts in the Early Pleistocene Deckenschotter Groups (Northern Switzerland)

Marius W. Buechi^{1,2}, Gaudenz Deplazes³, Flavio S. Anselmetti^{1,2}

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland, ²Oeschger Centre for Climate and Climate Change Research, University of Bern, Bern, Switzerland, ³National Cooperative for the Disposal of Radioactive Waste (Nagra), Wettingen, Switzerland

Abstract

The Höhere and Tiefere Deckenschotter Groups of Northern Switzerland mainly comprise glacial outwash sediments deposited by the first extensive glaciations of the Alps. Only in very few outcrops, however, the gravelly facies is associated with diamictos interpreted as glacial tills (e.g. Heim 1891, Frei 1912, Graf 1993). Despite the importance of these presumed glacial deposits as markers of ice-contact during the Early Pleistocene, they remain relatively poorly studied. We present results from an ongoing project to better constrain the depositional environment of these diamicts at selected key sites using detailed macro- to microscale sedimentology, fabric and geotechnical analyses. Our first results show that the investigated diamicts are of glacigenic origin. They appear, however, to be emplaced in a variety of subglacial to ice-marginal settings giving insights into the subglacial bed conditions, ice-bedrock interaction and paleo-landscape. Our analyses thus help to better constrain the extent and characteristics of glacier advances related to the first extensive glaciations of the Alps.

Glacial erosion on limestone and relief development in the Alps

Susan Ivy-Ochs¹, Olivia Steinemann¹, Marc Luetscher², Urs H. Fischer³, Christof Vockenhuber¹

¹ETH, Zurich, Switzerland, ²Swiss Institute for Speleology and Karst Studies, La Chaux-de-Fonds, Switzerland, ³Nagra, Wettingen, Switzerland

Abstract

By combining detailed field study and cosmogenic ³⁶Cl measurements, we look at the striking contrast between subglacial erosion rates measured on gneiss (Wirsig et al. 2017) and on limestone (Steinemann et al. 2019) in the Alps. The fundamental quandary exists: limestone is a rock that is enormously softer than gneiss, thus it should be much easier to erode beneath a sliding glacier. Observations at glaciated karst regions have been contrastingly interpreted as indicating either profound or insignificant glacial erosion. In the latter case the presence of a cold-based glacier is at times invoked.

At the Tsanfleuron glacier site in Switzerland, evidence of glacial erosion is abundant. But the true magnitude (depth removed by the glacier) is difficult to constrain based on observations alone. The obvious appearance of highly polished rock surfaces within the Little Ice Age-glacier footprint belies the likelihood that very little rock was removed during recent glacier advances. The underlying limestone is part of a well-studied karst system (Gremaud et al. 2009). Meltwater running off the glacier surface today is seen to pour into karst shafts within meters of the ice margin. Meltwater beneath the glacier is and was likely immediately and efficiently channeled down into the karst system. Glacier sliding, and thus erosion, is directly linked to the presence of water at the base of a glacier on a hard bed. Loss of water inhibits sliding, erosion slows (Bindschadler 1983).

This suggests that in strongly karstified areas it is the inability of glaciers (and of course rivers) to effectively erode limestone itself that led to the formation of the high limestone plateaus of the Alps over the numerous Quaternary glaciations. As the glaciers cleared away easier to erode overlying (silicate) rocks and eroded down to the massive limestones the plateau character emerged. The low relief of the thus created high-elevation flat surfaces further hampered sliding and a positive feedback developed. On the other hand, clearly some limestone terrains in the Alps are strongly glacially incised. What factors lead to certain areas of limestone being eroded less than their neighbors such that high standing plateaus form? As shown at the Tsanfleuron site, near horizontal, very thick-bedded, weakly fractured, massive limestone bedrock favors this process.

Fantastic flutes and where to find them: the world's oldest surging glacier land-system

Marie Busfield¹, Daniel Le Heron², Bernhard Grasemann², Pierre Dietrich³, Jean-Francois Ghienne⁴

¹Aberystwyth University, Aberystwyth, United Kingdom, ²University of Vienna, Vienna, Austria, ³University of Johannesburg, Johannesburg, South Africa, ⁴University of Strasbourg, Strasbourg, France

Abstract

Fingerprinting ancient surges is often hindered by the poor preservation potential of some common features (e.g. concertina eskers), alongside the absence of any single diagnostic landform of surge-type behaviour. It is necessary therefore to recognise a suite of closely associated landforms to reliably interpret palaeo-surge activity. This land-systems approach has been widely adopted on modern and Pleistocene glacier forefields, but here we demonstrate how it can be applied far deeper in geological time. Using new Unmanned Aerial Vehicle (UAV) imagery, we present the first palaeogeomorphological map of an Ordovician (443 million year old) surging glacier land-system: the oldest example recorded to the authors' knowledge. Three sets of cross-cutting landforms crop out over an area of $\sim 1 \text{ km}^2$ in the Western Cape Province of South Africa, interpreted to represent three stages of a complete surge cycle. Firstly, highly elongate ($>100 \text{ m}$) and narrow subglacial flutes reflect streamlining of dilatant sediments during active surging. These are cross-cut and overlapped by low amplitude transverse fold ridges, formed by 'rucking' of the subglacial bed at surge termination as lubricated sliding ceased. Finally, both structures are draped by sinuous sand bodies which represent the fill of a more efficient, channelized drainage system established during post-surge quiescence. We argue that the transverse fold ridges occur in place of the more typical crevasse-squeeze ridges due to locking up of the subglacial bed, either driven by freezing or desaturation. This inhibits bottom-up squeezing of dilatant crevasse fill, and instead promotes buckling of the stiffer, more competent bed. These transverse fold ridges may therefore represent an additional landform type which can be incorporated in the typical surging suite, thus expanding the available toolkit for identifying surges in both the ancient and modern depositional record.

Morphological and sedimentological studies of subglacial V-shaped hummocks – formation and significance

Gustaf Peterson^{1,2}, Mark Johnson², Christian Öhrling¹

¹Department of Physical Planning, Geological Survey of Sweden, Uppsala, Sweden, ²Department of Earth Sciences, Gothenburg University, Göteborg, Sweden

Abstract

Mapping of glacial landforms in the south Swedish uplands (SSU) using LiDAR-derived digital elevation models (DEM) has revealed a distinct type of hummock landform. The SSU is characterized, in general, by hummocky glacial landforms, often connected to stagnant ice environment during deglaciation. However, distinct V-shaped hummocks occur in places, with an apex generally pointing down ice and with an asymmetric vertical profile along its axis. They are roughly 10-100 meters wide, 5 to 50 m long, and 2-10 meters high.

The V-shaped hummocks occur in close relation to ribbed moraine and, in places, they are draped by eskers and overprinted by flutes, indicating a subglacial genesis. Generally, the landform occurs in fields that in places are elongated parallel to the overall ice-flow direction. We have surveyed all of Sweden for occurrences of these landforms, and this has revealed that they are most frequently occurring north of the Younger Dryas ice margin and in areas deglaciated during Bølling-Allerød. Detailed sedimentological studies in machine-dug excavations at multiple locations were performed and reveal a composition of heterogeneous sandy gravelly diamicton, with angular to sub-angular clasts. Lenses of sorted sediments are interbedded in the diamicton and boulders are common on the surface.

Crosscutting relationships suggest a subglacial origin and their distribution on an ice sheet scale suggest that they were formed during periods of rapid ice retreat. We list and discuss multiple hypotheses that can explain the geomorphological and sedimentological indications to shed light on the formative process. We hypothesize that their genesis is related to changing subglacial hydrologic conditions.

A bird's eye view of a Ediacaran-Cambrian subglacial landscapeA

Daniel Le Heron¹, Kwang Hongwei², Thomas Vandyk³, Yongqing Liu², Xiaoshuai Chen², Yuchong Wang², Zhenrui Yang², Bethan Davies³, Graham Shields⁴

¹University of Vienna, Vienna, Austria, ²Chinese Academy of Geological Sciences, Beijing, China, ³Royal Holloway and Bedford New College, Egham, United Kingdom, ⁴University College London, London, United Kingdom

Abstract

A spectacular subglacial landscape carved beneath Ediacaran-Cambrian ice masses crops out in the Shimengou area of central China. Despite being known for more than 30 years, no attempts have hitherto been made to map, document, and rigorously interpret this surface which was produced during the Luoquan glaciation. This glaciation occurred when the Shimengou area occupied tropical palaeolatitudes. New imagery from an Unmanned Aerial Vehicle (UAV) reveals a series of scallop-shaped bedforms over a wide (ca. 1 km x 100 m) area of dipping sandstone beds. A classic "p-form" assemblage is mapped and described, including general faceted forms, müschelbrüche, cavetto and spindle forms alongside striations. Some of these features cross-cut small scale orthogonal fractures and faults, the trend of which has been later exploited during subsequent regional tectonism. The small-scale fractures are interpreted as Riedel shears which developed in response to shear by an overriding ice mass. Significant lateral variation in bedform arrangement is interpreted to record complex local flow behaviour. Collectively, interpretation of the p-forms, striations and transverse fractures leads to a story of progressive abrasion, significant ice-bed coupling and stick-slip behaviour. Remarkably, and unlike many Quaternary examples, the pristine surface shows no evidence for meltwater reworking, perhaps pointing to rapid ablation, in spite of the evidence for vast hinterland ice sheets. This raises questions about the representativeness of subglacial structures seen throughout geological time.

Unmanned Aerial Vehicle (UAV) image (left) and interpretation (right).

Subglacial processes and mega-scale glacial lineations in North Lithuania

Violeta Pukelytė¹, Valentinas Baltrūnas¹, Bronislavas Karmaza¹, Danguolė Karmazienė²

¹Nature Research Center, Vilnius, Lithuania, ²Geological Survey of Lithuania, Vilnius, Lithuania

Abstract

The identification of mega-scale subglacial lineations (MSGs), i.e., determination of their morphological, structural and genetic features, is one of geological mapping problems. Confirmations are growing in scientific literature that such subglacial forms as MSGs are related to ice thickness and glacier movement rate (Rose, 1987; Brodzikowski, van Loon, 1991, Stokes et al., 2013; and other). To examine the problem, an area in North Lithuania (districts of Pasvalys and Biržai) has been chosen, there, “drumlinised” morainic surface of the Last Glaciation is fixed with well-expressed mega-scale lineations. The morphometric parameters of MSGs in Lithuania have been determined by cartometric measuring from topographic maps (1:10 000). A digital elevation model (DEM) with 2 m spatial resolution was used for some small areas in North Lithuania. The composition of the Pušalotas and Ruopiškiai MSGs, the thickness and sedimentological characteristics of the depositional units have been determined as well as clast fabrics and samples for anisotropy of magnetic susceptibility (AMS) have been taken from excavated pits. The orientation and dip of the long axes of 50 clasts with elongation ratios of $\geq 3:2$ have been measured at 2 sites in the MSGL using a geological compass applying the method outlined by A. Gaigalas. The petrographic composition of pebbles has been analysed using the following categories: crystalline rocks, sandstone, Devonian dolomite and dolomitized rocks, Ordovician and Silurian limestone, Devonian and Permian limestone and group of other rocks.

The data presented above show great resemblance between the implied MSGs formation type and the mechanism of surge phenomenon. In the case of Mūša–Lėvuo lobe, favourable geological, palaeogeomorphological and hydrological conditions also could be mentioned. Depressions in sub-Quaternary and Grūda–Baltija interstadial surfaces, intense drainage of meltwater and formation of glaciolacustrine basin formed conditions for rapid movement of Mūša–Lėvuo lobe into the area studied. Pebble long-axes and AMS orientation measurements confirm formation of older “loose” till typical for flutings and MSGs during the glacier’s erosion, when basal ice carries over macroclast material to the MSGs crests from the interridge areas in a spiral mode. In order that such process could occur, water should be available at the bedrock and glacier’s basal part as well as shear stress relaxation at the southern margin of the ice stream. The fact that Mūša–Lėvuo lobe moved into the glaciolacustrine basin is confirmed by parallel crests of MSGs becoming lower towards the central part of the basin.

Surface exposure dating of raised shorelines in Finnmark, Norway

Serdar Yeşilyurt¹, Ola Fredin^{2,3}, Anders Romundset², Marcus Christl⁴, Christof Vockenhuber⁴, Naki Akçar¹

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland, ²Geological Survey of Norway (NGU), Trondheim, Norway, ³Norwegian University of Science and Technology (NTNU), Trondheim, Norway, ⁴Laboratory of Ion Beam Physics (LIP), ETH Zurich, Zurich, Switzerland

Abstract

Ice sheet growth and decay profoundly impact global eustatic sea-level and, regionally, isostatic depression and uplift. Raised shorelines, beaches, deltas and wave cut rock platforms are all landforms typically bearing witness of higher relative sea-level stands following a deglaciation, along previously glaciated coasts where the ice sheet have glacio-isostatically depressed Earth's crust. In Scandinavia, the relative sea level history is commonly well studied in areas suitable for application of the isolation basin method. However, large uncertainties remain in many areas, e.g. along most of the arctic coastline of Finnmark, where Norway faces the Barents Sea. Here, we have employed a novel approach to reconstruct the chronology of postglacial shoreline displacement. We use terrestrial in-situ cosmogenic nuclide (TCN) dating directly on boulders and cobble found on the raised landforms (deltas and beach ridges).

We have targeted and dated deglaciation moraines, juxtaposed to raised shorelines, beaches and deltas and sampled for; i) n=25 rock samples from erratic boulders on top of moraines, ii) n=16 sediment samples from depth profiles in delta deposits, and iii) n=46 flat (<5 cm thick) cobbles from raised beaches, and measured the concentration of ³⁶Cl and ¹⁰Be in these samples. Overall, initial results show that the northern coast of Finnmark was deglaciated at 14-15 ka, and that the ice sheet withdrew to the inner fjord areas where prominent moraines were built during the Younger Dryas chronozone. The ages obtained on raised beaches and deltas representing marine limit generally reflect the deglaciation ages, Some ages were obtained from levels below marine limit; these represent later relative sea levels and our goal is to use the data collectively to reconstruct rates of relative sea level change through different periods, especially during the Lateglacial for which other chronological data (e.g. from isolation basins) do not exist. Our first results are promising, especially for flat cobbles on raised beach ridges, which yielded the most consistent results so far. Some of the TCN dates are, however, ambiguous, reflecting limitations with TCN field sampling and dating precision.

Coastal zone landscapes of the archipelago Novaya Zemlya and bird colonies

Danila Badyukov

Moscow state university, Moscow, Russian Federation

The position of the archipelago Novaya Zemlya contributed to the development in its coastal zone of unusually abundant and diverse life for these latitudes: the largest colonies of seabirds in the Russian Arctic.

Seabirds feed on fish and zooplankton, their excrement enriches coastal waters with nutrients. The metabolic cycle of seabirds is not a local phenomenon, but a regional cycle of great importance for the functioning of the marine ecosystem as a whole.

For occurrence of the bird's colony on the sea coast the combination of a number of natural conditions is necessary, the most important among which is the existence of sufficient forage base, a specific relief of the sea coast, hydrodynamic conditions of nearshore marine waters.

Almost all rookeries of the archipelago Novaya Zemlya are located on the Barents Sea coast. On the Eastern side of the rookeries were observed only in the North-East end of the North Island, and the most south is in the cape Bismarck.

The basis of the rookeries is nesting *Uria lomvia*. We estimate the total number of the main bird species in the bird colonies of Novaya Zemlya as close to 2 million individuals.

During the breeding season colonial seabirds of the Novaya Zemlya consume at least 54 409 tons of fish and zooplankton. The calculations carried out for each of the bird colonies of Novaya Zemlya have shown that as a result of the birds activity 33 380 tons of excrement are produced during the breeding season.

The total amount of phosphorus dissolved in sea water near the coast of Novaya Zemlya will be more than 20 tons, and nitrogen – almost 54 tons. The calculations show that the total area of aquatory enriched with nutrients for Novaya Zemlya is 1226 km² with a water layer thickness about 25 meters.

The coastal waters of the Oransky Islands, where there are bird colonies, numbering about 60 thousands birds, clearly have marks of eutrophication – rocky limestone bench, surrounding the westernmost of the Large Oransky Islands, to a depth of 3-5 m overgrown with filamentous algae (covered about 60%). The presence of bird colonies initiates an increased flow of nutrients into the aquatic ecosystem, which contributes to the increase of its primary production. The increased content of organic matter in the suspension is evidenced by the high content of organic carbon in the bottom sediments – 0,95-1,90%, which corresponds to the content of organic carbon in the rivers mouths of the taiga zone, such as the Severnaya Dvina.

P-3003

Stability and biodegradability of organic matter in permafrost-affected soils of coastal Yamal region, Russian Arctic

Ivan Alekseev, Evgeny Abakumov

Saint Petersburg State University, Saint Petersburg, Russian Federation

Abstract

Knowledge of permafrost soils in polar regions has advanced significantly in recent decades, despite the remoteness and inaccessibility of most of the region and the sampling limitations posed by the severe environment. This has led to significantly substantial increasing of estimates of the amount of organic carbon (OC) stored in permafrost-affected soils and improved understanding of how pedogenic processes unique to permafrost environments built enormous OC stocks during the Quaternary. Chemical composition of SOC determines its decomposability and may affect soil organic matter stabilization rate (Beyer 1995; Ejarque, Abakumov, 2015). This is quite important for understanding variability in SOC pools and stabilization rate in context of changes in plant cover or climate (Rossi et al. 2016). Moreover, ¹³C nuclear magnetic resonance spectroscopy, which provides detailed information on diversity of structural composition of humic acids and SOM, may also be used to study the SOM dynamics under decomposition and humification processes (Kogel-Knabner, 1997; Zech et al., 1997). This study is aimed to characterize molecular composition of the humic acids, isolated from various permafrost-affected soils of coastal Yamal region and to assess the potential vulnerability of soils organic matter in context of possible mineralization processes. Organic carbon stocks for studied area were $7.85 \pm 2.24 \text{ kg m}^{-2}$ (for 0-10 cm layer), $14.97 \pm 5.53 \text{ kg m}^{-2}$ (for 0-30 cm), $23.99 \pm 8.00 \text{ kg m}^{-2}$ (for 0-100 cm). Results of solid-state ¹³C-NMR spectrometry showed low amounts of aromatic components in studied soils. All studied humic powders are characterized by predominance of aliphatic structures, and also carbohydrates, polysaccharides, ethers and amino acids. High content of aliphatic fragments in studied humic acids shows their similarity to fulvic acids. Low level of aromaticity reflects the accumulation in soil of lowly decomposed organic matter due to cold temperatures. Our results provide further evidence of high vulnerability and sensitivity of permafrost-affected soils organic matter to Arctic warming. Consequently, these soils may play a crucial role in global carbon balance under effects of climate warming. This study was supported by the grant of Saint Petersburg State University "Urbanized ecosystems of the Russian Arctic: dynamics, state and sustainable development" and the Government of the Yamalo-Nenets Autonomous District.

Multiproxy records from the Laptev Sea shelf, Siberian Arctic: implications for reconstructing land-sea interactions and palaeoenvironmental changes since the mid-Holocene

Olga Rudenko¹, Ekaterina Taldenkova², Henning A. Bauch³, Yaroslav Ovsepyan⁴, Anna Stepanova⁵

¹Turgenev Oryol State University, Oryol, Russian Federation, ²Lomonosov Moscow State University, Moscow, Russian Federation, ³Alfred Wegener Institute for Polar and Marine Research, Bremerhaven c/o GEOMAR, Kiel, Germany, ⁴Geological Institute of Russian Academy of Sciences, Moscow, Russian Federation, ⁵Texas A&M University, College Station, Texas, USA

Abstract

Here we present multiproxy records from the inner Laptev Sea shelf. The sediment cores were recovered from two sites to the north and northeast of the Lena River Delta and at 27 m and 21 m water depths, respectively. High-resolution records of the distribution of various ecological groups of microfossils were established, including terrestrial (pollen and spores), marine (cysts of dinoflagellates, benthic and planktic foraminifera, ostracods) and freshwater (colonial chlorophycean algae). Together with benthic foraminiferal $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ records this allows for a detailed reconstruction of the regional palaeoenvironmental changes since 6.0 ka.

Two major factors are responsible for the observed environmental variability: progressive shelf flooding and coastline retreat due to thermoabrasion, and climatically-induced river runoff fluctuations (fluvial events). The latter are represented in the records by (1) increases in sedimentation rates; (2) high influx of terrestrial pollen, spores, freshwater green algae, wood and plant remains; (3) elevated percentages of far-distant, river-transported pollen of conifers vs local tundra shrub pollen; (4) negative $\delta^{13}\text{C}$ excursions and some radiocarbon age reversals due to the introduction of old carbon with dissolved inorganic carbon (DIC) of river water. Coeval positive $\delta^{18}\text{O}$ excursions and increasing representation of river-distal species among benthics, including rare planktic foraminifers, point to a presence of a reversed (north to south) bottom current activity along the submarine paleovalleys on the shelf. The most pronounced fluvial events were recorded at 5.3-5.9, 1.5 and <0.5 ka. As reflected in the pollen records, the oldest fluvial event coincides in time with the final phase of mid-Holocene regional climate warming. Although the rather brief fluvial event at 1.5 ka is recorded at both localities, it is more prominent at the northeastern site, thus, probably marking a diversion of the main Lena River outflow towards this direction. The most distinct major change, however, is noted at this site during last 500 years. A trend to extremely negative benthic $\delta^{13}\text{C}$ values is seen which could be a result of light DIC composition of the bottom waters, perhaps due to re-mineralization of organic matter produced by phytoplankton in response to increased outflow of nutrient-rich Lena river water. We therefore conclude that this unprecedented change in $\delta^{13}\text{C}$ provides further evidence for a principal diversion of the main Lena River outflow which since then occurs towards the east.

Distribution of recent and buried ice scours on the shelf of the East Siberian Sea

Vladimir Zhamoida, Leonid Budanov, Oleg Dron, Alexander Moskovtsev, Igor Neevin, Pavel Rekant, Daria Ryabchuk, Alexander Sergeev
Russian Geological Research Institute (VSEGEI), St.Petersburg, Russian Federation

Abstract

In August - September 2018 Russian Geological Research Institute (VSEGEI) together with Russian Marine Positioning and Survey Company (ROMONA) carried out 2100 km of acoustic-seismic ("SleeveGUN" and EdgeTech model CHIRP 3300HM), side-scan sonar (CM-2, C-MAX) and multibeam (R2Sonic 2024) profiling in the East Siberian Sea onboard RV "Ivan Kireev".

Numerous ice scours were fixed within the whole investigated area from the De Longa Strait to Kolyma Gulf. Several types of single and multiple ice scours can be distinguished. The width of the ice scours varies over a wide range from a few meters to 100 meters and more. The relative depth of scours usually does not exceed 1–1.5 m, but can reach 3 m. Some of them are characterized by "fresh" appearance with well-developed berms (ridges). The height of ridges achieves 1 m. Sometimes the scours are covered by bottom sediments.

The map of the ice scouring distribution in percentage of seafloor disturbance was compiled for the investigated area of the East Siberian Sea. The density of recent ice scouring traces, especially in the coastal area shallows, achieves 100% of bottom surface. Some ice scours within the open sea including the area of plaeovalleys were traced up to 50 m sea depth. The minimal disturbance of the seafloor by ice scouring was fixed in the De Longa Strait to the south of Vrangal Island.

It is possible to assume that scours are formed by rampant ice masses (toross) and grounded ice hummocks because no any icebergs are formed within the investigated area. The high degree of processing of the recent bottom surface by ice suggests that under the conditions of the East Siberian Sea, ice scouring, at least throughout the Holocene, was one of the leading underwater geological processes moving huge volumes of sedimentary matter. The acoustic seismic records showed that sediments processed by ice are revealed up to 12 m depth of subsurface geological section. Thus, it is possible to distinguish and map widely distributed Late Pleistocene - Holocene sedimentary strata with totally disturbed stratigraphic boundaries.

Records of long-term coastal evolution in the southern Laptev Sea: An interdisciplinary study of two Holocene lagoon/beach-ridge systems

Lasse Sander¹, Ivan Khristoforov², Kencheeri Danilov², Rune Michaelis¹, Svenja Papenmeier¹

¹Alfred-Wegener-Institute, List/Sylt, Germany, ²Melnikov Permafrost Institute, Yakutsk, Russian Federation

Abstract

The geomorphological record of coastal sedimentary systems, such as lagoons, beach ridges, barriers, chenier plains and spits, may provide useful insight into the local spatiotemporal development of landforms and the processes involved in their formation. In Arctic environments, the delivery of wave energy and sediment is intimately linked with the duration and extent of the sea-ice cover and the study of coastal sedimentary systems thus may allow inferences on the long-term climate forcing of the marine environment at a larger scale.

Two coupled lagoon/beach-ridge systems located in Buor Khaya Bay (southern Laptev Sea) are investigated. They present valuable records of coastal evolution in an area dominated by presently retreating permafrost shorelines and thus have the potential to shed light on the forcing of coastal change over Holocene timescales. The study aims at providing a full appraisal of the modern spatial properties of the two systems by combining the investigation of surface and subsurface properties of the lagoon environment by ship-borne ground penetrating radar, underwater video and side-scan sonar surveys with the study of the beach ridge deposits by remotely-sensed data, elevation surveying, absolute dating and extensive field work. Both systems were previously undescribed in detail and were surveyed during an expedition in summer 2018.

Our data show that the initial formation of barriers separating the lagoons from the open marine environment has occurred prior to the establishment of a similar-to-modern relative sea level at approx. 6.5 – 6.0 kyr BP. The beach-ridge systems are composed of coarse material and rapidly prograded until c. 3.0 kyr BP. Since then, the system developed at a much lower rate, punctuated by periods of stability, concurrent with the timing of changes in late Holocene climate conditions. The elevation of the beach ridges is 3-4 m above present mean sea level throughout the entire sequence, suggesting a development driven by storm wave forcing from an NE sector under a stable Holocene relative sea level. The bottom sediment of the freshwater lagoons is composed of marine gravel, exposed bedrock and sand sheets and is mostly barren. The lagoons are c. 20 m deep and are thus several meters deeper than the open water of Buor Khaya Bay. Frost polygons were observed in the shallow waters in proximity to the lagoon shoreline. These new observations and their paleoenvironmental implications contribute to an improved baseline understanding of the modern properties and the past responsiveness of Arctic coastal systems to changes in natural forcing.

Coastal dynamics of the accumulative Intsy cape (Zimniy coast of the White sea).

Nikolay Lugovoy, Tatyana Repkina
Lomonosov Moscow state University, Moscow, Russian Federation

The research is based on field survey in 2016, with the involvement of satellite images 1984-2017 and topographic maps 1833-1999. Part of the White sea named The Gorlo is a water area with very active hydrodynamics, where Northern and Western waves are superimposed on high speeds of tidal currents. The Holocene accumulative terrace of Intsy cape occupies 12 km of the shore between the eroded areas; its width exceeds 3 km. Climate and sea level changes cause erosion of previously formed accumulative coast.

Fig.1. The location of study area.

The sea terrace includes remnants of the moraine ridges up to 25 m high, one of which is located the Intsy lighthouse, built in 1900. At the time of construction, the distance from the lighthouse to the coast was more than 250 m and the moraine hill was not eroded by the sea. Our research has established: The average rate of retreat of the coastal ledge, cut out in the moraine hillside, for 185 years was 2.4 m/year. With the same speed the ledge has receded also in 2009-2016. For these 7 years the area of the hill has decreased by 14.5%, annual losses due to erosion and landslides are estimated at 0.32 ha. If the rate of destruction of the shore remains the same, the lighthouse of Intsy will be destroyed in 25 years.

On the surface of the terrace up to 3 m high above sea level there are several generations of palaeo coastal ramparts marking the stage of extension of the shore. At this time of the 12 km of the terrace, only about 3.5 km remain stable, the rest are eroding. The retreat of the shore increases the deflation of sand on the littoral and the beach. The exposed sand is accumulated in the depth of the terrace forming vast massifs of dunes up to 12 m high. The main conclusion of the study is that in this area, due to changes in lithodynamic factors, the accumulation that prevailed during the Holocene was replaced by erosion of the shore.

A study of tide-driven sediment transport in the Jujincheon(river) and estuary on the west coast of the Korean peninsula

Jin-Young Lee¹, Hoil Lee¹, Sang Deuk Lee², Suk Min Yun², Jaesoo Lim¹, Sujeong Park¹, Kota Katsuki³

¹KIGAM, Daejeon, Korea, Republic of, ²NNIBR, Sangju, Korea, Republic of, ³EsRec, Simane, Japan

Abstract

Jujincheon is a small river that flows into the Gomso Bay in Buan city on the west coast of the Korean peninsula. Salinity, grain-size distribution of suspended sediment, and diatoms in surface water samples were analyzed from the estuary of Jujincheon to the upper river in the order of Yongsan Bridge, Banam Bridge and Hoam Bridge, during one tide cycle (12 hours). The water level of the river was measured using a global positioning system (GPS). The change in river regurgitation at Yongsan bridge and high salinity was measured when the sea level in Gomso Bay was higher than the river level due to the change of tide. The backward flow of the river was also observed at Banam Bridge and Hoam Bridge, which are located upstream from the Yongsan Bridge. The change in the water level at Banam Bridge and Hoam Bridge at high tide was similar or slightly higher than the tidal surface level; however, the salinity level did not change. After analyzing the particle size in the suspended sediment, it was clear that sand particles dominated in the downstream water and silt particles dominated in the upstream water. In addition, marine diatoms, such as *Paralia sulcata*, appeared which confirms that suspended sediment is transported by the seawater.

Based on these results, the transportation of sediment can be explained by tide changes in Gomso Bay. During low tide, the water level in the river is higher than the sea level, and the sediment is transported from the upper river to Gomso Bay by the river flow. On the contrary, during high tide, the sea level is higher than the river, and the seawater flows upstream from the estuary to the upper river. In this case, it is clear that the outflow of fresh water mixes with the estuarine environments and the marine sediments are deposited upstream. These results provide important data for interpreting how sediments were deposited in estuarine environments in the past. Even if there is little evidence that sea water would have affected sediment deposits in estuary environments in the past, it could indicate changes in sea level, including the tidal effect in estuaries where estuarine deposits occur.

Marine sediment is an indicator of changing sea levels and tides, especially in estuarine environments that are formed by rivers with low flow discharge, such as the Jujincheon river. In an estuarine environment where sediment from the sea is transported to a tidal limit or high tide level, very little evidence of marine sediment is observed due to the sedimentation associated with sea level changes. This could be interpreted as a result of sea level changes.

Mid-Holocene sea-level highstand in the Malay Peninsula

Yaze Zhang¹, Yongqiang Zong², Zhuo Zheng¹, Haixian Xiong², Shuqing Fu³

¹School of Earth Science and Engineering, Sun Yat-Sen University, Guangzhou, China, ²Department of Earth Science, The University of Hong Kong, Hong Kong, China, ³Guangdong Open Laboratory of Geospatial Information Technology and Application, Guangzhou Institute of Geography, Guangzhou, China

Abstract

In order to better understand the postglacial ice melting history, this study has investigated an estuarine wetland on the east coast of Peninsular Malaysia. From this tectonically relatively stable far-field site, a number of sea-level index points were collected from mangrove sediments. Based on these index points, the relative sea-level history between 7000 and 2000 cal. a BP was reconstructed. The result shows that the relative sea level reached the present height around 7000 cal. a BP, continued to rise to c. 2.0 m by about 4000 cal. a BP; and fell back onto the present height by about 2000 cal. a BP. This result has filled the gap of mangrove-based sea-level data for the Peninsula. The rise of relative sea level at a rate of 0.67 mm/a between 7000 and 4000 cal. a BP provides supporting evidence for the assumption of a continuous ice melting in this time period. The sea-level highstand of c. 2.0 m around 4000 cal. a BP suggests that the amount of glacial isostatic adjustment is significantly lower than previously assumed.

Bioerosion notch reveals decimetre scale sea level variability during MIS 5 (Sur, Sultanate of Oman)

Michaela Falkenroth^{1,2}, Silja Adolphs¹, Mirjam Cahnbley¹, Miklos Kázmér³, Gösta Hoffmann¹

¹Institute for Geoscience and Meteorology, University Bonn, Bonn, Germany, ²NUG, RWTH Aachen, Aachen, Germany, ³Department of Palaeontology, Eötvös Loránd University & MTA-ELTE Geological, Geophysical and Space Science Research Group, Budapest, Hungary

Abstract

Coastal notches are cliff incisions that form primarily through a combination of bioerosion and abrasion and function as sea-level indicator since their apex aligns with Mean Sea Level (MSL) during formation. Our study area in Sur Lagoon at the northeastern coastline of Oman shows two coastal notches, one abrasional and one bioerosional. Both notches formed during the global sea-level highstand of Marine Isotopic Stage 5 (MIS 5) and are now located around 3.5 m above MSL. While the abrasion notch is less distinct, the bioerosion notch is very well preserved and shows body and trace fossils of a variety of organisms. Biological indicators adapt to sea-level variations with their distribution. Sea-level research often focusses on sea-level indicators emerging during stable conditions or on indicators roughly representing distinct climate periods. The combination of stable (coastal notches) and quickly corresponding sea level indicators (biological indicators) improves the information of sea-level changes before or after the stable sea level. These methods support the investigation of highly interesting periods like MIS 5.

With this study we aim to reconstruct short-term fluctuations in sea level during MIS 5 based on the shape and organisms of the bioerosion notch and thereby better understand the Quaternary sea-level history of the Omani coastline.

During fieldwork all occurrences of the notches were mapped around Sur Lagoon. The notch shape and distribution of the organisms were measured for each outcrop. Most common organisms are boring mussels, sponges, oysters, worms, and barnacles.

The interpretation of this field-data shows that the combination of a bioerosion notch and biological indicators can be used to determine sea-level development during MIS 5. Broadened and conflicting zonation provide evidence for a more complex sea-level history than simply one stable high stand. Proof of a sea-level rise of several decimetres after the notch formation and a subsequently dropping sea level was found.

High-latitude, coarse-grained beach ridges as archives of Holocene sea-level change

Christopher Hein¹, Mateusz Strzelecki², Sebastian Lindhorst³, Julie Billy⁴, Nicolas Robin⁴

¹Virginia Institute of Marine Science, College of William & Mary, Gloucester Point, USA, ²University of Wroclaw, Wroclaw, Poland, ³Universität Hamburg, Hamburg, Germany, ⁴Université de Perpignan Via Domitia, Perpignan, France

Abstract

Progradational beach- and foredune- ridge systems hold the potential to serve as archives of changes in sea level, storm frequency, climate, source and rate of sediment supply, as well as the coastal system's response to these changes across timescales. Here, we present records of millennial-scale Holocene sea-level change derived from two high-latitude, coarse-clastic beach-ridge plains, based on RTK-GPS mapping and geochronology. Internal beach-ridge structures are mapped at both sites using ground-penetrating radar to allow for characterization of beach-ridge indicative meanings based on the modern beach and foredune-ridge systems. At Bjornpynten, Svalbard 11 new radiocarbon dates derived from juvenile specimens of *Astarte borealis* shallowly buried within raised, gravel-dominated beach ridges across a ca. 1000 m wide plain reveal a period of rapid (ca. 9.0 mm/yr) sea-level fall of ca. 20 m from 11 to 9 ka. This resulted in reworking of pebble- to cobble- sized clasts alongshore to form seaward-dipping (~12–18°) beach ridges that are <50 cm in amplitude and spaced at 10–20 m. Decelerated sea-level fall between 9000 and 2000 years ago to 3.5 mm/yr resulted in slowed progradation (from 16.5 to 7.3 m per 100 years) and decreased ridge spacing to ~5-10 m. Together, these data confirm earlier reconstructions of Arctic sea level, and in particular the rapid sea-level fall following collapse of a major ice dome centered southeast of Kong Karls Land. In contrast, the mixed sand-and-gravel beach- and foredune- ridge plain of Miquelon-Langlade, France (50 km south of Newfoundland) records a period of slowly rising sea level in the North Atlantic during the last 2500 years. Development of this plain was through longshore delivery of coarse sediment sourced from erosion of proximal glacial deposits (moraines). Optically stimulated luminescence dating of the well-defined contact between coarse-grained, wave-built facies and overlying aeolian deposits is used to document a net sea-level rise of 2.4 m in three distinct periods: (1) an increase between 2400 and 1500 years at an average rate of + 1.3 mm/yr; (2) relatively stable or slowly rising relative sea level 1400-700 years; and (3) a rise of ca. 0.7 m during the past 700 years at a rate of + 1.1 mm/yr. These changes in sea-level rise are reflected in the development of the plain itself: periods of slower rise (0.2 up to 1.3 mm/yr) correlate to faster progradation. These data not only allow for the first sea-level reconstruction for the Saint-Pierre-et-Miquelon archipelago but also reveals further details of relative sea-level change in a region (Newfoundland) characterized by substantial variation reflecting its late Pleistocene ice-marginal position. Together, these two studies demonstrate the utility of Holocene (or earlier), progradational beach-ridge plains in archiving past changes in sea level, and associated coastal system response.

P-3012

Drastic Shore Line changes along Tamil Nadu Coast, India. Does it indicate the Sea Level changes?

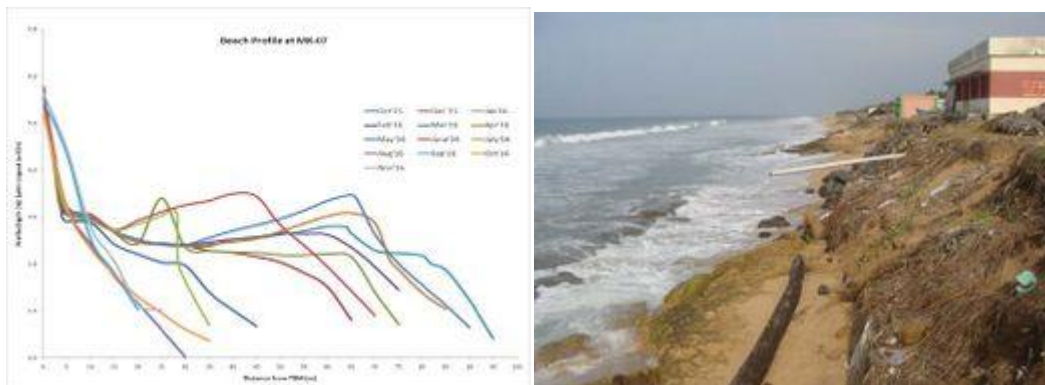

Selvaraj Settu

Department of Geology, National College (Autonomous), Tiruchirappalli, TamilNadu, India

As a part of Sustainable Shore Line Management (SSM) project, conducted by National Institute of Ocean Technology (NIOT), Ministry of Earth Sciences, Govt. of India, Beach Profiling was carried out at 60 locations along the coastal stretch between Poovar and Tuticorin, Tamilnadu Coast, India to monitor the behavior of coastal processes and shore line changes, for the period of 13 continuous months. The beach profiles show the rhythmic erosion and accretion pattern along the study area. In few locations, erosion is drastically active, and sea water inundation is prevalent. The general wave action is highly active and several meters of land has been inundated by sea water. Many roads and buildings are collapsed and washed out by the sea waves. In some places 50 – 75 meters of land has been encroached by sea water. This phenomenon of aggressive erosion corroborates the process of sea level changes taking place along Tamil Nadu coast. Many preventive structures like sea walls and groins have also been developed in such locations, but of no use. In fact the situation has been aggravated by these structures.

In a few locations accretion process is dominated, where beach area is prograded for several meters towards sea. Such abnormal behavior of the sea waves are recorded through beach profiles in the study area. Geotechnical and sedimentological researches have been initiated to find the causes.

Key Words: Beach Profiling, Erosion, Accretion, Sea level Changes.

Holocene uplift rates in Korea

Wook-Hyun NAHM¹, Hoil Lee¹, Chang-Pyo Jum¹, Gwang-Ryul Lee²

¹Korea Institute of Geoscience and Mineral Resources, Deajeon, Korea, Republic of, ²Department of Geography Education, Kyungpook National University, Daegu, Korea, Republic of

Abstract

The most common method for estimating the uplift rate is to measure the height of the coastal terrace. Coastal terraces are basically formed at the position of sea level. In the Korean peninsula, the heights of sea level and coastal terrace during the Holocene are uncertain and it is difficult to estimate the uplift rate. The current controversy over the presence of the mid-Holocene sea-level highstand is due to the fact that sea-level data and interpretations vary slightly depending on the researchers. Although it is known that the coastal terraces are rising about 0.1-0.3 mm annually, there are disagreements among the researchers on age-dating of the coastal terraces, recognizing the coastal terrace surface, and evaluating the impacts of local fault activities. The purpose of this study is to investigate the regional differences in uplift rates based on the height of sea level and coastal terraces during the Holocene. Comprehensively, coastal terrace and sea level data show that Gangwon and Jeolla provinces coasts are stable after at least the beginning of the Holocene. Gyeongsang area showed a considerable uplift after the mid-Holocene. This spatial pattern seems to be related to the regional tectonic structures of the Korean peninsula (Gyeonggi massif, Ogcheon belt, Yeongnam massif, Gyeongsang basin, etc.), and the faults between the massifs. The trend of Moho depths estimated from the seismic explorations and the gravity anomalies estimated from the gravity survey generally coincide with the tectonic structures. Therefore, the uplift rate varies depending on the characteristics of the massifs, such as the degree of response to the tectonic stress and the crustal thickness. It can be determined that this pattern has caused confusion in restoring the Holocene sea level changes.

Holocene sea-level changes in SE Asia

Maren Bender^{1,2}, Alessio Rovere¹, Dominik Kneer³, Paolo Stocchi⁴, Jamaludding Jompa⁵, Thomas Mann²

¹University of Bremen, MARUM – Center for Marine Environmental Sciences, Bremen, Germany, ²ZMT – Leibniz Centre for Tropical Marine Research, Bremen, Germany, ³Alfred-Wegener-Institut, Helmholtz-Zentrum für Polar- und Meeresforschung, List / Sylt, Germany, ⁴NIOZ Royal Netherlands Institute for Sea Research, Den Brug, Netherlands, ⁵Universitas Hasanuddin - Department of Marine Science Indonesia, Makassar, Indonesia

Abstract

The project “Holocene sea-level changes in Southeast Asia” aims to investigate which areas in SE Asia are highly vulnerable to ongoing and future sea-level rise based on paleo relative sea-level (RSL) changes in the Holocene. The first phase was a compilation of a Holocene sea-level database, where existing data from literature was re-analyzed following a standardized protocol. Each data point was classified into one of three different data types: sea level index points, describing samples indicating the position of the paleo sea level as well as marine and terrestrial limiting points, indicating the sea level position above or below the sample origin. In this phase we verified that, for Indonesia, there is only a small amount of data available. Therefore, fieldwork was conducted in the Spermonde Archipelago, south-western Sulawesi, Indonesia, to collect new sea-level data. Results provide ages of 26 fossil microatolls calculated from the radiocarbon analysis, where 16 samples show ages varying between 5956.5 ± 83.5 years before present (a BP) and 3614.5 ± 98.5 a BP. These samples indicate paleo RSL positions from $-1.59 \text{ m} \pm 0.1 \text{ m}$ up to 0.46 m . 9 samples show younger ages ranging from 236.5 ± 140 a BP to 36.5 ± 25 a BP and present paleo RSL positions between $-1.96 \text{ m} \pm 0.19 \text{ m}$ and $-0.15 \pm 0.13 \text{ m}$ a BP. One sample turned out to be modern. Finally, combining these RSL positions with Glacio Isostasy Adjustment models (GIA) this project will lead to future sea level predictions of the Spermonde Archipelago and the area of SE Asia and identify which areas are highly endangered by sea-level rise.

Modeling the Impact of Tropical Cyclones on Developed Coastlines Under Future Sea-Level Rise Scenarios

Patrick Boyden¹, Alessio Rovere¹, Elisa Casella², Christopher Daly³

¹MARUM, University of Bremen, Bremen, Germany, ²ZMT, Leibniz Centre for Tropical Marine Research, Bremen, Germany, ³Department of Earth, Ocean and Atmospheric Science, Florida State University, Tallahassee, FL, USA

Abstract

Global warming and climate change represent a severe hazard for the global population living within low-elevation coastal zones. Coastal communities are already experiencing social and economic impact under current sea-level rise, in the future however, their overall exposure to inundation and erosion will be even greater. These impacts are further magnified under extreme storm conditions, like tropical cyclones. In 2016, Hurricane Matthew skirted the coastline of Palm Beach, Florida. The category 4 storm subjected the area to significant storm surge and powerful wave conditions; leaving a swath of destruction in the storm's wake. In order to provide an insight into coastal change during tropical cyclone events under future sea-level rise scenarios, this study utilizes a coupled 2DH hydrodynamic and morphodynamic XBeach model that is evaluated under two local sea-level projections. Both sea-level rise scenarios are extracted from Kopp et al. (2014) and Kopp et al. (2017), and are applied to a validated hindcast of Hurricane Matthew. The effective doubling of sea-level rise projections under hurricane conditions significantly increases overwash and inundation of the beach. This greater exposure of the entire beach profile to hydrodynamic forces, drives increases in deposition along the backbeach, as well as erosion along the foot of coastal protection structures. Analysis of shoreline hydrodynamics indicate that wave velocities and wave height increase in conjunction with sea-level rise. This experimental structure shows the applicability of XBeach in modeling the impact of future tropical cyclones under changing sea-levels and opens the door for continuing investigations.

¹University of Padova – Department of Geosciences, Padova, Italy, ²CONISMA, Padova, Italy, ³CNR-ISMAR Institute of Marine Sciences, Bologna, Italy, ⁴University of Trieste - Department of Mathematics and Geosciences, Trieste, Italy,

⁵University of Zagreb - Department of Geology, Zagreb, Croatia

Abstract

Strong efforts have been done by the scientific community to reconstruct the last marine transgression and describe it through geophysical models that could match with the information observed in the field. However, because of the few available data, the eustatic curve is still affected by important uncertainties for the period before 8 ka BP.

Thanks to its gentle slope, the continental shelf of the Northern Adriatic Sea is one of the very few areas in the Mediterranean that preserves a partial record of the sea-level variations occurred between Late Glacial and Early Holocene. These changes are documented by sediments and landforms formed in lagoon and paralic environments, which are strongly susceptible even to subtle variations of the relative sea level.

We analysed the large dataset of CHIRP-Sonar profiles acquired in the Adriatic since 1990 by CNR-ISMAR during a series of oceanographic missions and the database of stratigraphic cores sampled in the off-shore and along the coastal plains of Northern Italy and Istria.

A major issue is represented by the recognition and characterization of the periods of rapid increase of the sea level, which punctuated the Late Glacial and the first part of Holocene. These phases caused the abrupt submersion of large sectors of the former coast and alluvial plain, inducing dramatic environmental changes.

In the study area, a large barrier-island system, which remnants can be found between -38 and -42 m Mean Sea Level (MSL), formed ca. 11-10 ka BP and was rapidly drowned in place soon after. Furthermore, important information about a sea-level jump occurred around 9.5-9.2 ka BP have been recently documented both in the deltaic plain of the Po River and in the submerged shelf at about -30 m MSL. This phase of transgression allowed to the Adriatic Sea to penetrate into the Gulf of Trieste, strongly transforming the area between Istria and the coast of Friuli. Another important phase of submersion is documented between 8.4-8.2 ka BP, when relative sea level in the area was around -15 m MSL.

In the studied area the reconstruction of the sea-level evolution rises a major question, represented by the uncertainties related to the stratigraphic, geomorphological and environmental indexes which could allow the identification and quantification of sea-level jumps. Moreover, considering the lagoon and coastal environments, the decreases of the rate of the relative sea-level rise documented in the stratigraphic record could be the product of eustatic stillstands or, partly, also of the environmental changes induced by the episodic strong increase of the sedimentary input from the continent and the consequent basinward shifting of the coastline.

Reconstructing of Holocene sea level in southwestern Baltic by means of geodynamic constraints and sea-level data

Volker Klemann¹, Meike Bagge¹, Milena Latinovic¹, Karl Stattegger², Bernhard Steinberger^{1,3}, Maik Thomas^{1,4}

¹GFZ German Research Centre for Geosciences, Potsdam, Germany, ²Kiel University, Kiel, Germany, ³University of Oslo, Oslo, Norway, ⁴Freie Universität Berlin, Berlin, Germany

Abstract

The evolution of the southwestern Baltic Sea during the Holocene is important to quantify its water exchange with the oceans through the Belt-Sea region. Especially, the timing of the transition from its fresh Ancylus-Lake to its brackish Yoldia-Sea state is of interest as it allows to constrain the glacial-isostatic adjustment (GIA) process in this region. The process is complicated by a number of aspects: the Trans-European Suture Zone representing the transition from the Baltic and East-European Cratons to the Phanerozoic orogens of South-West Europe; the eustatic sea-level rise due to the final melting of the Laurentide ice sheet; and the adjustment process due to the deglaciation of the Fennoscandian ice sheet.

In this study we present a forward modelling approach, where we discuss the impact of lateral heterogeneities in mantle viscosity on the flexural behavior of the GIA process and on the interpretation of geological sea-level data as proxies for Holocene sea-level change. By this, we aim at a better understanding of the timing and amplitude of this last transgression event of the Baltic Sea.

This study contributes to the German climate modeling initiative PalMod and benefited from discussions inside PALSEA 2.

Quantifying 20th century sea-level change in Southeast Asia using coral microatolls

Jędrzej Majewski¹, Aron Meltzner^{1,2}, Adam Switzer^{1,2}, Danny Natawidjaja³, Bambang Suwargadi³, Nicole Khan², Benjamin Horton^{1,2}

¹Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore, ²Asian School of the Environment, Nanyang Technological University, Singapore, Singapore, ³Research Center for Geotechnology, Indonesian Institute of Sciences (LIPI), Bandung, Indonesia

Abstract

Regional records of relative sea-level (RSL) change provide vital constraints for future sea-level rise projections. However, in Southeast Asia instrumental records from tide gauges are temporally and spatially limited and contaminated by non-climatic processes. Indeed, there are no records longer than 50 years in the tectonically stable region of Sundaland. Fortunately, coral microatolls provide a proxy for RSL, because of their vertical and age resolution. Coral microatolls record extreme low water levels with a potential resolution of ~3 cm over their multi-decadal lifetimes. In addition, their chronology can be deciphered at an annual resolution.

Here, we collected two living coral microatolls from Mapur Island in Indonesia, ~80 km from Singapore. Singapore is very susceptible to the future impacts of sea-level rise with a third of the island being in a low-elevation coastal zone. We reconstructed 8 sea-level index points from the coral microatolls and compared these to the instrumental records from Singapore and southern Peninsular Malaysia. The two-unponded microatolls provide an RSL history from 1915 and 1982 years to present. The proxy RSL record closely matches published instrumental data from Singapore from 1975 to 2009. The longest living coral microatoll which begun to record sea level in 1915 suggest RSL rose 27 cm in the 20th century. The rate of RSL rise increased from 2.5 mm/y in 1915 to 2.9 mm/y in 2016. Our findings indicate that coral microatolls can be used to reconstruct reliable sea-level records. Coral microatolls can be applied as surrogate for instrumental data in other regions of demographic or economic importance determining the rates, mechanisms, and geographic variability of sea-level rise.

Holocene relative sea-level change in Chile

Ed Garrett¹, Daniel Melnick², Tina Dura³, Marco Cisternas⁴, Lisa Ely⁵, Rob Wesson⁶, Julius Jara-Muñoz⁷, Pippa Whitehouse¹

¹Department of Geography, Durham University, Durham, United Kingdom, ²Instituto de Ciencias de la Tierra, TAQUACH, Universidad Austral de Chile, Valdivia, Chile, ³Department of Geosciences, Virginia Tech, Blacksburg, USA, ⁴Escuela de Ciencias del Mar, Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile, ⁵Department of Geological Sciences, Central Washington University, Ellensburg, USA, ⁶U.S. Geological Survey, Golden, USA, ⁷Department of Earth and Environmental Sciences, University Potsdam, Potsdam, Germany

Abstract

We present a comprehensive relative sea-level (RSL) database for north, central, and south-central Chile (18.5°S – 43.6°S) using a consistent, systematic, and internationally-comparable approach. Despite its latitudinal extent, the Chilean coastline has not previously received rigorous or systematic attention and details of the RSL history remain largely unremarked. To address this knowledge gap, we re-evaluate the context and age of previously published sea-level indicators, providing 80 index points and 84 marine or terrestrial limiting points that span the period from 11,000 years ago to the present day. We also describe two new limiting points from two sites in the Maule and Bío Bío regions. Our database incorporates a range of different types of sea-level indicator, including tidal marsh sediments, beach ridges, marine deposits and freshwater sediments, dated through radiocarbon and luminescence approaches. We compare the spatiotemporal distribution of sea-level indicators with a suite of glacial isostatic adjustment models and place first-order constraints on the influence of tectonic processes along the coastline. By compiling and comparing the RSL history for 11 different regions, we summarise current knowledge of Chilean RSL, highlight directions for future sea-level research, and provide a resource to assist attempts to understand the distribution of archaeological, palaeoclimatic, and palaeoseismic evidence in the coastal zone.

Late-Holocene sea level evolution in the Rhone delta (western Mediterranean Sea): implications for a sea level rise scenario by 2100

Matteo Vacchi^{1,2}, Marco Anzidei³, Luca Pizzimenti⁴, Antonio Vecchio⁵, Enrico Serpelloni³

¹Department of Earth Sciences, University of Pisa, Pisa, Italy, ²Geography, University of Exeter, Exeter, United Kingdom, ³Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, ⁴Radboud Radio Lab, Department of Astrophysics/IMAPP, Radboud University, Nijmegen, Netherlands, ⁵Lesia Observatoire de Paris, Meudon-Paris, France

Abstract

With an area of over 930 km², the Rhone river mouth (southern France) is forming the western Mediterranean largest river delta. The vast plain comprised between the Mediterranean Sea and the two main arms of the Rhone river includes large brackish lagoons or étangs, separated from the sea by sandbars and encircled by reed-covered marshes. These are in turn surrounded by a large cultivated area. The whole territory, known as Camargue is very sensible to future sea level rise. In fact, most of the Camargue area is lying at less than 1 m above the present mean sea level and 1/3 of the area is composed of marshes and lagoons presently placed at the mean sea-level. In order to assess the impacts of future sea level rise on this key natural area we reconstructed the sea level evolution in the last millennia in order to have a pre-anthropogenic picture of the delta evolution. The formation of Rhone river deltas may be broadly subdivided in two successive stages. The first corresponds to the delta inception scenario tied to the mid-Holocene sea-level stabilisation that occurred ca 7000 years ago. The second corresponds to the actual delta formation over the last 2500 years. In this period, the eustatic input is negligible and the whole relative sea-level variation in the Rhone delta is controlled by negative land-level changes due to isostasy and, in major part, by subsidence associated with the sediment compaction. We quantified these signals using a large set of past sea level indicators available in the area and we superimposed them to available the sea-level projections of 2050 and 2100. In the frame of the SAVEMEDCOASTS project (www.savemedcoasts.eu), we used a Lidar (1m/ pixel and 5m/pixel) and analyzed high resolution Digital Terrain and Marine Models of this area, available from <https://data.shom.fr/> (DATA.SHOM.FR - Information géographique maritime et littorale de référence), prone to be flooded by sea level rise in the next decades. From these data we extracted and investigated very high resolution DTMs at 5m/pixel. We used the IPCC projections for RCP4.5 and RCP8.5 climate change scenarios of the expected sea level rise by 2100 for the Mediterranean region, in combination with the trend of VLM from geodetic or geological data, to provide the relative sea level rise projections for 2100 in the Rhone delta. Finally, we produced multitemporal maps of sea level flooding scenarios showing the portion of the Delta that will be majorly affected by future sea level rise.

Sedimentological analyses of paleomangroves reveal Holocene climate and sea-level variations in Oman

Valeska Decker¹, Jessica Landgraf¹, Susanne Lindauer², Gösta Hoffmann¹

¹Institute of Geoscience and Meteorology, Bonn University, Bonn, Germany, ²Klaus-Tschira-Archaeometrie Zentrum, Mannheim, Germany

Abstract

We aim to understand processes of Holocene climate and sealevel variations within the northern Indian Ocean area by giving a spatio-temporal overview on paleomangrove ecosystems. Therefore, we use sediments deposited within paleolagoonal settings associated with mangrove forests as environmental archives. Such archives have the potential to study environmental changes in high resolution. On the one hand sedimentation record is well preserved. On the other hand, mangrove forests are sensitive to changes of both: climate and sea-level. Mangroves are a group of several plant species that are adapted to the intertidal zone and can be found globally between 30° north and south. This intertidal zone marks the transition between the marine and the terrestrial realm and requires plant adaptations regarding salinity and tides, respectively. Changes in precipitation lead to changes in freshwater supply which results in higher or lower soil salinity. Additionally, variations in sealevel result in a change of tidal range and thus to a shift of the intertidal zone. Therefore, these mangrove ecosystems are ideal archives that can be utilised to reconstruct environmental changes. Climate variability within our study area is linked to the Indian Monsoon circulation, an atmospheric system millions of people depend on. We focus on the coastlines of the Arabian Sea in the northern Indian Ocean, specifically the shores of Oman and western India. The recent climate in Oman is arid and there are few mangrove forests. These are made up of only one species, *Avicennia marina*. This species is known to be the most tolerant in terms of environmental conditions. Archaeological and sedimentological evidence suggests that mangroves in Oman were more widespread and also enriched in species at the transition from Early Holocene to Mid Holocene. Hence, either climate conditions were more humid at that time or sea-level was different.

P-3023

Relative sea-level and morpho-sedimentary evolution during the last eustatic cycle in the Mar Piccolo basin (Taranto, Northern Ionian Sea)

Eliana Valenzano¹, Giovanni Scardino^{1,2}, Paola Fago³, Giulia Cipriano⁴, Francesco De Giosa², Stefania Lisco¹, Daniela Mele¹, Massimo Moretti¹, Giuseppe Mastronuzzi^{1,2}

¹Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari, Bari, Italy, ²Environmental Surveys S.R.L., Taranto, Italy, ³CoNISMa, Rome, Italy, ⁴Dipartimento di Biologia, Università degli Studi di Bari, Bari, Italy

Abstract

The Mar Piccolo (Taranto, Southern Italy) is a small semi-enclosed basin with lagoonal features, affected by complex environmental issues. Its cliffs are known in the geological literature as a reference point for the detailed study of the last interglacial sea level fluctuations. On the contrary, post MIS5e deposits were never analyzed in detail, although they are fundamental to understand the present-day morpho-sedimentary processes and anthropic impact. We studied the 60 m thick basin infill using a new very high-resolution data set consisting of a dense grid of sub-bottom profiles, 23 cores, and ¹⁴C datings.

At the base of the succession, at a maximum depth of 59 m below mean sea level, an erosional surface was recognized as a paleovalley basal surface, formed during the last relative sea-level (RSL) fall.

The paleovalley was filled by a thick post-LGM transgressive succession, marked by the presence of peat levels with *Planorbis sp* freshwater gastropods next to lagoonal silts with *C. glaucum*. Peat levels vegetal remains were radio-carbon dated, providing consistent RSL index points for a time span of 8.5 – 11.3 cal ka BP in an area, the northern Ionian Sea, that lacked completely of Holocene sea-level markers. Furthermore, this data can be considered one of the most complete suites of RSL index points for the Mediterranean.

The transgressive succession also contains a tephra level recognized as Pomici di Mercato eruption (8890 cal yr BP) from the Vesuvius area. The tephra provides a further reliable time constraint to our study; it deposited in a marine realm and, therefore, can be considered a marine limiting point (*sensu* Vacchi et al., 2016).

Finally, the sea level rise was identified as the cause of important cliff retreat phenomena, that determined the passage from a fluvial morphology to the present-day sub-circular shape of the basin.

Figure 1. Geochronological constraints and RSL points, plotted together with the Lambeck et al. (2011) RSL curve. Horizontal error bar, represent the 2σ error in age; vertical bars represent the error associated to the drilling methods (0.15 m) plus the reference water level range (for peat is the tide range ± 0.3 m, for *C. glaucum* 0 to -2 m) as in Vacchi et al. (2016)

Abstract

A Holocene sea-level history for the southern Gulf of Carpentaria has been constructed based on a review of previously published data, combined with data collected for this study from a variety of sea-level proxies. These sea-level proxies include beach ridges, claypans, mangrove swamps, fossilized *in situ* coral reefs, beachrock and aeolinite deposits. Results confirm that rising sea-levels during the last Post-Glacial Marine transgression beached the Arafura Sill ca. 11,700 years ago (-53 m), resulting in a change from lacustrine to a marine environment. Sea levels continued to rise to ca. -30 m by 10,000 years ago. By 7,700 cal. yr BP sea-level reached PMSL and continued to rise an elevation of between 1.5 and 2 m above present mean sea-level by 7,000 years ago. Elevated sea levels resulted in the development of raised coral reefs, beach-rock and aeolinite deposits, and the initiation of chenier plains and beach ridges. Sea-level remained ca. +1.5 m above PMSL during the Holocene highstand, accompanied by distinct phases of beach-ridge and chenier plain development. The highstand was followed by a rapid regression to within ± 0.5 m of PMSL by ca. 3,500 cal. yr BP. When placed into a wider regional context results from this study show that coastal landscape evolution in the tropical north of Australia was not only dependent on sea-level change but also show a direct correlation with Holocene climate variability. Specifically, the formation and preservation of beach-rock deposits, intertidal successions, beach and chenier ridge systems hold valuable sea-level and Holocene climate proxies that can contribute to the growing research into lower latitude Holocene sea-level and climate histories.

Coastal submergence events identified by fossil diatoms and plant macrofossils at Ukishima-ga-hara adjacent to the Suruga Trough, central Japan

Yuki Sawai¹, Arata Momohara², Dan Matsumoto¹, Yumi Shimada^{1,3}

¹Geological Survey of Japan, Tsukuba, Japan, ²Chiba University, Matsudo, Japan, ³University of Tsukuba, Tsukuba, Japan

Abstract

We identified eight episodic submergence events based on paleontological analyses on peaty sediment samples at Ukishima-ga-hara lowland adjacent to the Suruga Trough, central Japan. The submergence events were shown by changes in compositions of diatom assemblages and plant macrofossils although lithostratigraphy has no clear changes in facies. For example, at about 2.3 m and 3.1 m below the ground surface, while aerophilic diatoms (such as *Diadesmis contenta*) dominate underlying peaty layer, freshwater and brackish planktonic taxa (*Aulacoseira* and *Thalassiosira*) abound in overlying layer. Radiocarbon ages of plant macrofossils taken from samples just above and below the event horizons were used to constrained ages of the events. As the results of applying Bayesian estimation of event ages using OxCal program, the youngest one may be correlated with either 1707 or 1498 earthquake. The second one was with either 1361 or 1498 earthquake. The third one covers ages of 1096 and 887 earthquakes. Further older events were correlated with prehistoric tsunami deposits reported by Fujino et al. (2018). These submergence events may be generated with coastal deformation associated with subduction zone earthquake along Suruga Trough and/or active fault earthquake at Fujigawa-kako-fault zone.

Tectono-geomorphic evolution of Taebaek Mountain drainage divide, Cenozoic extensional basin margin, Korean Peninsula

Yeong Bae Seong¹, Dong-Eun Kim¹, John Weber², Byung Yong Yu³

¹Department of Geography, Korea University, Seoul, Korea, Republic of, ²Department of Geology, Grand Valley State University, Allendale, USA, ³Korea Institute of Science and Technology, Seoul, Korea, Republic of

Schematic model of retreat along the main divide of the TBR. (A) Uplift of the TBR during opening of the East Sea (Sea of Japan). (B) Prior steady-state condition during which the uplift rate (U_0) is equal to the denudation rate (D_0). (C) Transient state condition during which the uplift rate since the late Quaternary (U_1) is higher than the denudation rate (D_0) because of tectonic inversion. To follow the increased uplift rate, the denudation rate would increase and the main divide would migrate to the west.

The Taebaek Mountain Range (TBR) initially formed via the extension of a back-arc basin (the East Sea) during the early-Miocene (ca. ~22 Ma), and constitutes a typical escarpment in a passive continental margin since its extensional cessation. The TBR acts as a major watershed divide across which topography rapidly changes; the western side slopes gently while the eastern side is steeper. Compared to the geologic history of the extensional basin based on analysis of the sedimentary basin, the geomorphic history of the margin of the post-extensional basin has been minimally studied because of a lack of terrestrial archives and tools to analyze them. We determined the rate of divide migration of the TBR using various geomorphic and chronologic analysis. The geomorphic analysis of relief, slope, river long profiles, swath profiles, hypsometric index, and χ parameters were used to validate a transient topography. The catchment-wide denudation rate (CWDR) using ^{10}Be was used to quantify the denudation rate of paired basins. Our study documents that CWDRs show the denudation rate of the eastern steep slope is nearly two times higher than that of the western gentle slope. Morphometric results also indicate that catchments on the eastern TBR have captured some of their counterpart catchments on the western TBR. Both results suggest that the retreat process of the main divide of the TBR has accelerated since the regional uplift (tilting or flexure) of the eastern TBR during the late Quaternary and/or since drainage capture occurred. From this moment onward, geomorphic disequilibrium on the current divide of the TBR has continued.

Preliminary results of a paleoseismological study of the south Yangsan fault indicate timing and characteristics of recent activity

Sung-Ja Choi, Jinhyuck Choi, Yong Sik Ghim, Kyoungtae Ko, Seung Ryeol Lee
Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

The Yangsan fault, a prominent fault in the southeastern part of the Korean Peninsula, is an NNE tectonic fault of dextral reverse sense. This fault has been known to be active and has recently attracted attention in the peninsula following a shallow-depth (<13 km) earthquake (Mw 5.1) in 2016. This study aimed to investigate a blind extension from known outcrops, the recent activation and average vertical slip-rate of the active fault segment. Following the identification of a fault scarp using aerophotography and LiDAR imagery, an excavation was performed on the wide fluvial terrace in the Eonyang region at the southern end of the fault. The fault scarp is approximately 700 m long with a vertical displacement between the terrace surfaces no bigger than 1.5 m. A trench of 5 m deep, 3.5 m wide and 18 m long, crossing the scarp, showed the existence of an active fault with a the-top-up-to-the-west attitude and reverse fault movement sense. The trench wall is composed of fluvial sediments 2 m and 15 - 20 m thick on the hanging wall and footwall sides, respectively. The age of upper sediment layers was measured as ca. 37,000 - 600 years BP by ¹⁴C and OSL dating. Considering the age, the terrace could be correlated to MIS 3 and is underlain by thick fluvial sediments of MIS 2. The active fault forms a boundary between unconsolidated gravel layers and an intermediate dike and has fault striation (108°/55°) with dip-slip sense. We estimate the last activation occurred around 8,300 years ago with a vertical displacement of about 1.5 m. Preliminary data shows that the vertical displacement rate is 0.18 mm/yr and the accumulated vertical slip-rate is 0.26 - 0.35 mm/yr. The Yangsan fault has been reactivated with the-top-up-to-the-west reverse sense during the Holocene period. This reaffirms that the peninsula is located within the influential range of E-W compression due to the westward subduction of the Pacific Plate, rather than that of the northward subduction of the Philippine Plate.

A 3.7 kyr paleotsunami record in the dynamic coastal lake system of Lake Cucao (Isla de Chiloé, south central Chile)

Philipp Kempf^{1,2}, Jasper Moernaut³, Maarten Van Daele⁴, Marc De Batist⁴

¹Ghent University, Innsbruck, Belgium, ²Geological survey of Belgium, Brussels, Belgium, ³University of Innsbruck, Innsbruck, Austria, ⁴Ghent University, Ghent, Belgium

Abstract

In AD 1960, Lake Cucao on the Pacific coast of Isla de Chiloé (south central Chile) was inundated by the tsunami of the Great Chilean Earthquake (M_w 9.5). The coastal lake basin is submerged since the postglacial sea level rise and may have recorded tsunami inundations in its sedimentary record since then. Sub-bottom profiles and side-scan sonar data near the lake outlet show a tidal delta with a crosscutting channel and fields of mega-ripples. Radiocarbon dates on sediment cores allow dating the seismic stratigraphy down to 3.7 kyr and suggest that tidal currents were active at least sporadically in this time frame. In a total of 21 sediment cores (including 9 cores that are up to 8 m long), 15 detrital layers are intercalated within overall organic-rich background sediments. Short-lived radionuclide data suggests that the youngest of these detrital layers corresponds to the AD1960 tsunami. The older detrital layers are interpreted as tsunami deposits with a varying confidence level, which depends on five criteria. There are site-specific criteria, e.g. i) high magnetic susceptibility of the sediment indicating high detrital content, ii) core correlation, iii) acoustic reflector correlation to the sedimentary record (indicating traceability of the detrital layer in the sedimentary record), and general criteria, e.g. iv) presence of mud rip-up clasts and v) age correlation to known paleotsunamis in the area. In this way 8 detrital layers are interpreted as tsunami deposits with a high level of confidence, 5 with a medium level of confidence and 3 with a relatively low level of confidence. The paleotsunami record of Lake Huelde, a mere 2 km north of Lake Cucao, contains 13 tsunami deposits in the same time interval. This study adds a long paleotsunami record on a coastline, where extreme tsunamis occur relatively frequently and where long paleotsunami records are still sparse. This study underlines the many challenges associated to paleotsunami research on coastal lakes and demonstrates how indispensable geophysical mapping and numerous coring sites are in understanding the depositional environment of dynamic coastal lakes for extracting high-quality paleotsunami records.

Sandy event deposits identified at Kogare-ike, Minami-ise Town, facing the Nankai Trough, central Japan

Yumi Shimada^{1,2}, Yuki Sawai², Dan Matsumoto², Yuichi Namegaya², Masanobu Shishikura², Shigehiro Fujino¹

¹University of Tsukuba, Tsukuba, Japan, ²Geological Survey of Japan (AIST), Tsukuba, Japan

Abstract

The Nankai Trough is well known to generate great earthquakes and tsunamis that have impacted western part of Japan. The trough is divided into three segments as Tokai, Tonankai, and Nankai areas from east to west, based on rupture areas of historical great earthquakes. Written records cover earthquake history more than 1100 years and long-term forecast for subduction zone earthquakes along the Nankai Trough is calculated using the historical records. However, they cannot reconstruct giant earthquakes such as the 2011 Tohoku earthquake, which may have recurrence intervals measured in centuries or millennia (Satake and Atwater 2007). Here we used stratigraphic and paleontological investigations at Kogare-ike in Minami-ise Town, eastern part of the Kii Peninsula (near central part of the Nankai Trough), to extend the history of subduction zone earthquakes along the Nankai Trough.

We identified sixteen sandy event deposits interbedded with organic mud in five lake-bottom cores taken at Kogare-ike, Minami-ise Town. The cores were taken using a Russian sampler on a plastic floating boat and then the cores were observed by eyes and computed tomography (CT). The CT images of the cores, of which length of the cores ranges 3.25 to 4.75 m, show sedimentary structures such as sharp lower stratigraphic contacts and parallel laminae. A tephra layer was also recognized in all cores. Candidate of the correlative tephra is either Kikai-Akahoya tephra (K-Ah) of 7.3 cal kyr BP, or Amagi Kawago-daira tephra (Kg) of 3.1 cal kyr BP. This presentation will provide results of radiocarbon dating, identification of tephra, and diatom analysis.

Palaeoearthquake and volcanic influence of Mount Fuji reconstructed from lacustrine sediments of Fuji Five Lakes, central Japan

Takashi Uchiyama, Shinya Yamamoto
Mount Fuji Research Institute, Fujiyoshida, Japan

Abstract

Mount Fuji is the largest active volcano in Japan, and its eruption started in ca. 100,000 years ago, as Hoshiyama stage of Fuji volcano, and next eruption stage, Fuji volcano Fujinomiya and Subashiri stage began from ca. 18,000 years ago (Takada et al, 2016). The Fuji Five Lakes, as popularly known Fuji-Goko in Japan, comprise Lake Motosu, Lake Shoji, Lake Sai, Lake Kawaguchi and Lake Yamanaka. They are located at north foot of Mount Fuji and were formed as a result of natural damming by lava flows and pyroclastic flows from Fuji volcano. Previously our investigation collected sediment cores from Lake Mototsu, Kawaguchi and Yamanaka show that they formed before ca 30,000 to 10,000 years ago (Koshimizu and Uchiyama, 2002; Yoshizawa et al, 2004; Koshimizu et al, 2007)

Lacustrine sediments of these lakes are good recorders to reconstruct the volcanic activity and estimate the changes of and impact on the natural environment around Fuji volcano. We deduced that lacustrine sediments in these lakes has the potential to record evidence of earthquake caused by volcanogenic and palaeoearthquakes from Nankai, Sagami Trough and Japan Trench (ex QuakeRecNankai team, 2015). For example, we know that seismic seiche occurred in Lake Sai due to the 2011 earthquake off the Pacific coast of Tōhoku.

We inferred that lacustrine sediment cores from these lakes illustrate the influence of volcanic activity of Fuji volcano on three lakes, which was greatly different in the place of each lake nad borehole Core from lakeside of Lake Motosu shows significantly understanding for palaeoearthquake shaking due to Nankai, Sagami Trough and Japan Trench, and reconstructing the changes of natural hazards around Fuji Five Lakes.

Inland fining and inland lightning characteristics of tsunami deposit

Yuichi Nishimura

Institute of Seismology and Volcanology, Hokkaido University, Sapporo, Japan

Inland fining is one of the most commonly observed characteristics of sheet-like distributing tsunami deposit. Thus, this feature is used for identification of a paleo tsunami deposit. Similarly, there are also some reports inferring that inland lightning can be seen in the deposit. In a case where the topography and surface situation is simple, these tendencies are thought to reflect those sand particles carried in the tsunami flow deposit in descending order of their settling velocity. In this study, we examined the combination of inland fining and inland lightning features of the 2011 tsunami deposits left in the coastal forest in Misawa, Aomori Prefecture, Japan. The tsunami heights were 6-10 m above the mean sea level. The beach sand in the coast is characterized by high content of heavy minerals such as magnetite. The tsunami and coastal sand consist of iron sand by 60 % or more by weight. We studied 15 excavation sites at 5 m intervals on an 80 m profile perpendicular to the coast. The maximum deposit thickness is ca. 30 cm and decreases toward the tsunami inundation limit. The average grain size of the tsunami deposits is about 2.2 phi in the first half of the profile and fines inland to be 3 phi. On the other hand, the specific gravity of the deposit decreases inland through the profile. In order to analyze this trend more precisely, the sand was divided into sand iron and the other (here we called non-iron sand) using a magnet. The specific gravity of the iron sands ranges from 3.4 to 3.6 and that of the non-iron sands is constant at 2.7. From the specific gravity and the grain size of the iron sands and the non-iron sands, we calculated the settling velocities of the particles and found that both the iron sands and the non-irons sands were almost the same. It is inferred that both inland fining and inland lightning reflects changes in the characteristics of sand expressed by the settling velocity. This means that sorting seen in sandy tsunami deposit that occurred in a flow may not be expressed by examining only one of the particle size and specific gravity of the sand for the case that the coastal sand consists of minerals with different specific gravity such as quartz and magnetite.

A new multi-millennial record of great earthquake deformation and tsunami inundation in south central Chile

Ed Garrett¹, Marco Cisternas², Daniel Melnick³

¹Department of Geography, Durham University, Durham, United Kingdom, ²Escuela de Ciencias del Mar, Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile, ³Instituto de Ciencias de la Tierra, TAQUACH, Universidad Austral de Chile, Valdivia, Chile

Abstract

We present a 2000-year-long record of palaeoearthquake deformation and tsunami inundation from a coastal marsh in northern Isla de Chiloé, south central Chile. The site preserves evidence for at least six episodes of abrupt decimetre- to metre-scale vertical deformation. Applying established palaeoseismic criteria, we interpret the alternating peat and silt stratigraphy as reflecting repeated coseismic deformation and tsunami inundation associated with great to giant ($M8 - 9+$) megathrust earthquakes. A microfossil-based transfer function quantifies the magnitude of deformation at the site during each earthquake, while a radiocarbon chronology enables correlation of evidence at a regional scale. We discuss the implications of this new record and of previously published palaeoearthquake archives in the region for understanding the variability in coseismic fault slip during sequences of multiple great earthquakes.

P-3033

Relative sea level changes and uplift across northwest Luzon Island, Philippines: Interpreted from late Quaternary emergent coral reef terraces

Kathrine Maxwell¹, Noelynna Ramos¹, Hiroyuki Tsutsumi², Fucai Duan³, Yu-Chen Chou³, Chuan-Chou Shen³

¹University of the Philippines, Quezon City, Philippines, ²Doshisha University, Kyoto, Japan, ³National Taiwan University, Taipei, Taiwan

Abstract

We examined the emergent coral reef terraces in northwest Luzon Island, particularly in Badoc Island, Badoc, and Currimao localities in Ilocos Norte, to understand relative sea level (RSL) changes and uplift along the Manila Trench forearc region during the late Quaternary. We mapped and described the late Quaternary coral reef terraces based on their geomorphological characteristics, elevation patterns, and ages and subdivided them into: the upper Pleistocene terraces and the lower Holocene terraces. The Holocene terraces in all three localities are subdivided into three to possibly four terrace steps (TI–TIV in ascending order) with the highest terrace (TIII–TIV) rising up to ~7–9 m above mean sea level (amsl). Fossil coral samples were collected on top of these emergent features and analyzed for U-Th isotopic compositions. Generally, the fossil corals sampled from terraces in Badoc and Currimao reveal ages between ~7000–6000 years before present (BP). Interestingly, we found two sets of coral ages in Badoc Island: mid-Holocene and late Holocene. The mid-Holocene corals range from $6,871.57 \pm 22$ to $6,060.87 \pm 31$ years BP and were sampled from the surface of TI with an elevation of 1.9 to 3 m amsl. The late Holocene corals were found at a higher elevation (TIII at 4.9 m amsl) than the mid-Holocene ones and reveal two sets of ages, $2,727 \pm 13$ years BP and 945 ± 5 – 903 ± 4 years BP. Based on the geomorphic data, we infer that during the mid-Holocene, around 6.8 kyr BP, ~3 m of rapid uplift occurred in northwest Luzon to account for the vertical separation of terraces TI and TII in Currimao site. A subsequent episode of RSL fall occurred at 6 kyr BP, based on dated coral samples, causing the emergence of the lowest terraces in the study sites. Meanwhile, the young coral ages derived could potentially mark significant events along the northwest Luzon region during the late Holocene. The very young corals possibly represent the timing of an extreme wave event ~1000 years BP that could have emplaced coral boulders on top of the 4.9 m amsl terrace surface. We also observed apparent tilting of Badoc Island further suggesting that offshore reverse faults could be potential causative faults. This study highlights the importance of studying emergent coral reef terraces to understand RSL changes and attendant coastal hazards along northwest Luzon and the Manila Trench forearc region.

Rethinking the 1737 Chilean earthquake: sedimentary versus historical evidence for a tsunami

Emma Hocking¹, Ed Garrett², Daniel Melnick^{3,4}, Diego Aedo^{3,4}

¹Northumbria University, Newcastle-upon-Tyne, United Kingdom, ²Durham University, Durham, United Kingdom,

³Universidad Austral de Chile, Valdivia, Chile, ⁴Millennium Nucleus The Seismic Cycle Along Subduction Zones, Valdivia, Chile

Abstract

We present new evidence from a tidal marsh site at Chaihuín, south-central Chile, for a tsunami in 1737, which is not documented in historical records, and calls for a re-evaluation of the proposed rupture mechanism. Four great ruptures (M8+) of the Valdivia segment of the Chilean megathrust have occurred in the last 450 years (Cisternas et al., 2005). Historical records document devastating tsunamis accompanied earthquakes in 1575, 1837 and 1960 CE, but there is no record of tsunami inundation in 1737. Previously, without any evidence for a tsunami in 1737, a narrow and deep megathrust rupture was proposed with maximum slip of a few metres. However, multiple core transects from Chaihuín reveal three laterally extensive sand sheets, the middle of which is consistent in age with this previously unrecorded tsunami in 1737. We present sedimentological and microfossil analyses which suggest the three sand sheets are of marine origin and accompanied by abrupt land-level change; the latter being crucial for ruling out deposition by other extreme wave events including storms and far-field tsunamis. Diatom assemblages also suggest abrupt subsidence of several decimetres occurred in 1737, rather than the coastal uplift that would be expected with a deep and narrow rupture. We therefore suggest that instead slip occurred at intermediate depths in 1737, resulting in coastal subsidence, offshore uplift and the generation of a locally significant tsunami. Improving understanding of this rupture is crucial in the assessment of the supercycle that probably commenced in 1575 and culminated with the M9.5 1960 earthquake.

New Bayesian quantitative paleoenvironmental reconstructions of AD 1700 coastal subsidence along the northern margin of the Cascadia subduction zone

Marie Bartlett¹, Andrea Hawkes¹, Niamh Cahill², Robbie O'Donnell¹, Chad Lane¹, Peter Bobrowsky³, Yuki Sawai⁴, Koichiro Tanigawa⁴, Tetsuya Shinozaki^{4,5}

¹University of North Carolina Wilmington, Wilmington, USA, ²Maynooth University, Kildare, Ireland, ³Geological Survey of Canada, Sidney, Canada, ⁴Geological Survey of Japan, Tsukuba, Japan, ⁵University of Tsukuba, Tsukuba, Japan

Abstract

Coastal estuaries adjacent to the Cascadia subduction zone (CSZ) archive evidence of large megathrust earthquakes over the last 7,000 years. The most recent of these events occurred in AD 1700 with coseismic subsidence ranging from 0.2–0.8 m. Prehistoric great CSZ earthquake evidence is recorded in saltmarsh stratigraphy containing abruptly buried high marsh and upland forest sediments overlain by intertidal muds and occasional landward tapering tsunami deposits. Foraminifera within these sediment sequences are used to estimate the former elevation of stratigraphic marsh horizons because they are sensitive to the duration and frequency of tidal exposure, making them excellent indicators of relative sea-level change. Analysis of fossil foraminiferal assemblages provides an estimate of coastal subsidence along the CSZ by comparing pre- and post-seismic paleo-marsh elevations by way of a transfer function that quantifies the relationship between species distribution and elevation. Quantitative high-resolution AD 1700 earthquake coseismic subsidence estimates in the central CSZ have enabled the development of 3D earthquake dislocation models that map slip patch segmentation and geometry. However, along the northern margin from Washington to Vancouver Island, BC, such estimates are lacking. Previous use of a microfossil-based transfer function on Vancouver Island produced a subsidence estimate of 0.71 ± 0.3 m for the AD 1700 earthquake. To increase the precision of paleommarsh elevation estimates using a recently derived Bayesian transfer function, consisting of 393 regional samples, inconsistencies with prior taxonomy must be rectified. New subsidence estimates will be produced for three sites on Vancouver Island at Tofino, Ucluelet, and Port Alberni. Coseismic subsidence is expected to be larger than previously estimated at Tofino and Ucluelet based on their proximity to the deformation front. Roughly 60 km inland, and further from the deformation front, estimates at Port Alberni will help to inform the downdip limit of deformation.

The use of a Bayesian transfer function allows for the incorporation of informative priors, such as lithologic context, with the purpose of reducing uncertainties and increasing the precision of paleommarsh elevation estimates. We assess the utility of a BC-specific bulk sediment geochemical database ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$, C:N, and total organic carbon) of 43 modern samples as informative priors to further constrain the paleoelevational range of fossil samples. Ideally, geochemical priors could replace lithologic priors as the former are statistically derived and could further refine the precision of coseismic subsidence estimates.

P-3036

Tectonic movements associated with megathrust earthquakes inferred from diatom assemblages in Tokachi coast, Hokkaido, Japan

Takashi Chiba¹, Yuichi Nishimura²

¹Faculty of Bioresource Sciences, Akita Prefectural University, Akita, Japan, ²Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, Sapporo, Japan

Abstract

Geological records have suggested that tsunamigenic megathrust earthquakes occurred twice in the last millennium, in the 17th (Event-1) and 12-13th (Event-2) century, off Hokkaido along the Kuril Trench. We conducted a survey in the Tokachi area where precise paleo-environmental studies have not been performed. We set a 3.5 km profile from the coast to inland to trace the two tsunami deposits using a 1-m-long geo-slicer, and in total 17 core samples were obtained along the profile and 8 of them were used for diatom analysis to estimate the vertical crustal movements associated with megathrust earthquakes.

As a result, tsunami deposits associated with Event-1 and Event-2 were traced inland up to 1.8 km and 1.2 km, respectively. These tsunami deposits showed thinning and fining inland trends. Commonly observed trends in the changes of diatom assemblages are a gradual decrease of freshwater species and an increase of freshwater-brackish species prior to the event depositions, and the opposite trends after them. These are suggesting a repeated occurrence of earthquake accompanying both large tsunami and significant crustal deformation such as inter-seismic subsidence and post-seismic (including co-seismic) uplift in this area. The amounts of uplift were estimated from the multiple core analyses. They are ca. 2.3 m and less than 1.0 m, respectively. The uplift amount for Event-1 is obviously larger than that have been reported for a megathrust earthquake occurred in the 17th century in eastern Hokkaido (130-200 km east from our sites). Thus, it is important to study the tectonic movements associated with megathrust earthquakes in many sites along the Pacific coast of Hokkaido, for the better understanding of earthquakes and tsunami hazards in Hokkaido.

New database of active faults of Eurasia

Vladimir Trifonov¹, Dmitry Bachmanov¹, Andrey Kozhurin^{1,2}, Egor Zelenin¹

¹Geological Institute of RAS, Moscow, Russian Federation, ²Institute of Volcanology and Seismology, Far East Branch of RAS, Petropavlovsk-Kamchatsky, Russian Federation

Abstract

Active faults are those that demonstrate records of tectonic movements in the Late Pleistocene and Holocene. The authors have finished compiling of new database of active faults of Eurasia (NDAF) in 2019. The NDAF accumulates the data of many researchers in a uniform format and includes more than 20,000 objects (faults, fault zones, and associated structural forms) that can be shown in scale 1:500,000. The NDAF contains justifying and estimated attributes of each object. The justifying attributes are: the object's name, morphology, kinematics, magnitudes of displacement for different periods of time, displacement rates estimated from the amplitudes, age of the latest records of activity, data on seismicity and paleoseismicity, sources of information, and other obtained data on the faults. The estimated attributes are represented by a system of indexes reflecting the fault kinematics according to the structural geology classification, three ranks of the Late Quaternary movement rates and four degrees of reliability of identifying the structures as active ones. With reference to the indexes, the objects can be compared with each other and correlated with any other digitized information in any GIS software. The NDAF format allows addition of new information, as well as update and revision.

Principles, methods and tasks of using the NDAF computer processing for neotectonic and geodynamic tasks are discussed. As the examples, some results of this processing are represented. The comparative analysis of active faults of different tectonic provinces of the Caucasus-Anatolian segment of the Alpine-Himalayan Mobile Belt gives a possibility to revise the Late Cenozoic kinematics of the provinces. For the whole central Alpine-Himalayan Belt, variations of directions of axes and values of lateral lengthening and shortening are calculated for estimation of peculiarities of tectonic flow of the upper crust. The distribution of shear deformation is calculated for estimation of parameters of rotation of crustal blocks. The NDAF and results of its processing are important for seismic hazard assessment.

The study was financed by the Russian Science Foundation, Project No. 17-17-01073.

Abstract

Perhaps the largest natural catastrophe affecting the UK over the last 11,000 years was the tsunami caused by the Storegga landslip on the continental shelf-edge to the north-west of Norway. A wide variety of sites with tsunami deposits relating to this event have been reported over a 600 km stretch of the North and North-east Scottish coastline (e.g. Smith et al 2010). Local wave run up is thought to have been in the order of 7 m (max 11 m) causing inundation many kilometres inland in places. There is renewed interest in this event due to it occurring at a similar time as the 8.2 ka cold climate event and the sea-level rise which flooded Doggerland in the North Sea. Extensive regional radiocarbon dating of pre-existing and sediments deposited subsequent to the event have determined this event took place circa 8100 ± 100 Cal BP (Dawson et al 2011). However, accurate dating using radiocarbon is challenging as underlying strata were eroded and reworked organic material may have been brought in with the tsunami or following it. No direct dates of the tsunami deposit in Scotland have been published.

Figure 1: The Storegga Tsunami sandy deposit in the Montrose Basin, Scotland.

Work presented here has focussed on the tsunami sediments found in the Montrose basin north of Dundee (Figure 1). It aimed to develop luminescence dating techniques to directly and precisely date the tsunami sediments. Luminescence, geochemical and sedimentological measurements from a series of 13 sub-sample through the deposit were used to understand the source of sediment transported and number of waves impacting on the coast.

Tracing tsunami signatures of at the Gulf of Kyparissia using Direct Push in situ sensing techniques combined with geophysical studies

Lea Obrocki¹, Andreas Vött¹, Dennis Wilken², Peter Fischer¹, Timo Willershäuser¹, Benjamin Koster³, Frabziska Lang⁴, Ioannis Papanikolaou⁵, Wolfgang Rabbel², Klaus Reicherter³

¹Institute for Geography, Johannes Gutenberg-Universität Mainz, Mainz, Germany, ²Institute of Geoscience, Christian-Albrechts-Universität zu Kiel, Kiel, Germany, ³Institute of Geoscience, Neotectonics and Natural Hazards, Rheinisch-Westfälische Technische Universität Aachen, Aachen, Germany, ⁴Department of Classical Archaeology, Technische Universität Darmstadt, Darmstadt, Germany, ⁵Institute of General and Environmental Geology, Agricultural University of Athens, Athens, Greece

Abstract

The western Peloponnese was repeatedly hit by major tsunami impacts during historical times as reported by historical accounts and recorded in earthquake and tsunami catalogues. Geological signatures of past tsunami impacts have also been found in many coastal geological archives. During the past years, abundant geomorphological and sedimentary evidence of repeated Holocene tsunami landfall was found between Cape Katakolo and the city of Kyparissia. Moreover, neotectonic studies revealed strong crust uplift along regional faults with amounts of uplift between 13 m and 30 m since the mid-Holocene. This study focuses on the potential of direct push in situ sensing techniques to detect tsunami sediments along the Gulf of Kyparissia. Direct push measurements were conducted on the landward shores of the Kaiafa Lagoon and the former Mouria Lagoon from which sedimentary and microfaunal evidence for tsunami landfall are already known. Direct push methods helped to decipher in situ high-resolution stratigraphic records of allochthonous sand sheets that are used to document different kinds of sedimentological and geomorphological characteristics of high-energy inundation, such as abrupt increases in grain size, integration of muddy rip-up clasts and fining upward sequences which are representative of different tsunami inundation pulses. These investigations were completed by sediment coring as a base for local calibration of geophysical direct push parameters. Surface-based electrical resistivity tomography and seismic data with highly resolved vertical direct push datasets and sediment core data were all coupled in order to improve the quality of the geophysical models. Details of this methodological approach, new in palaeotsunami research, are presented and discussed, especially with respect to the question how the obtained results may help to facilitate tracing tsunami signatures in the sedimentary record and deciphering geomorphological characteristics of past tsunami inundation. Using direct push techniques and based on sedimentary data, sedimentary signatures of two young tsunami impacts that hit the Kaiafa Lagoon were detected. Radiocarbon age control allowed the identification of these tsunami layers as candidates for the AD 551 and AD 1303 earthquake and tsunami events. For these events, there is reliable historical data on major damage on infrastructure in western Greece and on the Peloponnese. At the former Mouria Lagoon, corroborating tsunami traces were found; however, in this case it is difficult to decide whether these signatures were caused by the AD 551 or the AD 1303 event.

Abstract

Tsunami deposits are important archives for understanding tsunami histories and dynamics. While most research has focused on onshore preserved remains, offshore deposits have received less attention, although may offer a higher potential in terms of preservation and spatial coverage.

In 2009, during a coring campaign with the Italian Navy *Magnaghi*, four 1 m long gravity cores (MG cores) were sampled from the northern part of Augusta Bay, along a transect in 60 -110 m water depth, in the same area where a core (MS06) was collected in 2007, about 2.3 km offshore Augusta at a water depth of 72 m (Smedile et al., 2011). Core MS06 consisted of a 6.7 m long sequence that included 12 anomalous intervals interpreted as the primary effect of tsunami backwash waves in the last 4500 years. In this study (Smedile et al., 2019), tsunami deposits were identified, based on sedimentology and displaced benthic foraminifera (as for core MS06) reinforced by ITRAX X-ray fluorescence (XRF) data. Two erosional surfaces (L1 and L2) were recognized coupled with grain size increase, abundant *Posidonia oceanica* seagrass remains and a significant amount of *Nubecularia lucifuga*, an epiphytic sessile benthic foraminifera considered to be transported from the inner shelf. Relative maxima of Ti/Ca and Ti/Sr, coinciding with peaks in organic content (Mo inc/coh) suggest terrestrial run-off. Units L1 and L2 were attributed to two distinct historical tsunamis (AD 1542 and AD 1693) by indirect age-estimation methods using ²¹⁰Pb profiles and the comparison of Volume Magnetic Susceptibility data between MG and MS06 cores. One most recent bioturbated horizon (Bh), despite not matching the above listed interpretative features, recorded an important palaeoenvironmental change that might correspond to the AD 1908 tsunami.

Amongst all the techniques applied, sedimentology and micropalaeontology (displaced benthic foraminifera) remained the most informative, corroborated by the XRF results. Comparison of multiple cores collected at different depths along the shelf provided important insights about the dynamics of tsunami backwash and its imprint in the offshore stratigraphic sequence not easily gained from a single core. This work adds to previous studies in highlighting the growing potential of offshore investigations for reconstructing the palaeotsunami record of critical relevance to test tsunami hazard models and scenarios.

Tsunamis and tsunami deposits along the eastern margin of the Japan Sea

Atsushi Urabe¹, Yasuhiro Takashimizu¹, Gentaro Kawakami², Kenji Nishina², Yoshihiro Kase², Kyoko Kataoka S.¹
¹Niigata University, Niigata, Japan, ²Geological Survey of Hokkaido, Sapporo, Japan

Abstract

The research of tsunami deposits along the eastern margin of the Japan Sea region have been increasing after the 2011 off the Pacific coast of Tohoku Earthquake and tsunami. The distribution of the several wave source fault of the tsunami in the Sea of Japan are clarified, but the activity history of each fault is unclear. An investigation into tsunami sediment in each area is important to elucidate a tsunami history. The aim of this review is to enhance this record based on tsunami deposits reported from coastal area of Hokkaido to Toyama, northeast Japan, and draws their characteristics and spatio-temporal distribution. Most of the tsunami deposits were recognized in peaty and marshy deposits distributed at swales of coastal dunes, flood plains, and small valley plains. On the other hand, some gravelly deposits of possible tsunami origin were recognized on top of low marine terraces and slope-talus. Large number of tsunami sand layers were also identified in lagoonal deposits at Sado Island, Niigata and Okushiri Island, southwestern Hokkaido.

Although several historical tsunamis of the 19–18th centuries are known in this region, there are few localities of tsunami deposits correlatable to such records. On the other hand, tsunami deposits indicate four tsunami events during 15–9th centuries despite of the insufficient historical record of tsunamis older than the 18th centuries. The distribution of deposits of these four events are as follows: 14th century, Aomori to northern Yamagata; 12th century, southwestern Hokkaido; 11th century Sado (Niigata) to southern Yamagata; 9th century, Yamagata to Aomori. These events are also well recorded in deep-sea Japan Basin as seismo-turbidites. Most of the tsunami deposits older than 9th century have been identified only in remote islands, Okushiri, Tobishima, Sado and several coastal lagoon. This review will be useful for future studies to clarify images of paleo-tsunami events along the eastern margin of the Japan Sea.

Identification and characterization of tsunami deposits based on historical documents and field data in the peri-alpine Lake Lucerne, Switzerland

Valentin Nigg¹, Stéphanie Girardclos², Katrina Kremer³, Flavio Anselmetti¹

¹Institute of Geological Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ²Department of Earth Sciences and Institute for Environmental Sciences, University of Geneva, Geneva, Switzerland, ³Swiss Seismological Service, ETH Zürich, Zürich, Switzerland

Abstract

Historical documents report that fjord-like, perialpine Lake Lucerne in Central Switzerland hosted two devastating tsunamis in the 17th century, which both were caused by subaquatic mass movements. The chronicle of the local city clerk describes a tsunami in Lake Lucerne in the year 1601 after a strong magnitude 5.9 earthquake nearby that caused several casualties. Alluvial plains surrounding the lake were flooded by half a kilometre from the shore, with run-up heights of up to 4 m. Additionally, it is stated that the lake outlet, the river Reuss, dried up and flooded repeatedly within the first hours after the earthquake, an oscillating movement that lasted for several days with a declining amplitude. On the basis of this chronicle and another documented tsunami event in the year 1687, caused by a spontaneous delta collapse, with similar run-up heights, several limnogeological studies have been conducted on Lake Lucerne during the last decades using the lake as analogue model for marine mass-movement processes and slide-induced tsunami phenomena. These studies documented that several episodes of sublacustrine mass-movements occurred during the last 15'000 years in Lake Lucerne, with some of them exceeding the volumes of the 1601 event. These findings led to the hypothesis of repetitive occurrence of tsunami events in Lake Lucerne during the post-glacial epoch.

This study focuses on the characterization and identification of tsunami deposits in a lacustrine setting based on historical documents and field work. At the lake shore prone to be inundated during a tsunami event, sediment cores were recovered in mostly shore-perpendicular transects. On the basis of the recovered sediment cores, we identify sedimentary signatures related to the tsunami processes using petrophysical sediment analysis encompassing density, magnetic, X-ray imaging scans, lithological analysis as well as geochemical element measurements using an ITRAX XRF core-scanner. Results indicate that the concepts to identify marine tsunami deposits need to be modified to a certain degree in order to be applicable in lacustrine settings. Despite the challenging recovery of these very heterogeneous sedimentary successions, the artificial shoreline changes, and the limited sediment-availability in the foreshore area, several candidates for potential tsunami deposit have been observed and were lithologically characterized. Radiocarbon dating will relate these detrital deposits in organic-rich background sediments to known and unknown tsunami events, thus completing the tsunami event catalogue for an area with a currently densely populated and vulnerable lake shores.

Use of passive remote sensing to assess cyclone impacts on coastal features to aid understanding of the submerged archaeological record.

Peter Ross¹, Ingrid Ward², Stephen Sagar³, Robbi Bishop-Taylor³, Piers Larcombe⁴

¹Flinders University, Adelaide, Australia, ²University of Western Australia, Perth, Australia, ³Geoscience Australia, Canberra, Australia, ⁴RPS Metocean, Perth, Australia

Abstract

In looking at the potential for preservation of submerged prehistoric cultural sites over millennial timescales, it is important to also factor in episodic and short-term change over decadal and possibly annual timescales. In NW Australia one of the key drivers of marine and coastal geomorphological change is cyclones (Larcombe et al. 2018). This study explores the use of historical aerial photos and time-series satellite imagery to help identify 1) cyclone-specific coastal change, 2) abrupt and longer-term geomorphological change from other physical drivers, and 3) archaeological feature assessment, shell mounds specifically. Comparison can be made visually but also empirically using changes in surface reflectance revealed by the high spectral resolution of earth observation satellites (e.g. Figure 1). Initial results in the Dampier Archipelago region indicate an overall strong resilience in the majority of shell mounds over decadal timescales in what is arguably already a largely eroded environment. However, there is evidence for significant coastal change at discrete and localised scales. These regional and local-scale differences relate in part to the frequency and associated effects of cyclones (e.g. near-shore coastal and bathymetric features (e.g. mangroves, reefs, etc.) and the nature of the archaeological sites themselves (e.g. location, morphology, etc.). By combining our understanding of current archaeological sites with past coastal morphology and processes, we can better predict the locality and likely preservation potential of submerged cultural sites in this region and ultimately test these predictions using ground-truthing.

Tsunami threats facing Fiji's capital city (Suva) from submarine landslides, as reassessed from Holocene and recent reef-boulder deposits

A.Y. Annie Lau¹, James Terry², Alan Ziegler³, Arti Pratap⁴, Daniel Harris¹

¹School of Earth and Environmental Sciences, The University of Queensland, Brisbane, Australia, ²Department of Environmental Sciences, Zayed University, Dubai, UAE, ³Department of Geography, National University of Singapore, Singapore, Singapore, ⁴School of Geography, Earth Sciences and Environment, University of the South Pacific, Suva, Fiji

Abstract

Wave transported coastal boulders are one of the proxies that improve our understanding of cyclones and tsunami hazards for predicting future hazard impacts. While many boulder fields formed in modern storm and tsunami events have been analysed in detail for providing analogues for interpreting earlier counterparts, there remains a lack of research on boulders results from landslide tsunamis. Here we present the characteristics of a reef-top boulder field created by a local submarine landslide tsunami (the 1953 Suva tsunami) for the first time. Our examination of large reef-derived boulders near Suva City, Fiji, revealed that the 1953 tsunami flow velocity was over 9 m/s at the reef edge. While prior research has demonstrated the head-ward retreat of Suva Canyon in response to the repeated occurrence of earthquakes in the past, our results suggest the lingering vulnerability of this Fijian coastline to high-energy waves generated both in the presence (tsunami) and absence (storm) of submarine failures and/or earthquakes as subsequent storms appear to have remobilised some boulders. The boulder distribution confirms that the shorter-period-than-normal tsunami waves generated by submarine landslides would create a boulder field resembling typical storm boulder fields due to relatively short transport distances. This boulder field can be used as a reference set in identifying possible prehistorical local submarine landslide tsunami occurrences elsewhere and it will be particularly useful for tropical Pacific island coasts where submarine slope failures are relatively common and past hazards are not well documented.

Selective representation of sediment sources in tsunami deposits from the Shetland Islands (UK)

Max Engel^{1,2}, Tasnim Patel¹, Sue Dawson³, Anna Pint², Philipp Kempf¹, Pedro Costa⁴, Isabelle Schön¹, Vanessa Heyvaert^{1,5}

¹Royal Belgian Institute of Natural Sciences, Brussels, Belgium, ²University of Cologne, Cologne, Germany, ³University of Dundee, Dundee, United Kingdom, ⁴University of Lisbon, Lisbon, Portugal, ⁵Ghent University, Ghent, Belgium

Abstract

Tsunami deposits provide information on inundation hazard and recurrence patterns. Their composition is mainly a function of the site-specific coastal sediment system and the tsunami's physical characteristics. However, tsunami deposits often have a low preservation potential and experience significant post-depositional changes, the magnitude of which is poorly understood and mostly depending on the complex geographic setting. Here, we compare a tsunami sand dated to c. 1500 yrs BP (Bondevik et al., 2005) from the Shetland Islands (UK) with its local sediment source (intertidal, shallow subtidal) and discuss possible reasons for the discrepancies noted. Inside the fjord of Dury Voe, the tsunami deposit is exposed in coastal peat sections. It has a thickness of 3–5 cm at the shore and was traced for c. 400 m inland, where it becomes discontinuous and reduces its thickness to <2 cm. Seven sections of the tsunami deposit were sampled using short push cores. Twelve modern surface samples were taken in the bay from the local intertidal area down to a water depth of 42.5 m. Samples were subjected to grain size and foraminiferal analyses; XRD and geochemical analyses are in progress. First results indicate large discrepancies between the composition of the tsunami sand and the local shallow subtidal and intertidal sediment source, which can be assumed to have not changed notably over the last 1500 years due to a quasi-stable sea level (Bondevik et al., 2005). The modern samples are very poorly (very shallow subtidal) to poorly (intertidal) and moderately (deeper subtidal) sorted. Siliciclastic sands dominate, accompanied by mud and shell debris in the subtidal. Foraminiferal concentrations range from low/moderate (intertidal) to high (subtidal), while diversity ranges from two taxa in the intertidal (*Miliammina fusca*, *Elphidium williamsoni*) to almost 60 in the deepest samples (dominated by *Cibicides lobatulus*, *Egerella scabra*). The tsunami deposit, however, is restricted to fine and medium sand, while mud and any foraminifera or other skeletal grains are absent. Differences in grain size can be explained by hydraulic sorting of the heterogeneous source sediment, which is also evident from landward fining (Bondevik et al., 2005). The absence of foraminifera is likely related to chemical dissolution in the acidic environment created by the blanket peat bog, while any sedimentary structures associated with tsunami deposition may have been removed by intense post-depositional bioturbation. Thus, it has to be considered that tsunami deposits may only represent specific sediment fractions from the source area as a function of (i) hydraulics of tsunami inundation and (ii) selective resistivity towards post-depositional degradation.

Bondevik, S., Mangerud, J., Dawson, S., Dawson, A., Lohne, Ø., 2005. Evidence for three North Sea tsunamis at the Shetland Islands between 8000 and 1500 years ago. *Quat. Sci. Rev.* 24, 1757–1775.

P-3046

A multi-proxy approach to examine terrestrial and aquatic environmental change resulting from palaeo-hurricane events.

Emma V. A. Readitt, Joanne Egan, Claire Jones, Cherith Moses
Edge Hill University, Ormskirk, Lancashire, United Kingdom

Abstract

Hurricanes are one of the most hazardous natural events to occur regularly around the world and it is suggested that these large scale weather events are set to increase due to global warming and climate change. As official hurricane records date only as far back as the 1850's, a further palaeo-record is required to analyse the frequency and intensity of hurricanes. Palaeotempestology is the study of hurricane events during the Holocene by a multitude of geological proxies. Using a multi-proxy approach, this study analyses Holocene hurricane frequency and intensity, and assesses environmental change caused by these large scale events at Gulf Shores, Alabama, USA.

A 6 m lake core (MLC1) was collected in May 2018 from Middle Lake, Alabama. Evidence of hurricane events are represented by sand layers in lake and marsh sediment cores, where beach debris has been transported inland by storm surges and wind. Initially, the core was visually inspected for these sand layers. Following visual inspection, the core was processed through an ITRAX for elemental analysis. ITRAX XRF data is presented with specific ratios such as Si/Ti, K/Ti and Ca/Si.

Organic matter content (LOI) and particle size has been calculated for MLC1 at 1 cm resolution. MLC1 shows a decline in organic matter content and an increase in particle size at visible sand layers. Two large sand layers identified between 199- 211 cm, suggest large scale hurricane events.

Preliminary results from diatom and pollen analysis will be presented. Diatoms are excellent indicators of environmental change due to their sensitivity to features such as temperature and salinity. However, because the field of palaeotempestology is still developing, there are minimal studies that use diatoms to infer environmental change resulting from hurricanes. This study examines the aquatic environmental change as a result of hurricane events inferring from diatoms analysis. Furthermore, pollen analysis is used to assess the terrestrial impacts associated with hurricane events, examining the change in vegetation and/or the recovery time for species to reach pre-event conditions.

Identification of hurricane frequency and intensity as well as the environmental impacts (both terrestrial and aquatic) in palaeo records are essential to understanding hurricanes today. These data also has the potential to be fed into future climate forecast models.

P-3047

The off-shore Lisbon 1755 tsunami sediments

Klaus Reicherter¹, Pedro Costa², RV Meteor M 152 cruise team^{3,4,5}

¹Neotectonics and Natural Hazard, RWTH Aachen University, Aachen, Germany, ²Instituto Dom Luiz, Departamento de Geologia, Faculdade de Ciências da Universidade de Lisboa, Lisbon, Portugal, ³RWTH Aachen University, Aachen, Germany, ⁴Univ. Bremen, Bremen, Germany, ⁵Univ. Mainz, Mainz, Germany

Abstract

The RV Meteor M152 expedition mapped and sampled two transects perpendicular to the south coast of the Algarve, off Portugal, in water depths from 60 to 800 meters. The special focus was on the areas to the east of Portimão and the west of Sagres/Martinhal transects, close to the famous Martinhal, Boca do Rio and Salgados AD 1755 onshore sedimentary imprints. This part of the coast was heavily affected by tsunami inundation exactly 263 years ago on All Saints Day 1755 following a strong earthquake offshore. Shortly after the earthquake a tsunami hit the coastlines. It was one of the most consequential and impressive natural hazards ever reported destroying the Portuguese capital and many villages were destroyed, Faro was sheltered by sandbanks, whereas in Lagos the waves overtopped the city walls.

Deposits of the Lisbon 1755 tsunami have been well studied along the southern Portuguese coast, but the impact of backwash, the retreating flood into the sea has not been well understood and studied. To date, very scarce information on backwash deposits is available from other areas, so this is unknown terrain, especially in these water depths.

We focus on the following scientific questions: Do we find variations in thickness and sediment composition, distribution and preservation of the tsunami layer? What effects on benthic life after tsunami deposition can be observed? Can we develop a tool for the identification of historic and prehistoric tsunami deposits on the inner shelf? Can we detect predecessor events along the Algarve coast, and obtain information about timing, frequency and magnitude of these natural hazards thus extending the time-window of observation?

We collected pre- and post-tsunami deposits (the background sedimentation) along the transects for comparison, e.g. of the benthic life and its resilience. Other proxies such as geochemistry and physical properties are analyzed as well. Radiocarbon and OSL dating methods are used for establishing a geochronological framework and to estimate ages of preceding events identified macroscopically in the sediment cores. Overall, the lithostratigraphic column can be characterized as a silty-dominated sequence, likely reaching the Younger Dryas. More importantly, we detected a gravelly high-energy layer at a depth of approx. 16-25 cm depth in many cores, characterized by an erosive base, shell debris and well-rounded extra-clasts of fluvial origin. A surprising finding was a second medium to coarse sand layer at depths of around 150-180 cm with clear indications of a high-energy depositional environment (e.g. sharp erosional base, mineralogical diversified composition, macrofossil diversity, etc.). Both of the layers are found within cores of the two transects; they are preliminarily interpreted as two events, the upper is regarded as deposits of the 1755 event, whereas the lower dates younger than 4000 yrs BP.

Extreme ocean waves events reconstructed from a stalagmite in the coastal zone of central Chile

Juan Luis Bernal Wormull^{1,2}, Ana Moreno¹, Isabel Cacho³, Jaime Frigola³, Mercè Cisneros³, Marcelo Solari^{4,5}, Francisco Hervé^{5,6}, Fernando Poblete⁷

¹Pyrenean Institute of Ecology-CSIC, Zaragoza, Spain, ²Earth Sciences Department, University of Zaragoza, Zaragoza, Spain, ³CRG Marine Geosciences, Faculty of Geology, University of Barcelona, Barcelona, Spain, ⁴Amphos 21 Consulting Chile Ltda., Santiago, Chile, ⁵Geology Career, Engineering Faculty, Andrés Bello University, Santiago, Chile, ⁶Geology Department, University of Chile, Santiago, Chile, ⁷Institute of Engineering Sciences, University of O'higgins, Rancagua, Chile

Abstract

Changes in climatic conditions or seismic events can lead to the generation of extreme sea waves directly affecting coastal areas. This study explores the use of stalagmites to record extreme coastal conditions with the aim to better understand these events and their periodicity. This work applies a multi-proxy study on a speleothem from a coastal cave developed in schists under a Miocene marine terrace in Central Chile, a very unusual context. An innovative approach is applied combining macro and microscopic visual properties (thin slides), geochemical analysis (through high resolution non-destructive and destructive methods), U/Th dating and optical color/reflectivity properties.

The results of this work show continuous growth of a speleothem between 450 year Before Common Era and 650 year Common Era constrained by 11 U/Th dates. Along the stalagmite, the frequent dark laminas identified by their reflectivity and the concentration in Fe are associated to detrital material incorporated during extreme flood events into the cavern (tsunamis or large storms). Apart from these dark layers, the stalagmite is divided into several domains with a different geochemical composition. The highest values of Sr are found along the darkest sections of the stalagmite, probably indicating drier conditions, while Mg values are associated to sea spray. Preliminary results from frequency analyses on color and reflectivity data point to solar forcing as a likely mechanism to account for the observed variations.

This work concludes that stalagmites from coastal caves have the potential to record the paleo-evolution of extreme ocean waves and, once the calibration of such events against the instrumental record is carried out, will surely be of great interest for policies on coastal management.

Boulder transport along the coast of Eastern Samar (Philippines) – Implications for Holocene extreme-wave events

Fabian Boes^{1,2}, Max Engel^{1,3}, Rodrigo C. Eco⁴, Jam A. Galang⁵, Lia A. Gonzalo⁶, Francesca Llanes⁶, Eva Quix¹, Andrea Schröder-Ritzrau⁷, Helmut Brückner¹

¹Institute of Geography, University of Cologne, Cologne, Germany, ²ARC Centre of Excellence for Australian Biodiversity and Heritage (CABAH), School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia, ³Geological Survey of Belgium, OD Earth and History of Life, Royal Belgian Institute of Natural Sciences, Brussels, Belgium, ⁴National Institute of Geological Sciences, University of the Philippines Diliman, Quezon City, Philippines, ⁵Geosciences Division, Mines and Geosciences Bureau – MIMAROPA Regional Office, Manila, Philippines, ⁶NOAH Center, University of the Philippines Diliman, Quezon City, Philippines, ⁷Institute of Environmental Physics, Heidelberg University, Heidelberg, Germany

Abstract

The Eastern Visayas region in the Philippines is significantly exposed to high-energy marine inundation events. It gets regularly hit by some of the strongest tropical cyclones on Earth, recently by Typhoon Haiyan (2013) or Typhoon Hagupit (2014), causing extreme waves at the coastline. The region is also closely located to the Philippine Trench and experienced several tsunamis in the historical past, therefore flooding through extreme-wave events represents a strong hazard to the coastal population.

As there is not much known about frequency-magnitude relationships or maximum magnitudes of coastal flooding events over larger timescales, geological archives such as subaerial boulder deposits can derive information on occurrence patterns of extreme-wave events over centennial to millennial scale. To understand the mechanisms of boulder transport and the underlying extreme-wave events, we study a large boulder field in San Policarpo, Eastern Samar. A multi-temporal analysis of satellite images is conducted to quantify recent boulder movement during the typhoons Haiyan and Hagupit. In a systematic geomorphic mapping campaign, we recorded location, size, shape, morphological features and also lengths and orientation of the main axes of 269 boulder with a-axes between 1.5 m and 10.7 m to estimate spatial extent, height, velocity and direction of flow during extreme-wave events. The boulder field was also mapped by an unmanned aerial vehicle (UAV) to create structure-from-motion (SfM) models to improve inverse modelling of transport flows of recent and past events. A poorly developed exponential fining landward of the clasts and their landward distribution way beyond the limit proposed for storm boulders in literature suggest the occurrence of very strong events such as tsunamis or infra-gravity waves in the past. The latter were associated with Typhoon Haiyan elsewhere in Eastern Samar and locally shifted some of the largest boulders ever documented for storms. In order to date possible events, samples of post-depositional, secondary calcite flowstones and pre-depositional coral were taken for U-Th and ¹⁴C dating.

Can sediment source signals be used to reconstruct paleotsunami?

Hui Tang^{1,2}, Robert Weiss³

¹University of Arizona, Tucson, USA, ²GFZ German Research Centre for Geosciences, Potsdam, Germany, ³Virginia Tech, Blacksburg, USA

Abstract

Tsunami deposit can be eroded and transported from both marine and terrestrial environment. An interesting question will be how sediment source information can be applied to reconstruct paleotsunami events or assess tsunami hazard. In this contribution, we employ a state-of-the-art tsunami sediment transport model, GeoClaw-STIRCHE, to carry a parameter study. In this parameter study, we change the onshore slope, the initial wave amplitude, and the grain size in the sediment source to study the marine-terrestrial signals in the tsunami deposit. We define the normalized location where the marine sediment becomes easily recognizable (> 5%) to characterize the distribution of the marine sediments. Meanwhile, the normalized location can be used as a quantitative tool to estimate maximum inundation from the spatial distribution of tsunami deposits. Based on the parameter study, both the initial wave amplitude and the grain size in the sediment source significantly influence the percentage of marine sediment in the tsunami deposit. Our method successfully estimates the offshore wave amplitudes for the 2010 Chile tsunami in Las Cañas area. Based on the data from Goff et al., 2015 and our parameter study, the normalized wave amplitude ranges from 0.03 to 0.04, which is consistent with simulation results from GeoClaw.

P-3051

Spatial distributions of the 2011 Tohoku-oki tsunami deposits, Odaka area, Fukushima, Japan

Yasuhiro Takashimizu, [Atsushi Urabe](#)
Niigata University, Niigata, Japan

Abstract

Spatial distributions of the 2011 Tohoku-oki tsunami deposits, Odaka area, Fukushima, Japan was reconstructed based on a field survey, facies descriptions, bed thickness, magnetic susceptibility, anisotropy of magnetic susceptibility (magnetic fabric), grain size distribution, and topographical data. The behavior of the tsunami reconstructed in this study was summarized as follows;

- (1) In the Odaka area, two tsunamis struck from the northeast and east. The water collided with the embankments of the prefectural road 260 and the Odaka River, and joined at the western part of the area. The head part of the tsunami eroded the soil in the rice paddy fields and the eroded mud clasts were taken in by the tsunami waters. As a result of this, the mud content increased in the fluid inland.
- (2) The integrated tsunami inflow at western part changed direction and started to outflow toward the northeastern mouth of the river. This outflow caused accumulation of the muddy fraction along the embankments, and resulted in lower mud content in the fluid toward the downstream area.
- (3) In the northern part of the area, tsunami deposits included abundant coarse materials with artificial tsunami debris derived from the residential area located toward the east of the study area.

Micromorphological analysis on the Storegga and the AD 1755 tsunami deposits: compositional determination and definition of inundation phases

Pedro José Miranda Costa¹, César Andrade¹, Sue Dawson²

¹Instituto Dom Luiz, Departamento de Geologia, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal,

²Geography & Environmental Science School of Social Sciences, University of Dundee, Dundee, United Kingdom

Abstract

In this work preliminary data based in high-resolution micromorphological observations of sandy tsunami deposits of the AD 1755 tsunami and the Storegga tsunami deposit are presented. Through an analysis of the vertical compositional variations it is possible to attempt to recognize different phases, synchronous with the inundation, and its associated sedimentological signature.

At Boca do Rio (Portugal), the sandy deposit associated with the tsunami has been found to consist of quartz, feldspars, micas, pyroxenes, amphiboles, plant fragments, shell fragments and mud balls. Samples taken from the tsunami deposit show an overwhelming prevalence of quartz, plant fragments and feldspars ($\pm 90\%$ of the sample).

In the Boca do Rio tsunami deposit, it was possible to identify 3 inundation phases and correlate them with the synchronous event that affected near-by Salgados and its 3 major inundation phases (established using textural and geochemical data). The initial phase presents the wider compositional diversity (reflecting several sedimentary environments crossed by the tsunami waves). In contrast, the second phase exhibits a quartz dominance which translates a narrower (coastal) source area. Finally, phase three presents more micas which reflect the waning of tsunami inundation. We interpreted the initial phase comprising a strong erosive component on the dune, which leads to a dissipation of transport competence into the alluvial plain, leading to lower expression (thickness) in the geological record. The second phase, with thicker depositional signature, is characterized by lower compositional richness. Such stratigraphic expression is a result of the partial removal of the dune, facilitating the sediment transport competence, extension and duration of the inundation. Finally, in the third phase there is less sediment available and less energy capacity. In this final phase synchronous with the tsunami inundation, it is possible to observe an increase in the proportion of micas corresponding to a period of greater calming and slower flow velocity.

Investigation of the Storegga deposit reveal that the tsunami unit is mainly composed of quartz, micas, plant fragments and amphiboles. In terms of inundation phases, only two were identified. An initial one presenting larger compositional diversity and higher concentration of sediments (arrangement/packing), while the other phases seem to be a return to pre-event conditions (recovery phase) and is characterized by the large presence of micas, poor packing and lack of rip-up clasts.

This ongoing innovative study contributes to a greater understanding of the tsunami-related hydro-morphodynamic processes and offers the potential to better define inundation phases in historical and pre-historical tsunami events.

Abstract

The Portuguese coastline was severely struck by the AD 1755 Lisbon tsunami, which has been documented in many historical accounts and confirmed by geological evidence at numerous sites. But had there been a preceding event? To date, the focus has always been on the deposits of the Lisbon tsunami. The same holds true for our research at the well-studied site of Boca do Rio, a N-S oriented flood plain at the western Algarve, Portugal, with a well-preserved sedimentary record of the AD 1755 Lisbon tsunami. Two transects, one parallel, the other perpendicular to the coastline were studied, comprising 7 sediment cores with depths up to 4.5 m. All of them clearly show tsunami deposits originating from the AD 1755 event that had effected the coasts of the southern Iberian Peninsula, including those of the Gulf of Cádiz and the Algarve. In one core, however, a distinct second event layer was found about 30 cm below the known tsunamite. This layer, which had never been described before, and the AD 1755 tsunamite were analysed in a multi-proxy approach, including granulometry, micropalaeontology, and geochemistry. As for the chronology the ¹⁴C and OSL dating techniques were applied. Based on a synopsis of the results and the calculated age estimate (1004 ± 26 cal BP, AD 985-1148; ¹⁴C), the lower event layer may preliminarily be classified as a storm deposit (tempestite), since it roughly fits to a period of increased storminess during the 4th – 8th centuries (Dark Ages Cold Period). However, the interpretation as a potential predecessor of the AD 1755 tsunami cannot be excluded as yet, based on the location of the deposit (too far inland for a storm), and the contained deep water foraminifera. Additional studies, e.g., mapping the event layer's onshore distribution and comparing it with the offshore record (cf. Reicherter et al.'s talk about the METEOR 152 research cruise) need to be conducted to make a final decision about the deposit's origin.

Organic geochemical signature of deposits by the 2011 Tohoku-oki tsunami (Northern Japan)

Piero Bellanova^{1,2}, Mike Frenken^{1,2}, Jan Schwarzbauer², Yuichi Nishimura³, Klaus Reicherter¹

Abstract

The 2011 Tohoku-oki tsunami caused massive damages along the coastal areas of the main island of Japan. The tsunami, triggered by the 9.1 M_w Tohoku-oki earthquake, overtopped the coastal defense wall with waves of 6-10 m height along the shores of the Aomori Prefecture in Northern Japan. The interaction of tsunami and earthquake caused devastating damages, leading to the release of pollutants in the nearfield environment, and the deposition of tsunami-derived sand up to 550 m inland. The released pollutants associated as biological and anthropogenic markers give the tsunami deposit an unique geochemical signature, that is detectable and distinguishable from sediments deposited prior and following the 2011 tsunami. Along with the sedimentary record of the tsunami, the use of organic geochemical indicators can provide a better understanding of the extend and processes, such as the backwash, of the inundation by the 2011 Tohoku-oki tsunami.

At the field sites, a small fishing port and an industrial park, well-preserved, sandy tsunami deposits present a thickness of up to 18 cm with sedimentary features, such as fining upward sequences, mud caps and rip-up clasts. Further, observation show that the coastal forest stopped indicators of an inundation such as barrels, which were deposited in backwash position. Based on the release of pollutants, due to the destruction of the industrial park, and the deposition of barrels with possible leakage, these sediments are suited for organic geochemical analysis. Preliminary results show a strong increase of anthropogenic (i.e., PAHs, pesticides) and a variation of biological markers (i.e., fatty acids, ketones) close to the industrial park and the small harbor. The release of pollutants can be helpful to identify "invisible" tsunami layers, as the tsunami eroded the upper soil (composed of peat, wood and plants). These eroded materials float on top of the inundating water and deposited beyond the limit of visible tsunami deposits.

At a distance of 300-350 m from the shoreline a thin organic- and peat-rich layer starts to emerge on top of the tsunami sand, which thickens inland as the sand thins out. This layer is interpreted as the continuation of the tsunami deposit beyond the point of coarse sediment transport. This is supported by a tsunami-transported plastic particle that was deposited within this peaty, "invisible" tsunami layer.

The record of tsunamis on arid coasts: examples from the southern Atacama Desert (Chile)

Manuel Abad¹, Tatiana Izquierdo¹, Joaquín Rodríguez-Vidal², Francisco Ruiz²

¹Universidad de Atacama, Copiapó, Chile, ²Universidad de Huelva, Huelva, Spain

Abstract

Studies focused on identifying, dating and describing tsunami deposits in the geological record during the Late Holocene are very scarce on arid coasts. Their low preservation potential in this context partially justifies this circumstance because they can be reworked by winds or eroded by flash-floods. In addition, the absence along this type of coast of environmental settings that favour their preservation in the sedimentary record, such as coastal wetlands or lagoons, hinders the identification and study of these sandy deposits. Coarser deposits (like boulders) have a higher preservation potential as they are less likely to be transported after the event. Consequently, the hyperarid and active tsunamigenic coast of the Atacama Desert can be considered a suitable area for the study of so far undescribed coarse clast record of palaeotsunamis. The southern Atacama Desert coast (26° - 27°) is characterized by the presence of rocky cliffs of variable height that are interrupted by fluvial mouths and small bays with sandy beaches. In this context, the appearance of boulder fields at heights that vary between +2.5 and +20 m a.s.l. constitute the most probable record of recent tsunamigenic events with epicentres near the Atacama coasts. Two types of record can be differentiated: 1) cliff-top boulder deposits; and 2) isolated boulders and boulder fields in beaches and littoral plains. This different record can be explained by means of the height wave, the coarse-grain sediment availability and the geomorphologic configuration of the coast. In this way, tsunamis with wave heights lower than the cliffs or those that impact low gradient beaches have generated extensive boulder fields in the intertidal and supratidal zones, between -0.5 m to +9 m a.s.l. In other cases, large, several tens of cubic meters, isolated fragments of low-lying cliffs formed in marine terraces have been eroded and mobilized towards the sea. Most likely these examples record the effects of the 1922 Atacama tsunami, which reached wave heights up to 9 and 6 m in the cities of Chañaral and Caldera, respectively. On the other hand, isolated boulders and boulder fields appear between +10 m and +20 m forming classic examples of cliff-top deposits. These deposits, eroded from the cliff edge of the marine terraces and transported tens of meters inland, record large tsunami waves of more than 20 m in height and have been associated with a major tsunamigenic event that occurred at the beginning of the 15th century. The correct identification and dating of these tsunami coarse-grained deposits is the most effective tool to develop a catalogue of Late Holocene tsunamis on the hyperarid and steep coasts of the southern Atacama Desert.

Ground-penetrating radar (GPR) investigation of Storegga slide tsunami deposits

Lucy Buck, Charlie Bristow

Birkbeck, University of London, London, United Kingdom

Abstract

Ground-penetrating radar (GPR) is a portable geophysical survey system that provides almost continuous images of the shallow subsurface. Reflections on GPR profiles are produced by changes in the dielectric properties of the soil which are largely controlled by the electromagnetic properties of the materials and the water content. In the Shetland Islands the tsunamigenic sand layers are commonly overlain by, and sometimes interbedded with, peat. Peat has a velocity of around 0.035mns^{-1} (Comas et al., 2005, Kettridge et al., 2008, Proulx-McInnes et al., 2013.), while sand layers saturated with fresh water typically have velocities of $0.09\text{-}0.13\text{ mns}^{-1}$ (Baker et al., 2007), although they are typically around $0.055\text{-}0.06\text{ mns}^{-1}$ (Reynolds 1997).

The mean dielectric constant for peat is 63ϵ (Parry et al., 2014) and between 25 and 30ϵ for wet sand (Reynolds, 1997). It is the dielectric constant that is used to differ between materials in the gprMax modelling program. Modelling can be used to predict how the response from the peat layers will differ from that of the sand and therefore predict the potential response from the GPR system will be.

We have used a Pulse Ekko GPR system with a range of antennas to image the deposits of the Storegga slide tsunami deposits on the East coast of Scotland and on the Shetland Islands. The results of the GPR surveys are shown here and compared with the predictions from modelling.

Emergent Sea-Level Indicators, Coastal Boulders, and Washover Deposits as Evidence of Coastal Tectonics and Extreme Wave Events in the Philippines

Noelynna Ramos¹, Kathrine Maxwell¹, Sheinna May Claro¹, Alec Benjamin Ramirez¹, Edrian Tubalado^{1,2}, Ace Matthew Cantillep¹, Hiroyuki Tsutsumi³, Chuan-Chou Shen⁴, Daisuke Ishimura⁵, Kenji Satake⁶

Abstract

As we recognize the Philippine archipelago as a tectonically active region surrounded by subduction zones and a country frequented by strong typhoons yearly, coastal communities remain at risk, hence an improved understanding of coastal hazards and their impacts is essential. Over the past years, we have been studying geological and geomorphological features to understand how tectonic processes and their accompanying hazards may affect Philippine coastlines and coastal communities. Along the coasts of Luzon, Cebu, and Mindanao islands facing subduction zones (e.g., Manila Trench, Philippine Trench) or other potentially active offshore upper plate faults, emergent coral reef terraces and their implications for long-term tectonic deformation and prehistoric relative sea level changes were studied. Coseismic uplift of the coast following major earthquakes in central Philippines in 2012 (Mb6.9 Negros earthquake) and 2013 (Mw7.2 Bohol earthquake) further demonstrated one of the possible mechanisms in the emergence of sea level indicators. We have also investigated the origin and emplacement of moderate to large coastal boulders atop emergent coral reef platforms along the coasts of northwest Luzon. Initial hydrodynamic calculations and numerical modeling infer the occurrence of a prehistoric extreme wave event which affected the eastern South China Sea region. We also studied the coastal areas in Zamboanga del Sur to understand and characterize washover sediments from tsunamis as a number of tsunamigenic earthquakes have occurred along the Cotabato Trench. All these geologic and geomorphic data are significant in refining fault rupture models and hazard scenarios, while also important in constraining long-term deformation and relative sea level changes in this tectonically active block of the Southeast Asian region.

Tsunami boulder transport simulated in a numerical two-phase mass flow model and flume experiments – a combined approach

Jan Oetjen¹, Max Engel^{2,3}, Holger Schüttrumpf¹, Shiva Pudasaini⁴

¹RWTH Aachen University, Aachen, Germany, ²Royal Belgian Institute of Natural Sciences, Brussels, Belgium,

³University of Cologne, Cologne, Germany, ⁴University of Bonn, Bonn, Germany

Abstract

Numerical models simulating the transport of coastal boulders by tsunamis provide pivotal information regarding physical characteristics of the hydraulic event. However, model results need to be validated, due to the complex and sensitive transport mechanics, e.g. by physical experiments, in order to generate reliable implications for tsunami hazard evaluation. Current numerical models only simulate the behavior of idealized boulder shapes like cuboids, spheres or prisms and do not account for sedimentary load in the tsunami wave, which might substantially influence transport dynamics and distance. Therefore, we propose a novel approach, based on the immersed boundary technique in combination with the general two-phase mass flow model of Pudasaini (2012), for simulating an arbitrary shaped boulder interacting with a sediment-laden flow. In corresponding flume experiments, we observe a dominating influence of boulder shape not only in terms of the transport distance but also on a standardized and repeatable boulder behavior. Experiments were conducted for subaerial, partially submerged and submerged conditions utilizing idealized (cuboids) and complex boulder shapes, the latter resembling a previously studied wave-transported boulder from the island of Bonaire (Engel and May, 2012). Transport patterns were analysed by video processing. Test runs were repeated until the results showed a normal distribution for boulder-transport distance. While under partially submerged conditions, the cubic boulder required ≥ 37 runs to obtain normally distributed results, the complex boulder required ≥ 16 and the flat one at least nine. In general, median transport distances of the cuboid boulder were significantly higher compared to the complex and flat ones. Thus, the need for numerical boulder-transport models accounting for non-idealized boulder shapes is obvious. By applying an immersed boundary approach, the arbitrary shaped boulder is implemented as a highly resolved point cloud in Lagrangian coordinates. The developed algorithm detects the boulder shape, a convex hull with allowance of concave segments, and its orientation to the Cartesian grid of the main program with every computational time step. Subsequently, the velocities of the fluid and solid phases at every boundary node are interpolated and recalculated from influencing grid cells outside the boulder, while the velocity inside the boulder remains zero. Boulder transport is not determined by submergence-depending threshold functions but by a dynamical formulation that is generally valid. Results of the physical experiments will be presented focusing on the model sensitivity and the behavior of different boulder shapes. Furthermore, the functionality of the numerical model and its performance is demonstrated by comparing the numerical results with those of the experiments.

The sedimentary imprint of the CE 1936 tsunami event in Lake Lovatnet, western Norway

Kristian Vasskog¹, Nicolas Waldmann², Guy Simpson³, Emmanuel Chapron⁴, Louise Hansen⁵, Daniel Ariztegui³, Atle Nesje¹

¹University of Bergen, Bergen, Norway, ²University of Haifa, Haifa, Israel, ³University of Geneva, Geneva, Switzerland,

⁴University of Toulouse, Toulouse, France, ⁵Geological survey of Norway, Trondheim, Norway

Abstract

Several historical rock fall events between CE 1905 and 1950 have caused devastating tsunamis in Lake Lovatnet, western Norway, claiming a total of 174 human lives. Based on detailed sedimentological and geophysical surveys of the sedimentary infill in Lovatnet, we present a 2200 year long reconstruction of mass wasting events in the lake, with particular focus on the largest recorded historical tsunami that occurred in CE 1936. This particular event was caused by a 1 million m³ rock fall from the Ramnefjell Mt., located in the SE end of the lake. The resulting tsunami wave had a maximum run-up of about 70 m, and a hydrodynamical model indicates that the wave propagated along the entire 8 km length of the narrow (1-1.5 km) lake within about 12 minutes.

We mapped the lake bathymetry with a 125 kHz interferometric side-scan sonar, whereas the sub-surface was imaged using a single-channel high-resolution Geoacoustic 3.5 kHz pinger unit. The seismic stratigraphy reveals several mass transport deposits (MTDs) with thickness of up to 2 m in the deepest part of the lake (134 m), i.e. in the basin proximal to the Ramnefjell rock fall area. A piston core (420 cm) and a shorter gravity core (89 cm) were retrieved in the NW shallower lake sector (89 m water depth), about 6 km distal to the CE 1936 rock fall area. The cores were subjected to a multi-proxy analysis, which included lithostratigraphical logging, radiographic and optical imaging, and magnetic susceptibility- and X-ray fluorescence (XRF) scanning. A chronology was established for the cores using a combination of radiocarbon dates (n=4) and measurements of ²¹⁰Pb and ¹³⁷Cs-activity. Based on the ¹³⁷Cs chronology we dated a prominent 33.5 cm thick, complex MTD, to have been deposited between CE 1938 and CE 1924, which we interpret as a result of the CE 1936 tsunami event. The MTD features an erosive lower boundary, and is characterized by several types of sedimentary facies commonly associated with tsunami deposits. This includes a 10 cm normally graded unit at the base consisting of very fine gravel to medium sand, overlain by an 'organic conglomerate' and a silty layer rich in plant macrofossils, with a mud cap on top. Another potential tsunami deposit is seen around 2000 cal a BP, whereas the remaining 65 event layers are probably the result of snow-avalanches entering the lake and smaller, local sliding events within the lake.

P-3061

Sedimentary record of historical storm surges along Gulf of Gdańsk, SE Baltic Sea

Damian Moskalewicz¹, Witold Szczuciński², Przemysław Mroczek³, Giedre Vaikutienė⁴

¹University of Gdańsk, Gdańsk, Poland, ²Adam Mickiewicz University, Poznań, Poland, ³Maria Curie-Skłodowska University, Lublin, Poland, ⁴Vilnius University, Vilnius, Lithuania

Abstract

Baltic Sea is commonly viewed as a region with a low frequency of coastal hazards like tsunamis or extreme storm surges. However, historical archives indicate that during the past millennium several catastrophic storm surges resulted in coastal floods and related casualties. However, the sedimentary record of them is poorly known. Consequently, several locations along southern Baltic Sea coasts were investigated in order to find past storm surge deposits within coastal peatlands and recognize their sedimentary features, which could be used in further studies extending the storm surges history.

Based on digital spatial data (satellite and aerial images, digital elevation models) several key locations were selected for detail field work. After the preliminary geomorphological investigation, cores and surface samples were collected and subjected to grain size, heavy minerals, diatom, and loss on ignition analyses. The age of sediments was estimated with ¹³⁷Cs, ²¹⁰Pb, and ¹⁴C methods.

Two types of event deposits were identified. They were interpreted to be storm sediments formed under inundation regime and breaching regime, respectively. The deposits formed under inundation regime were marked by sharp, erosive lower boundary, massive structure and presence of rip-up clasts, while sands formed under breaching regime consisted of low-angle planar cross-stratification sands and intercalations of finer sediments of massive structure.

Grain size distributions in storm surge sediments were mainly unimodal, moderately well sorted, fine skewed, and mesokurtic. Mineral composition was dominated by the light mineral fraction (85-99%). In heavy mineral fraction increase content of very dense minerals of rounded shape (e.g. garnets, zircon, staurolite) was observed. Diatoms were found only in one core. Comparison of storm surge sediments with deposits from adjacent sedimentary environments (dune, beach, nearshore, river) showed the possibility of distinguishing them from each other applying the listed above methods.

Dating results compiled with historical archives showed that deposition of sediments occurred during the storms in 1872 and in the period of 1898-1914. Several geological evidences also suggest the record of storms from 1497, 1625 and 1825. The results showed that only the most extreme events (mainly from XIX century) were capable to leave the geological record. Notably, none of the historical storm during past 100-year period formed a distinguishable sedimentary layer. These findings clearly show that hazard assessment models and storm return period predictions, which are based on instrumental measurements from past decades, should also involve geological evidence. The strongest storms from the past century may not be an adequate example of the worst case scenario event.

Luminescence analyses as a novel proxy for tsunamigenic stratigraphies

Gloria I. López^{1,2}, Pedro J.M. Costa³, César Andrade³

¹CENIEH, Burgos, Spain, ²University of Haifa, Haifa, Israel, ³Universidade de Lisboa, Lisbon, Portugal

Abstract

Optically Stimulated Luminescence (OSL), now a well established chronological method, provides a direct age estimate of the last exposure of commonly occurring mineral grains to daylight. The uniqueness of this trapped charged technique is its intrinsic relation to transport mechanisms and depositional processes forming a sedimentary deposit. The extraordinary sensitivity of this signal to environmental conditions allows to differentiate degrees of sedimentary chaos: sediments incompletely bleached at burial or transported by highly turbulent regimes, such as tsunami or storms, thus the applicability of the OSL signal as a sedimentary proxy.

Recent work along Southern Portugal has revealed a complex coastal stratigraphic sequence evidencing multiple potential palaeotsunami and palaeostorm events. This rugged coast of the Central Algarve has witness severe shoreline erosion over the last 300 years, nonetheless small embayments such as the infilled coastal lagoon of Almargem have demonstrated to be good event entrapment basins, allowing preservation of complex sedimentary facies.

A series of large trenches dug along two N-S cross-shore profiles were excavated with their long axis both parallel and perpendicular to shore to potentialise the geometries of the different sedimentary units and structures, increasing visualization and stratigraphic correlation. The trench walls with most significant visual stratigraphic differences were sampled throughout their entire profiles. Individual small to micro (10 to 1 g) bulk samples were collected from different laminae for Portable OSL Reader (POSL) analyses, small 3 to 5 cm-diameter PVC tubes were inserted in key layers for OSL dating and Single Grain Over-Dispersion (SG-OD) OSL analyses, and multiple box-cores were retrieved throughout the trench walls for all the various other analyses (detailed sedimentology, mineralogy, petrophysics, bio-stratigraphy).

So far, our research has revealed at least one massive bioclastic-rich layer and multiple heavy mineral laminae associated to extreme marine incursions. Diverse luminescence analyses were undertaken not only to establish chronologies of such events (OSL dating) but also as sedimentological characterisers: a) transport and depositional variations between individual storm-laid and tsunamigenic layers are being identified by means of SG-OD analyses; while b) luminescence profiles created from the measurement of small to micro bulk samples (e.g., individual lamina) using POSL have been useful to interpret changes in stratigraphic patterns, defining the continuity of deposition.

The luminescence analyses on the multiple storm and tsunamigenic layers are detecting the variations imposed by their mechanism of formation, concurring with the other analyses done so far. Despite its massive character, the bioclastic-rich layer is most likely linked to the 1755 Lisbon Earthquake and Tsunami Event while the multiple heavy mineral laminae are most probably the result of successive storm washover events. The presence of numerous layers of different origins in such a small enclosed area makes this a challenging tsunami vs storm study site.

Abstract

South west coastal Mexico is located in the interaction between the Rivera plate, the Jalisco block and the Cocos plate. Six different high magnitude earthquakes ($M_w > 7.0$) have been documented since 1837 AD including the M_w 8.2 earthquake of 1932 AD in Jalisco. These low frequency but severely damaging natural phenomena in the geological records of lagoons can be in detail through the paleoenvironmental analysis of cores from coastal lagoons. Based in a multiproxy analysis (mineralogy, magnetical susceptibility, ostracods, diatoms and geochemistry) from four cores from laguna Chacala and Laguna Coyutlán, Colima were identified three exceptional events linked to the tectonic activity of these plates.

Indicators of marine invasion includes abrupt erosive contacts that initiate with mixed coarse sand with clay sediments and an increase in the material swept along by an oceanic incursion; mixing of marine diatoms with fresh water diatoms, large fragments of charcoal and presence of Ti, Fe, and Na are. Afterwards the lagoon experimented a process of evaporation halite and carbonates possibly formed in situ and trapped in the lagoon after salinity increased due to a marine incursion. The earliest tsunami we recorded dated between 517 ± 87 and 518 ± 88 AD, 879 ± 103 followed by a second tsunami dated at 879 ± 103 AD. The latest is contemporary with the 1816 AD earthquake that flooded the saltpans of San Pantaleón.

The event effects distributed along over 50 km of the coastline of the state of Colima with waves of over 15 m in height that reached distances of over 2.5 km inside the continent.

It is observe a 361 to 468 years recurrence of tsunamis events.

Documentation of the past records of tsunamis helps in identification of the recurrence intervals in regions with higher population.

Abstract

Cyprus has a long record of tsunami waves, as noted by archaeological and geological records. Large boulder deposits have been noted in southeastern and western part of the Island. In the area of Cape Greco (southeastern Cyprus) large boulders have been noted, however, no detailed geomorphological research exists so far and the related high energy event remains undated. In this context, we focused at Cape Greco Peninsula at the southeastern coast of Cyprus, in order to record in detail large boulders deposits. The accumulation of the boulders along the uplifted coastline (3m amsl) was recorded. The boulders are fragments of a layer of an upper Pleistocene aeolianite, which is overlaying unconformably a lower Pleistocene calcarenite. Dimensions and spatial distribution of 272 small, medium and large boulders were documented. The precise distance of the boulders deposition from the coastline was recorded by field measurements and remote sensing with the use of GNSS, Drone mapping and GIS technics.

Several large boulders weighting more than ~30 metric tons were located up to 60m inland. Geomorphologic mapping and morphometric measurements, along with the presence of marine organisms suggests that some of the boulders were removed from their original intertidal zone and were transported inland by the force of large waves. Samples of *Vermetus* sp. were collected from the displaced boulders in order to date the extreme event. In this work, we report and compare preliminary results from the application of widely accepted hydrodynamic equations (e.g. Pignatelli et al., 2009), in order to determine the extreme event that caused their transport inland. We further attempt a correlation of the event with already known tsunami events from Eastern Mediterranean, based on the estimated wave heights and the radiocarbon dating of marine gastropods (*Vermetus* sp.).

Phytolith analysis for differentiating between broomcorn millet (*Panicum miliaceum*) and its weed/feral type (*Panicum ruderale*)

Jianping Zhang^{1,2}, Houyuan Lu^{1,2,3}, Minxuan Liu⁴, Xianmin Diao⁴, Konglan Shao^{1,3}, Naiqin Wu^{1,5}

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ²Center for Excellence in Tibetan Plateau Earth Science, Chinese Academy of Sciences, Beijing, China, ³University of Chinese Academy of Sciences, Beijing, China, ⁴Institute of Crop Science, Chinese Academy of Agricultural Sciences, Beijing, China, ⁵Institutions of Earth Science, Chinese Academy of Sciences, Beijing, China

Abstract

Domestication of broomcorn millet is one of the most significant events in prehistoric East Asia, which provided enough food for explosive growth of Neolithic population and the transition into complex socialites. However, to date, the process of broomcorn millet domestication is still unknown, particularly due to the lack of clear diagnostic feature to distinguishing between the millet and its wild related grasses from archaeological residuals. Here we examine the percentage of silicified epidermal long cell undulated patterns in the glume and palea from the inflorescence bracts in 21 modern of broomcorn millet and 12 of its weed/feral type *Panicum ruderale* collected cross north China. Our results show that the percentage of η III patterns in the domesticated broomcorn millet ($23.0\% \pm 5.9\%$) ($n=63$) is about 10% higher than in *P. ruderale* ($10.8\% \pm 5.8\%$) ($n=36$), with the quartiles of 17.2%-28.3% and 5.1%-15.5%, respectively. The increase of η III pattern percentage has a significant correlation with the decrease of ratio Length/Width of grains. The results statistically suggest that the direct wild ancestor of *P. miliaceum* could possibly has lower η III type in the lemma and palea, providing us a potential method to trace the domestication process of broomcorn millet, and will contributing to the methodology which can be applied to distinguish other cereal crops and wild grasses.

New methods and progress in research on the origins and evolution of prehistoric agriculture in China

Houyuan Lu

Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, Center for Excellence in Tibetan Plateau Earth Science, Chinese Academy of Sciences, Beijing, China, University of Chinese Academy of Sciences, Beijing, China

Abstract

China is one of the main global centers of origin of agriculture. Foxtail millet (*Setaria italica*), common millet (*Panicum miliaceum*), and rice (*Oryza sativa*) were the first crops to be domesticated in China. There remain many uncertainties and controversies in our current understanding of the chronology, locations, and plant types at the origins and the process of evolution of prehistoric millet and rice farming, and their relationships with climate change and human adaptation. This review summarizes the research progress made by Chinese scientists over the last decade on the origins and evolution of prehistoric agriculture. It highlights novel techniques and methods for identifying early crop remains, including plant macrofossils (carbonized seeds, spikelets), microfossils (phytoliths, calciphytoliths, starch, pollen), and biomarkers; new evidence on the origins, development, and spread of early agriculture; and research related to climate and environmental changes. Further, we pinpoint and discuss existing challenges and potential opportunities for further in-depth investigation of the origins and evolution of agriculture and the adaption of human activities to climate change.

³University of Victoria-Anthropology, Victoria, Canada

Abstract

Kilgii Gwaay is a Late Pleistocene-early Holocene archaeological wet site located in the intertidal zone of a small island (6 ha) on the North Pacific coast of Canada. The site includes one of the oldest known shell middens in western North America and provides evidence of early marine adaptation. Cultural deposits include hearth features and thousands of lithic, bone and wood artifacts, with human occupation dating from 10,800 to 10,600 cal yr BP, when relative sea level was 1-3 m lower than at present. The site became exposed in the late Holocene and is currently only accessible at low tide.

We conducted multi-proxy paleoenvironmental analyses (magnetic susceptibility, pollen, charcoal, macrofossils) on paleopond sediments at Kilgii Gwaay that were submerged and capped by marine deposits about 10,600 cal yr BP, as relative sea level rose. Pollen analysis indicates establishment of herb-shrub tundra by 14,500 cal yr BP. Pine-dominated communities were present by 13,800 cal yr BP and then replaced by spruce forest about 13,250 cal yr BP. Salmonberry seeds indicate availability of this important food resource starting 13,500 cal yr BP. Macroscopic charcoal is abundant during the period of confirmed human occupation; however, intermittent increases in charcoal begin following establishment of spruce forest, well below the known occupation horizon. Forest fires are infrequent in this wet hypermaritime setting with fires absent from some areas of the outer coast for the entire Holocene. Thus, the charcoal record from Kilgii Gwaay pond serves as a potential proxy for human occupation, suggesting human presence as early as 13,000 cal yr BP, approximately 2000 years earlier than documented by AMS-dated cultural deposits and artifacts.

The earliest direct archaeological evidence for human occupation in the region dates to 12,600 cal yr BP. Human occupation of ancient shorelines near Kilgii Gwaay at 13,000 cal yr BP is therefore plausible and would make such a site one of the oldest archaeological sites on the North Pacific coast of North America. The record at Kilgii Gwaay provides indirect support for the hypothesized coastal migration route into the Americas at the end of the last glacial maximum and highlights the utility of multi-proxy analyses of non-cultural deposits at archaeological sites.

Abstract

Small islands present environmental archaeologists with the opportunity to study the sustainability and resilience of complex socioecological systems over time. This project is investigating the changing landscapes, environment and population of 6 small islands around the Sea of Moyle over the last three millennia. Today the area is seen as a remote border zone between Scotland and Ireland. In the past this was not the case and the Sea of Moyle was at times a coherent and central geographic region crossed by sea voyagers and linked by culture and kinship. The islands (Rathlin, Tory, Iona, Islay, Gigha & Colonsay) all saw the establishment of early Christian communities, were within the Dalriada over-Kingdom in the 6th to early 7thC, were subject to early Viking Raids and then formed part of the Scandinavian Suðreyjar, or "Southern Isles". The later Medieval and post Medieval history of the islands is more complex and divergent but all six islands saw major, if not remarkable changes in population over the last 300 years. Cores from lakes on each island will be analysed using sedaDNA metabarcoding and lipid biomarkers, particularly faecal stanols and bile acids. Along with some traditional proxies, ¹⁴C AMS dating and tephrochronology the results will be used to examine changes in island ecology and particularly the history of domesticates. This will be combined with landscape archaeological surveys around the sites and soil DNA studies of relic field systems. The project will be the first to explicitly compare archaeological proxies from islands in the same region with archaeological and historical data using sedaDNA and lipid biomarkers in a controlled archaeological setting.

¹Key Laboratory of Vertebrate Evolution and Human Origins of the Chinese Academy of Sciences, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China, ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ³University of Chinese Academy of Sciences, Beijing, China, ⁴State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China, ⁵Institute for Archaeology and Culture Conservation of Qingdao, Qingdao, China

Abstract

Coastal archaeological sites, recording the evolution history of coastal environment and preserving the behavioral information of earlier human ancestors, are an ideal carrier to explore some academic issues such as the utilization of marine resources, the strategy of marine adaptation, and the route of coastal migration during the late Pleistocene. However, little information concerning the time and process of early human occupation has come to light in coastal areas of China. Here, we report on the chronology, archeology and paleoenvironmental reconstruction of the Pleistocene Dazhushan site on the east coast of the Shandong Peninsula in north China, which is the first Paleolithic site with stratigraphic information in Qingdao. In this study, we reconstructed the history of environmental changes in the area, with pollen, magnetic susceptibility, and optically stimulated luminescence (OSL) dating. Our preliminary results are as follows: 1) Dazhushan site appeared in the late Pleistocene, and its absolute burial age of archaeological remains is 65.7-52.9 ka, which corresponds to late MIS4 to early MIS3. Meanwhile, archeology evidence indicates that prehistoric humans employed a flake technology; 2) multiple evidences show that human activities which occupied by terrestrial herbivores increased significantly in the early stage of MIS3, and the region was an inland area dominated by a mixed broadleaved forest and grassland environment, despite locating on the current coastal area of the northern China. In general, the climate trend is indicative of a good correlation with the regional context; 3) rapidly warming climate and stable living environment provided an appropriate ecological background to survive in the early stage of MIS3. Subsequently, however, as temperatures fell and coastline retreated, the massive reductions of archaeological remains may indicate the weakening of human activities or migrations to other areas. The fluctuation of the intensity of human occupation in different period shows that the survival strategy of early human had been profoundly influenced by the variable living environment. Finally, based on the collected topographic and geomorphic data of the coastal region in the eastern China, and considering the striking advance and retreat of sea level in late Pleistocene, we conducted a deeper discussion on the relationship between the migration and adaptation of prehistoric humans and the geomorphological evolution of coastal environment.

Reconstructing Mid-Holocene paleoenvironments in the vicinity of the submerged pile-dwelling in Zambratija Bay (Istria, Croatia)

Katarina Jerbic¹, Nikolina Ilijanic², Slobodan Miko², Ozren Hasan²

¹Flinders University, Adelaide, Australia, ²Croatian Geological Survey, Zagreb, Croatia

Abstract

A unique characteristic of post-LGM marine transgression reconstructions is the use of submerged archaeological RSL indicators, such as shell middens, coastal buildings, or traces of human occupation. In the rare cases when underwater archaeological research takes place on those sites, it involves diving and excavation, both of which represent a stressful risk for the archaeologists and the investors. The high likelihood of a negative archaeological result, regardless of the promising preliminary surveys, most often means that archaeological research is considered unreliable or unnecessary. This can change by applying interdisciplinary research methods, where environmental data can also answer archaeological research questions. A geoarchaeological submerged case study in Zambratija Bay, Croatia, demonstrates alternative ways to use seabed core environmental data, by using multiproxy analysis of a nearby sediment core (sedimentological, mineralogical, geochemical and palinological analyses). Preliminary archaeological, geophysical investigations and analysis of dated cores revealed that the site, today submerged three metres under the Adriatic Sea, is a 6,000-year-old freshwater pile-dwelling built on the outer edges of a karstic sinkhole. Seven cores taken on site revealed that the submerged sinkhole contains marine, brackish, organic and lacustrine sedimentary sequences. Holocene marine transgression is evident by marine carbonate sediments containing marine shells, covering terrestrial grey and brown clay sediments. These clayey sediments show succession from highly magnetic sediments containing pyrrhotite minerals, formed under marine influence through karstic underground. One-meter thick organic sediments are composed of peaty sediments with high TOC (15-30 %) and N (1.1-2.8 %) and compact fine-grained peat with high P, Fe and Mo, as well as significant amounts of vivianite. These organic sediments are characterised by lower values of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ implying freshwater environment. Occurrences of vivianite are still visible in underlying brown clay freshwater pond sediments, containing much more siliciclastic material compared to above organic sediments. Vivianite is a mineral that occurs on various Quaternary, postglacial and modern aquatic systems worldwide, which includes marine, freshwater and terrestrial waterlogged soils. It is known to appear on archaeological sites in teeth and bones on waterlogged bodies, and anthropologically influenced muddy wastewater layers settings with higher P levels, which implies that its occurrence might indirectly mirror a human impact on aquatic environments.

Abstract

Erica is a dominant vegetation type in many Subafro–alpine ecosystems such as the Bale Mountains in Ethiopia. However, the past extent of *Erica* is not well known and climate versus anthropogenic influence on altitudinal shifts are difficult to assign unambiguously especially during the Holocene. The main objective of the present study is to chemotaxonomically characterize the dominant plant species occurring in the Bale Mountains using lignin phenols and *n*–alkane biomarkers and to examine the potential of those biomarkers for reconstructing vegetation history. Fresh plant material, organic layer and mineral topsoil samples were collected along a northern and a southwestern altitudinal transect (4134–3870 and 4377–2550 m a.s.l. respectively). Lignin–derived vanillyl, syringyl and cinnamyl phenols were analyzed using the cupric oxide oxidation method; leaf wax–derived *n*–alkanes were extracted and purified using soxhlet and aminopropyl columns. Individual lignin phenols and *n*–alkanes were separated by gas–chromatography and detected by mass spectrometry and flame ionization detection, respectively.

We found that the relative contribution of vanillyl, syringyl, and cinnamyl phenols allow us to chemotaxonomically distinguish contemporary plant species of the Bale Mountains. Particularly, *Erica* is characterized by relatively high cinnamyl contributions of >40%. However, litter degradation strongly decreases the lignin phenol concentrations and completely changes the lignin phenol patterns. Relative cinnamyl contributions in soils under *Erica* were <40%, while soils having developed under Poaceae (*Festuca abyssinica*) exhibited relative cinnamyl contributions of > 40%.

Similarly, long-chain *n*–alkanes allowed differentiating between *Erica* versus *Festuca abyssinica* and *Alchemilla* based on lower C31/C29 ratios. However, also this characteristic plant pattern was lost due to degradation in the respective O–layers and A_h–horizons. In conclusion, neither lignin phenols nor *n*–alkane biomarkers allow developing unambiguous proxies for reconstructing the past extent of *Erica* on the Sanetti Plateau, Bale Mountains, Ethiopia.

Key Words: Chemotaxonomy, biomarkers, molecular proxies, humification, soil organic matter, pedogenesis, Sanetti Plateau, *Erica* and *Festuca abyssinica*

Direct push sensing in wetland (geo)archaeology – Minimal-invasive investigations of archaeological and sedimentological issues

Johannes Völlmer¹, Johannes Schmidt¹, Peter Dietrich^{2,3}, Ulrike Werban², Sven Linzen⁴, Stefanie Berg⁵, Lukas Werther⁶, Christoph Zielhofer¹

¹Physical Geography, Institute of Geography, Leipzig University, Leipzig, Germany, ²Department Monitoring and Exploration Technologies, Helmholtz Centre for Environmental Research (UFZ), Leipzig, Germany, ³Centre of Applied Geosciences, Eberhard Karls University, Tübingen, Germany, ⁴Leibniz Institute of Photonic Technology (IPHT), Jena, Germany, ⁵Bavarian State Department for Cultural Heritage (BLFD), Munich, Germany, ⁶Seminar of the Archaeology of Prehistory to the Early Middle Ages, Friedrich Schiller University, Jena, Germany

Abstract

Buried archaeological sites in wetlands provide important information about pre-historic and historic buildings as well as archives for landscape and environment development. High groundwater table and unstable sediments complicate excavations. Alternatively used vibra-corings suffer from imprecise depth accuracy caused by high compaction rates of the sediments.

In this study, we apply and integrate minimal-invasive direct push sensing on cross sections in a multi-methodical approach to get high resolution and depth-accurate data from a buried Early Medieval canal. We used the technique to clarify the geometry and the fillings of the canal. Furthermore, we want to clarify accompanying structures in the subsurface and the landscape development at the site.

Direct push sensing implies a set of tools for underground investigations by pushing steel rods with different probes into the unconsolidated sediments driven by a flexible vehicle. Thus, different probes allow the characterisation of various parameters *in situ*, e.g. electrical conductivity or colour, for a cost- and time-effective site investigation. Recorded data provide a high depth-accuracy and a resolution in the cm-scale. In the forecast, we detect linear anomalies with SQUID magnetic survey. For the ground truth and sampling we used classical vibra-corings.

The *Fossa Carolina* is the first attempt to bridge the Central European watershed between the Rhine-Main- and the Danube-Catchment. The building was initiated in 792/793 AD by Charlemagne with a length of approx. 3 km near Treuchtlingen in S-Germany.

Our data clearly indicate the Carolingian floodplain surface, probable remnants of Carolingian construction works, the Carolingian trench, buried dams, post-Carolingian trench fillings and the onset of flood loam deposition in the 15 century.

Furthermore, we provide an additional example for direct push sensing in the surrounding of the *Fossa Carolina* to clarify artificial water supply. However, Radiocarbon datings and a fossil half-bog top soil indicate active and passive phases in landscape development during the Holocene and negate an artificial water inlet.

Finally, our approach provides an alternative for (geo)archaeological excavations. The results show detailed features of buried historic constructions with less labour and time effort. The data is also suitable for stratigraphical interpretation and the reconstruction of the landscape development.

Palmitone as a species-specific biomarker for the crop plant taro (*Colocasia esculenta* Schott.) on remote Pacific islands

Christiane Krentscher^{1,2}, Nathalie Dubois^{1,3}, Giorgia Camperio^{1,3}, Matthew Prebble⁴, Nemiah Ladd^{1,3}

¹Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Department of Surface Waters – Research and Management, Dübendorf, Switzerland, ²Swiss Federal Institute of Technology (ETH-Zürich), Department of Environmental Systems Science, Zürich, Switzerland, ³Swiss Federal Institute of Technology (ETH-Zürich), Department of Earth Sciences, Zürich, Switzerland, ⁴Department of Archaeology and Natural History, College of Asia and the Pacific, Australian National University, Acton, Australia

Abstract

The ecosystems of remote Pacific islands were dramatically transformed following the arrival of humans within the last ~3000 years, as the new settlers required technological innovations and environmental modifications to maintain their populations. These modifications included the introduction of numerous exotic species, including the important crop *Colocasia esculenta* Schott. (taro) and the development of water gardens suitable for its cultivation. Reconstructing the history of *C. esculenta* use in the Pacific has been challenging because of the non-specificity of its starch granules and its limited pollen production during periods of intense cultivation. Here, we assess a lipid biomarker approach to trace *C. esculenta* cultivation in the past. We characterized the neutral lipid compositions of leaf samples from common cultivars and widespread indigenous species from the archipelago of Vanuatu by gas chromatography – mass spectrometry (GC–MS). The compound palmitone (16-hentriacontanone) was a major leaf wax constituent in *C. esculenta* cultivar samples (mean concentration of $402 \pm 63 \mu\text{g/g}$ (dry wt.)) and was only detected in one other species, the ornamental tree *Cananga odorata* ($175 \mu\text{g/g}$ (dry wt.)). The structure of palmitone is favorable for its long-term stability, and we demonstrate its preservation potential in a ~1000 year sedimentary record from Vesalea Lake on Espiritu Santo, Vanuatu, where *C. esculenta* is grown today. Palmitone concentrations in this core fluctuated up to $4.1 \mu\text{g/g}$ (dry wt.). Our results indicate that in appropriate environmental contexts, sedimentary palmitone concentrations can be used to reconstruct *C. esculenta* cultivation and to provide insights about past horticultural innovations in Remote Oceania.

Late Glacial and Holocene landscape evolution of the Sanetti Plateau, Bale Mountains (Ethiopia), deduced from biogeochemical properties of lacustrine sediments

Betelhem Mekonnen¹, Bruno Glaser¹, Michael Zech², Frank Schlütz³, Agerie Addis⁴, Sileshi Nemomissa⁵, Tamrat Bekele⁵, Wolfgang Zech³

¹Institute of Agronomy and Natural sciences, Soil Biogeochemistry, Martin Luther University Halle-Wittenberg, Von-Seckendorff-Platz 3, 06120, Halle, Germany, Halle (Saale), Germany, ²Institute of Geography, Technical University of Dresden, D-01062, Dresden, Germany, Dresden, Germany, ³Institute of Soil Science, University of Bayreuth, D-95440 Bayreuth, Germany, Bayreuth, Germany, ⁴Department of dry land crop science, Jigjiga University, Ethiopia, Jigjiga, Ethiopia, ⁵Department of Plant Biology and Biodiversity Management, Addis Ababa University, Addis Ababa, Ethiopia, Addis Ababa, Ethiopia

Abstract

The Bale Mountains are one of the three extensively glaciated higher elevation areas in Ethiopia during last glacial maximum. After deglaciation, several small depressions on the Sanetti Plateau turned into shallow lakes. Today, some of these lakes dry out seasonally due to the alternation between monsoonal precipitation in summer and dry north-easterlies in winter. With this study we aim at contributing to the reconstruction of the Late Glacial and Holocene environmental history (including particularly sedimentation, fire and vegetation reconstruction) of the Bale Mountains using a multi proxy approach.

We investigated partly laminated lake sediments at high-resolution from a catchment located at an altitude of 4115 m asl on the Sanetti Plateau. Stable isotopes, alkanes, black carbon (fire proxy) in combination with pollen were used to infer environmental dynamics. Radiocarbon ages show that the depression became ice free around 18 cal. ka BP. The sedimentation rate was 24.57 yr/cm for the laminated lower part of the profile (255 to 70 cm) and 186 yr/cm for upper 70 cm. Total organic carbon (TOC) concentration reaches almost 7% between 16 to 18 cal. ka BP, whereas low TOC values ($\leq 1\%$) typically dominate in the younger upper part (≤ 12 cal. ka BP). More positive $d^{13}C$ values in the lower part of the sediments (-20 to -14‰) might indicate expansion of C4 grasses. However, the influence of other process such as methanogenesis and (semi-)aquatic plants using the bicarbonate metabolism cannot be excluded. By contrast, more negative $d^{13}C$ values during Late Glacial-Holocene transition and during the Late Holocene indicate increasing input of terrestrial C3 plants. Low $d^{15}N$ values during deglaciation show that the N cycle was relatively closed probably due to cold temperature at that time. Low odd-over-even predominances (OEP) of *n*-alkane lipid biomarkers as well as low TOC/N ratios corroborate the interpretation of highly degraded organic material building up the upper 70 cm. High concentration of black carbon (BC) recorded between 15.5 and 13.8 cal. ka BP is in agreement with high *Erica* pollen concentration at 13.7 cal. ka BP which likely reflects periodical burning of *Erica* during this time period.

P-3211

Resource partitioning and interspecific interactions among Pleistocene large herbivore species: a tooth wear approach

Florent Rivals

Institut Català de Paleoeologia Humana i Evolució Social (IPHES), Tarragona, Spain, ICREA, Barcelona, Spain

Abstract

Niche and resource partitioning are key concepts for the understanding of interactions among species and to explain (paleo)biodiversity. It is known that differentiation of ecological niches reduces competition and promotes co-existence between species. Among the proxies used to reconstruct paleodiets in fossil large mammals, tooth mesowear and microwear are ideal to study niche partitioning because the two proxies reflect the dietary traits at the time of death i.e. the diet that each species had when they occurred in the same area. This topic will be discussed on selected examples from archaeological and paleontological localities across Europe (Germany, UK, France and Spain): Steinheim and Swanscombe (MIS11), Joint Mitnor Cave (MIS 5e), Portel-Ouest (MIS 4), and Jou Puerta and Kent's Cavern (MIS 3). The combination of mesowear and microwear provides a powerful tool for examining dietary flexibility and resource partitioning at different temporal scales. Mesowear provides a dietary signal integrated over several months at least, and allows us to contrast more eurytopic species (e.g. *Megaloceros giganteus*, ranging from grazing to browse-dominated mixed-feeding) to more stenotopic (e.g. *Capreolus capreolus*, always browsing). Dental microwear provides an independent proxy that records relatively short-term diet. For stenotopic species (e.g. the browser *Capreolus capreolus* or the grazer *Coelodonta antiquitatis*) the two proxies tend to match. For other species, however, there is sometime discrepancy between meso- and microwear signals that often difficult to interpret but always clearly informative about the diet at the time of death.

Magnetostratigraphy of the Miocene mammalian fauna in the Lanzhou Basin, Northeast Tibetan Plateau: implications for mammal migration

Peng Zhang^{1,2}, Hong Ao^{1,2}

¹State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China, ²Open Studio for Oceanic-Continental Climate and Environment Changes, Pilot National Laboratory for Marine Science and Technology (Qingdao), Qingdao, China

Abstract

The fluvio-lacustrine sequence in the Lanzhou Basin, located at the northeastern margin of the Tibetan Plateau, is a rich source of Cenozoic mammalian fossils, critical to our understanding of the terrestrial Asian mammal and environmental evolution. While the Oligocene, Early Miocene and Late Miocene mammalian faunas have been dated with magnetostratigraphy, the numerical age of the Quantougou (QTG) Fauna remain controversial. The accurate age of the QTG Fauna is crucial to understand the mammal and environmental evolution in the Eurasia, because the Myocricetodontinae in the QTG Fauna were regarded as the Earliest appearance of this subfamily in East Asia. Here, we present a high-resolution magnetostratigraphic dating of the Miocene mammal assemblages from a 280-m thick fluvio-lacustrine section in the Lanzhou Basin located at the northeastern margin of the Tibetan Plateau (China). The section is suggested to span from polarity chron C5Cn.2r to chron C5n.2n, i.e. ranging from ca 16.5 to 10 Ma (except for a sedimentary hiatus between ca 15-13.5 Ma). This magnetostratigraphy provides new numerical ages for the QTG mammalian fauna (12.5-12.0 Ma) and enables precise correlation of the QTG fauna to the European Land Mammal Age and North American Land Mammal Ages. Consequently, the appearance of Myocricetodontinae in East Asia is much later than that of Indian Subcontinent (19-16 Ma), which provides new evidence for the Indian Subcontinent origin for the Myocricetodontinae. Further, the Paleogene-Quaternary paleoenvironment evolution of the Lanzhou Basin is summarized based on the mammalian fossils excavated in this basin.

Non-pollen palynomorphs webpage and database

Lyudmila Shumilovskikh^{1,2}, Elena Shumilovskikh²

¹Georg-August-University of Göttingen, Göttingen, Germany, ²Tomsk State University, Tomsk, Russian Federation

Abstract

Non-pollen palynomorphs (NPP) represent a large group of microscopic remains found in palynological slides besides pollen and spores. They are represented by algal remains, fungal spores, resting stages and eggs of invertebrates, allowing a deeper understanding of biotic interactions in the Quaternary palynological records. Starting in the 1970s with studies by Bas van Geel and colleagues, large numbers of new described types are published every year. In order to get an overview to the wide world of these “extra fossils” in pollen slides, we created a webpage with a database aiming to gather information about NPP, structuring it by nomenclature and where possible taxonomy and help by identification: <http://nonpollenpalynomorphs.tsu.ru/>. It is developed with PHP and MySQL. The database contains illustrations, original descriptions and ecological information about the NPP. A search function allows easier identification of the palynomorphs.

P-3214

Exploring plasticity in herbivore dietary ecology in late Pleistocene France using isotope zooarchaeology

Kate Britton^{1,2}, Elodie-Laure Jimenez¹, Mael Le Corre¹, Joshua Wright¹, Vaughan Grimes³, Steeve Côté⁴, Sylvain Renou⁵, William Rendu⁵, Michael Richards⁶, Jean-Jacques Hublin², Marie Soressi⁷

¹University of Aberdeen, Aberdeen, United Kingdom, ²Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany, ³Memorial University, St. John's, Canada, ⁴Université Laval, Quebec, Canada, ⁵Université Bordeaux, Bordeaux, France, ⁶Simon Fraser University, Burnaby, Canada, ⁷Universiteit Leiden, Leiden, Netherlands

Abstract

The isotope analyses of archaeo-faunal assemblages has significant, but largely unrealised, potential for gaining new palaeoecological insights into the long-term adaptability and resilience of mid- and large-sized herbivores. This is particularly the case for certain species, such as reindeer (*Rangifer*), which are intermediate feeders and can also exploit food resources with characteristic isotope ratios (i.e. lichens) that most herbivores cannot when other plants are scarce due to environmental conditions or competition.

Here, we present a targeted diachronic study of herbivore dietary ecology from the late Middle and Upper Palaeolithic archaeological site of Les Cottés using the stable carbon and nitrogen isotope analysis of bone collagen. Spanning a 10,000-year period from the late Mousterian to early Aurignacian, the abundant remains of diverse fauna from this well-dated site represent an excellent opportunity to investigate and characterise herbivore dietary ecology in late Pleistocene France. Data reveal niche partitioning amongst the late Pleistocene herbivore communities of Les Cottés, with *Rangifer* exhibiting consistently elevated $\delta^{13}\text{C}$ values relative to horses and bovids, which is likely a consequence of lichen consumption. However, data from *Rangifer* (and to an extent *Bos/Bison*) deviate from the shifting isotopic 'baseline' of exclusively-grazing species to varying extents, highlighting plasticity in the behaviour of these intermediate-feeding genera through time. The implications for future studies are explored.

P-3215

Disappearance of *Globigerinoides fistulosus* was caused by hydrological changes in surface water at ~1.74 Ma in the tropical Pacific

Kuo-Yen Wei¹, Chen-Yin Chen², Li Lo¹, Chih-Kai Chuang¹

¹Dept. of Geosciences, National Taiwan University, Taipei, Taiwan, ²Dept. of Geosciences, National Taiwan University, Taipei, Taiwan

Abstract

Planktonic foraminifera *Globigerinoides fistulosus*, considered to be a morphotype of the terminal ontogenetic stage of *Globigerinoides sacculifer*, originated at 2.9 Ma and disappeared at 1.74 Ma in the tropical oceans. Relationship between the disappearance of *G. fistulosus* and the thermo-hydrological conditions of surface water over the period of 1.789 – 1.728 Ma were studied using ODP Hole 1115B (ODP Leg 180, 151°34'E, 9°14'S, water depth 1149 m) at the southern periphery of western Pacific warm pool (WPWP).

Kummer and sac morphotypes of the *G. sacculifer* complex appeared in all the six size fractions of >250 μm to >600 μm, but the *fistulosus* form occurred only in the size fractions >355 μm, suggesting it is indeed the terminal stage of *G. sacculifer*. The $d^{13}C$ increased from 0.3 to 2.7‰ in the *G. sacculifer* morphological complex with increasing test sizes, indicating a deeper dwelling depth for the final ontogenetic stage, *G. fistulosus*. The $d^{18}O$ increased slightly by ~0.2‰, suggesting also a deeper habitat for *G. fistulosus*. Mg/Ca (as a sea-water temperature proxy) of foraminifera shells increased slightly with increasing sizes too, but within the same size fraction the Mg/Ca of *G. fistulosus* were less than other forms' by at least 0.2 mmol/mol, implying a cooler (deeper) water environment in which the chambers were formed in the late ontogenetic stages.

The *fistulosus* morphotype disappeared between 1.742 and 1.737 Ma when the temperature gradient between the surface and subsurface waters increased suddenly from 3.5-6.0 °C (as indicated by Mg/Ca of *G. ruber*, and *Neoglobigerinoides dutertrei*). Before the disappearance of *G. fistulosus* the upper 100 meter of the water column has a less temperature gradient and a quick drop of temperature in 100- 150 m. At about 1.74 Ma the upper 150 meter waters were less stratified, the vertical temperature profile shows a gradual decreasing trend towards the deeper part. Consequently, the temperature at ~100 m depth became cooler and the former habitat condition of *G. fistulosus* vanished. At the same time, the specimens in the larger size fractions (>425 μm) of *G. sacculifer* decreased significantly. We interpreted that in order to keep the same buoyancy, individuals in the *G. sacculifer* complex had to decrease their Reynold's number and therefore their test sizes. The morphological expression of the *G. sacculifer* complex turned into a paedomorphosis direction and the ontogenetic final stage shown as *G. fistulosus* disappeared forever.

Regional and continental extinction of Pleistocene mega-herbivores in Australia, and its ecological effects.

Chris Johnson¹, Susan Rule², Frederik Saltre³, Jessie Buettel¹, Barry Brook¹, Simon Haberle⁴

¹University of Tasmania, Hobart, Australia, ²Australian National University, Canberra, Australia, ³Flinders University, Adelaide, Australia, ⁴Australian National University, Canberra, Australia

Abstract

In Australia many species of large vertebrates went extinct in the late Quaternary. These extinctions resulted in the disappearance from the continent of many large herbivores, including all species above a body mass of about 40 kg and all large browsers. Pleistocene megafaunal extinction in Australia resembled similar extinctions in other parts of the world; as in those other cases, its cause and ecological consequences are controversial. We clarify the timing of extinction of large herbivores across Australia, and investigate its ecological effects, by combining data from dated fossils and several regional records of change in dung fungi.

Fossils and dung fungi provide independent lines of evidence on mega-herbivore extinction, which agree in indicating extinction between 42 and 40 ka. This is shown for the whole southern half of the continent using fossil data, and for specific localities—in the north-east, south-east, south-west and north-west of Australia—by dung fungi. These data provide powerful evidence for synchronised continent-wide extinction of mega-herbivores, which can now be dated with quite high precision. The loss of mega-herbivores was unrelated to climate events, which had varying patterns in those regions; it is possible that it was caused by human impact.

We go on to use new time-series analyses of dung-fungus records along with other palaeoecological proxies to investigate variation in the ecological dynamics of extinction in different regions and to test for differences in the association between extinction and changes in vegetation and fire across the continent. These analyses show that the tempo of mega-herbivore decline was similar in different places, involving relatively abrupt reductions in populations of large herbivores, which extended over periods of one to two thousand years. However, association of extinction with dynamics of vegetation and fire varied among regions. This variation supports the hypothesis that in more productive environments the decline of large-herbivores triggered large increases in the density and biomass of vegetation, which led to increased biomass burning. In environments with low primary productivity, the responses of vegetation to relaxation of herbivory were constrained by abiotic factors, and change in fire was reduced or absent. Evidence for this preliminary hypothesis will be explored.

P-3217

Insights into Mediterranean aridity during the Late Pleistocene using mammalian tooth crown height of large herbivores

David Arnold, Danielle Schreve, Simon Blockley
Royal Holloway University of London, Egham, United Kingdom

The Late Pleistocene was characterised by abrupt shifts in climate in Europe, driven by a range of forcing factors. Evidence of the spread of semi-arid environments is highlighted by the westward migrations of arid adapted mammals. However, relating these faunal migrations to the wider unstable climatic regime is hampered by a current lack of quantitative precipitation estimates at a representative spatial scale and within a robust dating framework. Recent work on both modern herbivores and Neogene fossils has revealed the utility of large herbivore hypsodonty (tooth crown height) as a method of quantifying past and present precipitation. In order to improve the reliability of this method for quantifying present and past environmental variables, a new, geographically extensive and species diverse modern training set using well-provenanced museum specimens has been created. The first application of this new understanding to fossil measurements from Late Pleistocene sites across the Mediterranean is presented here.

Measurements were taken from a number of well-dated sites: Abric Romani (Spain; 40-70 kyr BP), Teixoneres (Spain; 14-100 kyr BP), Le Portel-Ouest (France; MIS 5-3), Grotta del Romito (Italy; c. 24-14 kyr), Qafzeh (Israel; 93 kyr and 31-25 kyr) and Tabun (Israel; c. 300-50 kyr). Here, we show how the mean hypsodonty index of the mammal communities throughout sequences at these sites varies through time, potentially reflecting local or regional aridity patterns. Comparisons are made with pre-existing palaeoenvironmental information from these sites to validate what is seen in the hypsodonty index changes, as well as seeing if abrupt changes in palaeoenvironmental and palaeoclimatic proxies are reflected in our measurements. It appears that at several of these sites changes in mean hypsodonty index are contemporaneous with landscape evolution from open to more forested conditions, suggesting that the hypsodonty indices may indeed reflect aridity patterns.

Existing independent high-resolution chronologies from these sites are used to deliver a robust chronology of hypsodonty-inferred aridity at local and regional scales through the Late Pleistocene. This permits us to assess not only the potential controls of abrupt climate changes on aridity at different spatial and temporal scales but also the effects of these changes upon the palaeoecology, faunal migration and hominins of the Mediterranean.

Cross-trophic assemblage dynamics at the Rancho La Brea Tar Pits

Jessica Blois¹, Nathaniel Fox¹, Katherine Glover², Jacquelyn Gill², Taran Rallings¹, Justin Yeakel¹, John Southon³, Gary Takeuchi⁴, Aisling Farrell⁴, Emily Lindsey⁴

¹University of California - Merced, Merced, USA, ²University of Maine, Orono, USA, ³University of California - Irvine, Irvine, USA, ⁴The La Brea Tar Pits and Museum, Los Angeles, USA

Abstract

Inferring interactions among species within past communities is complex, and requires understanding how such dynamics are structured by environmental change and community context, as well as the process of fossil deposition. We explore niche dynamics, species interactions, and community structure with multi-trophic paleo food webs through time and along climatic gradients, using fossil mammal and vegetation data from the Rancho La Brea (RLB) tar pits in Los Angeles, CA. We first determine community composition and deposition time of both the small mammal and plant assemblages recovered from multiple asphaltic deposits at RLB. We then assess variation in relative abundances among small mammals and plants through time, and use isotopes to infer changes in dietary niche breadth of several focal taxa (ground squirrel *Otospermophilus beecheyi* and rabbits (genus *Sylvilagus*)). Finally, we integrate mammalian and plant data and simulations to build a preliminary model of the consumer-resource interactions that structure the community.

The fossil deposits date to between ~30 ¹⁴C ky BP and >49 ¹⁴C ky BP and capture typical southern California late Quaternary small mammal fauna and flora. Preliminary dates indicate 1) there are some small offsets in the ages of fossils deposited across different taxa within a deposit, but 2) the age distributions of different taxa within a single deposit overlap to a large extent, indicating the potential for the sampled taxa to interact ecologically. Relative abundances among taxa differed substantially between deposits, indicating a dynamic environment over the 20,000 year sampling period. Further, the isotopic niche breadth of both squirrels and rabbits was narrower in the younger deposits and $\delta^{15}\text{N}$ became increasingly positive through time in both ground squirrels and rabbits. These isotopic changes potentially signal dietary changes associated with increasing aridification. We are now exploring which consumer-resource interactions most strongly structured the community through time using, in part, a newly developed foraging profitability model to infer herbivore-plant interactions.

An automated system for recognition and picking of foraminifera using convolutional neural networks

Thibault de Garidel-Thoron, Ross Marchant, Martin Tetard, Adnya Pratiwi
Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, France, France

Paleoclimatic reconstructions at high resolution or at high precision require to process respectively a large number of samples or replicates. In paleoceanography, the main proxy and chronostratigraphic indicator are foraminifera. They are used for geochemical and faunal assemblages' ecological reconstructions. Yet, the protocol used to extract and recognize the foraminifera has not changed since the mid-18th century : manual picking using a brush with a stereomicroscope. However, recent progresses in image processing, and image recognition have paved the way for automated procedures to classify natural objects such as foraminifera.

Here we will present the results we achieve by developing an automaton, the MiSo (Microfossil Sorter) automaton, to automatically pick microfossils from the sediment coarse fraction. This automated system is fully operational and works 24/7 at CEREGE. In this study, we will detail the basic workflow of the automaton and its ability to cope with the large morphological and structural variability of particles encountered in real marginal to deep-sea sediments. We use convolutional neural networks adapted and trained on deep sea sediment samples to classify the coarse sediment particles, including planktonic and benthic foraminifera.

As a test case, we will compare paleoceanographic records generated by a micropaleontologist with the ones generated by our automaton: relative abundance, fragmentation rate, biometrical changes. We have studied two deep sea cores from the equatorial Pacific ocean to document past hydrographic changes in the late Quaternary, and and at high resolution since the last deglaciation. Using the automaton, we processed more than 250,000 foraminifera, the largest image dataset to date. We will show the accuracy of recognition (typically around 85 to 95% depending of the morphoclasses), the morphoclass size probability density function and compare it to multi-proxy (micropaleontological and geochemical) records. Last, we will outline the applications we envision for this automated picking machine.

P-3220

Understanding changes in British palaeobiodiversity through the collagen fingerprinting of Late Pleistocene bone fragments

Michael Buckley

University of Manchester, Manchester, United Kingdom

Ancient faunal remains offer zooarchaeologists and palaeobiologists valuable insights into past ecosystems, particularly with respect to human-driven vs climate-driven impacts. With improved retrieval techniques, excavations can now uncover assemblages that number in the thousands of specimens, and in many cases hundreds of thousands of skeletal remains. However, more often than not, only a relatively small fraction of these are utilised for palaeoecological interpretation. This could largely be due to the highly fragmentary nature of the remains, particularly if predators such as humans or hyaenas were one of the original accumulators, or simply due to lacking widespread expertise for less well-studied taxa, such as microfaunal remains. To harness the full potential of these faunal archives of the past, biomolecular approaches could be utilised, whether this is through DNA, protein, or lipid based studies, each of which have advantages and disadvantages with regards taxonomic resolution and preservation potential of the biomolecule. Here proteins are considered of great potential because they are able to retrieve species information and survive for much greater lengths of time than DNA, in some cases for several millions of years at least. This presentation highlights the application of a recently developed method of species-level identification using collagen fingerprinting, also known as Zooarchaeology by Mass Spectrometry (or ZooMS) to the study of over 13,000 bone fragments from Pin Hole Cave (Derbyshire, UK). This cave assemblage is thought to span three phases of human occupation during the Late Pleistocene and is from within the Creswell Crags magnesian limestone gorge, home to Europe's most northerly prehistoric cave art. The results from the biomolecular species identification analyses not only indicated a range of fauna typical of this period, dominated by fragmentary reindeer remains, but also highlighted the potential for improved taphonomic understanding through comparison of morphologically-identifiable remains with overly fragmented remains. Additionally, decay measurements within the collagen fingerprints were able to be used to identify intrusions in the assemblage, such as pig and sheep, offering information beyond species identification alone. In addition to previously published analyses of megafaunal and microfaunal mammal remains, this presentation also highlights the taxonomic resolution across all vertebrate classes, including birds, reptiles, amphibians and fish, and their application to improving our understanding of vertebrate palaeobiodiversity during the Pleistocene.

Insects, postglacial colonisation and refugia in northern Norway

Aythya Young¹, Eva Panagiotakopulu¹, Inger Alsos²

¹The University of Edinburgh, Edinburgh, United Kingdom, ²The Arctic University of Norway, Tromsø, Norway

Abstract

Although northern Norway is a geographically important region to investigate, palaeoecological studies of Quaternary insect data are limited. A variety of different questions, including immigration of the biota at the end of the last glaciation, evidence for refugia, environmental change and human impact can be answered using the fossil record. This study will investigate climatic and environmental conditions during the Lateglacial and Holocene in northern Norway using fossil insects. A number of sites have been investigated in order to test the possibility of insect survival in refugia during the LGM and whether human presence and impact can be inferred from the fossil insect assemblages.

On northern Andøya, the northernmost island in the Vesterålen group, a lake core which spans from 22 ka to 10 ka BP was taken from Øvre Æråsvatnet for pollen, plant macrofossil and aDNA. This is currently being assessed for beetles and chironomid remains, which have been extracted from these samples to obtain information about insect faunas and climate change in the context of other research from northern Norway.

In terms of Holocene climate and environmental change, fossil insect results from a peat section excavated from the Hollabåttjønnen bog, Tønsnes, provide new information which has been compared to existing pollen and molecular biomarkers studies from the site. The overall findings show that the earlier samples are dominated by heathland associated species indicating a dry environment, and the date and temperature reconstructions place this within the Holocene Thermal Maximum. Change, either edaphic, climatic or a combination of both, led to bog development which persisted through most of the mid-late Holocene. Trees were present throughout the Holocene, as species such as *Deporaus betulae* found largely on tree birch but also on alder, occurred in most samples. Temperature reconstructions from this beetle assemblage will be utilised to understand climate change during this period. Pitfall traps were used to sample the modern insect faunas at the site, and an almost entirely different fauna was recorded, suggesting that a more recent shift has occurred, as a result of human impact in the area.

P-3222

An interdisciplinary approach to climate change studies in southern Colorado using wetlands, geomorphology, soils, forestry, and social science.

Jared Beeton

Fort Lewis College, Durango, USA

Multi-proxy paleoenvironmental research has been conducted for over a decade in the semi-arid mountains of southern Colorado, USA. We have used pollen analysis, soil science, forestry, and radiometric techniques to study modern and paleo wetlands, previously glaciated environments, mountain river systems, paleontological sites, archeological sites, and alluvial fans. Here, we synthesize these data to better understand how environments have changed from the late Pleistocene through the Holocene and offer a unique solution to forest management in a warming and drying climate. A radiocarbon and optically stimulated luminescence controlled study of two paleo wetlands shows pollen species and groundwater levels fluctuating between cooler, wetter environments and warmer, drier conditions through the late Quaternary with a modern warm and dry signal. Temporally controlled data from moraines, kames, glacial outwash deposits, and fluvial terrace sediments also suggest a cooler and wetter Younger Dryas and a fluctuating Holocene climate. Further, temporally controlled soil and sediment data from four archaeological and paleontological sites suggest a similar climate pattern along with the presence of higher water tables and additional surface streams in the late Pleistocene and into the early Holocene compared with today. Forestry data from the Rio Grande and San Juan National Forests provide a strong modern signal of warming and drying through the accelerated presence of pine/spruce beetle outbreaks. As forests become warmer and drier, forest managers are promoting the removal of many beetle-kill spruce trees. A unique solution lies in using these trees for guitars. Ongoing natural and social science research examines management of North American spruce forests for guitar tone woods and experiences of luthiers, manufacturers, harvesters, and players. Our hope is to promote beetle-kill spruce while reducing harvest pressure on living forests. A synthesis of these environmental studies suggests two major conclusions: 1) A multi-proxy approach to paleoenvironmental research can help draw connections between paleo and modern climate change. Specifically, our study of paleo wetlands and fluctuating water tables ties the late-Pleistocene and Holocene geomorphic story to current environmental changes, while our study of beetle-kill forests ties the modern wetland pollen data to a concrete, highly visible example of the modern signal. 2) Throughout the late Quaternary and into the 21st century, when temperatures warm in southern Colorado it gets drier, and when temperatures cool it gets wetter. This has major implications for future climate change in the already semi-arid southwest USA.

P-3223

Disentangling the influences of climate and human management on fire in the Yosemite region of California, U.S.A.

Richard Vachula, James Russell, Yongsong Huang
Brown University, Providence, USA

Abstract

Recent large fires have sparked great interest in the drivers and controls of fire in the western U.S.A. Understanding the relative influences of climate change and human management has great societal importance as fires in these ecosystems gain increasing prominence in political and public discourse. Lake sediment records offer paleoenvironmental context with which we can assess the magnitude of observed burning and infer fire-climate relationships on centennial and millennial time scales. We present a charcoal-based fire reconstruction from Swamp Lake, Yosemite National Park, spanning the last 1,400 years, anchored by a high-resolution, varve-based chronology. We compared recent changes in charcoal accumulation to historical records of area burned in order to determine the spatial footprint of three size fractions of charcoal to reconstruct fire history within 25 km (charcoal > 250 μm), 35 km (charcoal > 150 μm), and 150 km (charcoal 63-150 μm) of Swamp Lake. We also compare our reconstruction with detailed paleoclimate, archaeological, and historical datasets to dissect relationships between fire, climate, and human activities. Fire activity in this region was generally correlated across local and regional scales, and climate (temperature and aridity) was the dominant control on fire activity throughout the record. A warmer and drier climate resulted in increased burning, which does not bode well for the region in light of the warmer and drier conditions predicted for the western U.S.A. in the future. However, we also observe time periods in which fire activity at different spatial scales do not correlate. These time intervals coincide with periods of pronounced human influence upon the environment, during which humans strongly influenced local fire activity while climate remained the predominant control of regional fire. Thus, climate acts as a top-down control while human management acts as a bottom-up control on fire. Despite the societal impacts of recent fires, burning in the last 50 years, partly influenced by fire suppression efforts and their legacy, was low relative to the last millennium. Taken together, these results indicate that, without active management, burning in this region is likely to be more spatially extensive and frequent in the future.

Abstract

Colca Valley, one of Peru's top tourist destinations, comprises deep canyons with multiple terraces. Tectonism, volcanism and landslides have formed this stunning landscape, but also pose major hazards. A cooperative research venture – between Simon Fraser University's Centre for Natural Hazards Research, the Peruvian Geological Survey (INGEMMET) and Université Clermont Auvergne – is investigating the Maca and Lari landslides and related aspects of the geomorphic evolution of Colca Valley. Knowledge being gained through this collaboration is fundamental to effective hazard and risk management, supports geoscience outreach to local communities and will possibly be incorporated into existing Geopark displays.

We conducted a field-based textural, structural and stratigraphic study of Quaternary deposits to reconstruct the valley's geomorphological evolution. We combined mangentostratigraphy, cosmogenic dating, tephrochronology, optically stimulated luminescence dating (OSL), and radiocarbon dating to constrain the age and spatial relation of debris avalanches, lava flows and lacustrine sediments. The valley contains at least three levels of lake sediments spanning ~1.1 Ma that record impoundments by landslides or lava flows from the nearby Hualca Hualca stratavolcano. We gave particular attention to the stratigraphy of the active landslides affecting the towns of Maca and Lari. Both are large, hummocky rock avalanches deposited onto the middle and lowest lake terraces, respectively. Both have reactivated as complex failures due to undercutting of underlying lake sediments by Río Colca. Recent deformation involves the entire sequence and affects the towns. A 5.3 M earthquake on August 14, 2016 killed four people and exacerbated movement on both failures. Multicomponent monitoring by INGEMMET indicates increased movement correlates with high rainfall and seismic events.

Both rock avalanche deposits contain multiple sedimentary facies, indicating variable emplacement rheology. Lari debris includes large rip-ups of lacustrine sediments and may have been deposited in a paleolake. Lake and distal fan sediments blanket much of the landside, producing a more subdued topography than Maca. The Maca landslide is ~8000-9000 cal years old based on radiocarbon analysis and ¹⁰Be on feldspar. Lari is older; cosmogenic, OSL and radiocarbon samples were collected in May 2018 to better refine its age. Sediments directly above and below both landslides are normally magnetized. Preliminary magnetostratigraphy of lacustrine sediments and associated volcanic rocks infilling Colca Valley record an N-R-N polarity sequence, indicating that infill began by at least the Jaramillo subchron (1.072-0.988 Ma).

The high landslide hazard of Colca Valley has a multitemporal dimension. Rapid tectonic uplift, consequent deep canyon incision, and subsequent active volcanism led to very large landslides that produced lakes and their deposits. Fluvial incision and undercutting of these sediments drives modern instability that directly affects the valley's communities. A better understanding of past mass movements and their relation with the paleo-environment is helping understanding current and future hazards.

¹ISEM, University of Montpellier, CNRS, EPHE, IRD, Montpellier, France, ²CEREGE, Aix Marseille University, CNRS, IRD, Aix en Provence, France, ³Institute of Geosciences, University of São Paulo, São Paulo, Brazil, ⁴CEREGE, Aix Marseille University, CNRS, IRD, Aix en Provence, Brazil

Abstract

The Colônia crater is one of the best natural laboratories to test vegetation and climate dynamics through the quaternary in South America. Particularly, the intriguing geological origin of the basin which is thought to be formed by a meteorite impact has allowed having a continuous sedimentary infill that until now is known to have 300 meters depth. In this context, the crater is an excellent site for coring long sedimentary records. In addition to that, the Colônia basin is also a key site to research the long-term processes that have affected the landscape in the past, due to its location between the southernmost influence of the South American Summer Monsoon (SASM) and the northernmost limits of polar air advection. In this regard, and based on previous studies, a scientific deep drilling project was built with the aim of understanding the long-term biotic and abiotic processes that have occurred in the Crater. A new sedimentary record was recovered at Colônia, Southeastern Brazil. The new sediment archive includes a lake and a bog deposit accumulated during several glacial-interglacial cycles in the basin of Colônia. A total of 115 meters of overlapping sediment cores were drilled from three closely-spaced holes. Here we will present the first results from multi-sensor core logging, sediment description, chronology, and multi-proxy analyses. The chronological frame includes radiocarbon, Optically-Stimulated Luminescence (OSL), paleomagnetism and ¹⁰Be dating, which led to an approximate age of 1.7 million yr BP. The multi-proxy data includes X-ray fluorescence spectrometry (XRF), pollen, diatoms and biomarker analyses. The results provide clear signatures for alternating glacial-interglacial sediment facies in phase with global changes of the early Quaternary.

P-3226

Modelling the evolution of Brazil's Atlantic Forest through the Quaternary in high spatial, temporal and taxonomic resolution.

Oliver Wilson¹, Richard Walters^{1,2}, Francis Mayle¹, Débora Lingner³, Alexander Vibrans³

¹University of Reading, Reading, United Kingdom, ²Lund University, Lund, Sweden, ³Universidade Regional de Blumenau, Blumenau, Brazil

Abstract

Brazil's Atlantic Forest is a global biodiversity hotspot with a precarious present and uncertain future. 20th-Century habitat changes decimated the different forest types in the south of the biome, as well as its highland grasslands which have occupied the high elevations since the last glacial period. With the coming decades set to bring warming temperatures and disrupted rainfall regimes, 21st-Century climate change presents a further threat to the biome's survival. Understanding how the southern Atlantic Forest has responded to previous changes in conditions may help forecast the biome's dynamics into the future, but its past is unclear.

A number of fossil pollen studies have examined ecotones between Araucaria forest and grasslands at high elevations in the east of the southern Brazilian highlands, but the palaeoecology of the region's other forests is far less well understood. Existing pollen records agree that grasslands covered the highlands from the last glacial period, but their spatial limits are not known. The extent to which subsequent late-Holocene forest expansion was driven by climate changes or pre-Columbian societies is another topic of considerable debate. Broad-brush modelling studies have predicted a large area of high biome stability in southern Brazil, with potentially sizable refugia of Araucaria forest and grasslands identified and smaller forest microrefugia inferred. However, the locations of these putative areas are not well constrained, and the type of vegetation which occupied them is largely unknown: the region's forests exhibit significant floristic heterogeneity, containing variable mixtures of temperate, cold-adapted and tropical taxa – the biome is unlikely to have remained unchanged since the previous glacial period.

Here, we provide detailed insights into the dynamics of the whole southern Atlantic Forest through the Quaternary, using robust models with high spatial, temporal and taxonomic resolution. By combining published palaeoclimate data with statistical downscaling techniques, we make detailed projections of the extent of the region's various vegetation types at dozens of key intervals since the Last Interglacial, identifying potentially microrefugial areas. Modelling ecologically key taxa from five different vegetation types allows floristic changes within the forests over time to be examined, identifying no-analogue assemblages and highlighting areas where non-climatic drivers (e.g. grazing, fire or competition) may have dictated community composition. We make detailed comparisons between the models' outputs and an extensive suite of palaeoecological records, allowing our predictions to be verified and potential causes of disagreement (e.g. changed CO₂ concentrations or human land use) to be explored.

By shedding light on the Atlantic Forest's past in this unprecedented detail, we hope to inform the ongoing debate around the origins and maintenance of the biodiversity in this hotspot, as well as helping to secure it in the face of an uncertain future.

P-3227

Hunting deer at Cerro Mangote: A Panamanian Late Preceramic site

María Fernanda Martínez-Polanco

Àrea de Prehistòria, Universitat Rovira i Virgili (URV), Tarragona, Spain, Institut Català de Paleoecologia Humana i Evolució Social (IPHES), Tarragona, Spain

Abstract

People used pacific isthmus route to migrate to South America, as the Panamanian archaeological record shows. The first populations take advantage of natural resources and they direct impact the pristine environment that they found. Late Preceramic Communities (7000-6000 BP) located on the coast and in the foothills of Panama practiced a mixed economy of fishing, hunting, shore-line foraging, wild fruit collection and farming. Cerro Mangote (5900-3020 cal yr BP) is a preceramic dump site where abundant marine shells and cultural debris are present. Cerro Mangote is situated top of a small hill on the north bank of the Santa María River, at the inland edge of high tidal flats, or "albinas". This site evidences coastline changes in Parita Bay, because at the time when was occupied it was likely to have been 7 km further inland, today the site's eastern edge is now 8 km from the active marine shoreline of Parita Bay. The actual environment surrounding the site is characterized by the presence of cane fields and cattle pastures and remnants of wooded savannas. The zooarchaeological record of the site evidences mud flats, mangroves, riverine woods and open areas.

The subsistence strategies held by the human groups that inhabited Cerro Mangote consisted in hunting deer (*Odocoileus virginianus*), raccoons (*Procyon lotor*), iguanas (*Iguana sp.*) and other small reptiles. They also birding in mangroves and scrub forest, collecting shellfish, crabs. As well, collected and cultivated plants. They hunted deer's one of the most important prey because they provided meat, fat and bone marrow. The white-tailed deer has a great plasticity for its nutritional requirements. They also are well adapted to crops. Crop cultivation could increase the deer population, because it has been observed that deer prefer second-growth vegetation and would thus have been favored by the disturbance of primary forest cover by the expansion of agricultural fields. The aim of this presentation is to better understand the evolution of human subsistence strategies through time towards deer hunting and the importance of environmental patterns in these changes in Panamanian pre-ceramic groups focus on the archaeological sample of Cerro Mangote. To achieve so, I propose a multi-proxy zooarchaeological and taphonomical analysis. I will present the results of a taphonomic and zooarchaeological analysis of deer remains.

P-3228

Late Holocene climate implications and later prehistoric landscape modifications in the tropical and semi-arid regions of Indian Peninsula

ARJUN RAVINDRA RAO

School of Business Studies and Social Sciences, CHRIST (Deemed to be University), Hulimavu 560076, Bangalore, India

Abstract

This paper stress on the number of cultural features studied as a signature for micro studies in our archaeological projects to understand the changes in economy, politics of south Indian later prehistoric population resulted at major landscape modifications, and site formation processes associated with frequent climatic variations occurred during the late Holocene. Paleoclimate studies on reconstructing the Indian Summer Monsoon (IMS) from various lakes, river and ocean sediment cores identified aridification of climate in the Indian subcontinent during last c. 4500 to 1500 ka. Unstable river behaviors such as weakening of river dynamics and occurrence of recurrent flash floods determined by the monsoon precipitation in the rivers of Western Ghats originate (example Kaveri, Krishna and Tungabhadra) in Indian Peninsula have implications on the developments of later prehistoric societies during the last three millennium BCE (Neolithic, 3000-1200 BCE and Iron Age during 1200-300 BCE). Such developments in the environment coincided with the nature of expansion of agricultural population, crop suites, subsistence changes and settlement established away from the riverine environs. However, recent archaeological studies by the present author in South India focusing on two different ecology, such as the tropical Western Ghats (Koppa Archaeological Research Project) and semiarid region of central Deccan plateau (Brahmagiri Landscape and Settlement Survey project) are showing differences in population adaptability to regional ecologies and resources. Their commonalities are relatively contemporary in the expansion of sites at such above dynamic environments bearing with similar production of cultural materials in the society. Yet in the terms of their landscape modification and how they managed space within the sites and nearby sites have major variations to record from the cultural features (stone tools, ceramics and burials) and spatial patterning beyond the cultural materials; which are associated with the ritual and economic practices invariably governed by fluctuating climate and nature of landscapes. Number of key distinctions is evident on this regards from the various sites in above study areas; one, water collection and management led by fluctuating monsoon precipitation taking shape in local politics and resource of economic importance regulated through the introduction of artificial pools/ reservoirs. Two, sites shifting from riverine to non-river environs and surrounding the natural springs in shaping the site economy; three, living in the rock shelters and open scrubs on whether imprints of rock art and sonic production due to nature of denudational and pediplain landscapes etc. They collaterally indicate at the development of new cultural landmarks with changes in climate and availability of suitable landscapes.

Abstract

The global increase in species diversity towards the equator, referred to as the latitudinal diversity gradient (LDG), is one of the most striking biodiversity patterns on Earth. In this study, we propose a spatially explicit model of diversification to evaluate the predictions of four major hypotheses potentially explaining the LDG, namely, the 'time-area', 'tropical niche conservatism', 'ecological limits' and 'evolutionary speed' hypotheses. This mechanistic model consists of simulating the evolutionary dynamics of species ranges by explicitly linking speciation, extinction and dispersal processes to both changes in habitat configuration and climatic conditions through geological time. We compare simulation outputs to observed diversity gradients in the global reef fish fauna, which are a dominant group of vertebrates with thousands of species found in shallow reefs worldwide. The distribution of reef fishes has been intensively studied for decades, but its underlying causes and processes are still under scrutiny. Simulations were run based on the paleo-environmental reconstruction of potential reef habitats in temperate and tropical regions over the last 130 million years. Our results show that the relative importance of these hypotheses depends on the time scale considered. Habitat changes caused by plate tectonics determined the global distribution of reef fish diversity during deep geological periods, while ecological constraints due to the shrinkage of tropical habitats during the Neogene likely produced the marked LDG that we observe today. Overall, this study calls for studies combining different disciplines, such as biogeography, macroevolution and paleoenvironmental reconstruction, in order to provide a temporal and spatial understanding of the role of speciation, extinction and dispersal in generating contemporary biodiversity patterns.

Palaeoenvironmental reconstruction of four shell midden sequences in caves within the Tràng An massif, northern Vietnam

Evan Hill¹, Ioanna Bachtsevanidou Strantzali¹, Christopher Stimpson¹, Marcus Verhoeven², Shawn O'Donnell¹, Ryan Rabett¹

¹Queens University Belfast, Belfast, United Kingdom, ²RAAP Archaeological Consultancy, Veenendaal, Netherlands

Abstract

Over the course of the past two decades there has been a growing research interest in the site formation processes associated with shell middens and how these features can enhance dietary, cultural and palaeoenvironmental reconstruction. Coastal shell middens have drawn particular attention; comparatively less has been devoted to middens containing fresh water or terrestrial molluscs from more inland localities. This paper examines midden formation from caves set within a sub-tropical karst landscape in northern Vietnam – the Tràng An massif, World Heritage Site – that has experienced both coastal and inland conditions.

Four cave sites are discussed (Thung Binh 1, Hang Moi, Hang Boi and Hang Trong), combining previous work with assessments of new archaeomalacological assemblages. Excavation of these sequences has been undertaken as part of the SUNDASIA project, a multi-disciplinary research initiative focusing on the past 40,000 years of archaeological, geological and ecological development of the Trang An massif in Ninh Binh Province, northern Vietnam.

Within the studied midden sequences, the terrestrial Mollusca component, mostly comprising various species of intact Cyclophoridae (>90% of midden assemblages) is dominant throughout. Most contexts in each studied sequence also contain varying quantities of freshwater and estuarine species of Mollusca, mainly; *Sermyla riqueti*, *Unio* sp., cf. *Meretrix* sp., *Ostrea* sp. and *Crassostrea* sp. Taphonomically, the majority of midden assemblages contained intact or near intact specimens. This suggests that, along with the presence of burnt shell layers of *Ostrea* sp. and *Crassostrea* sp. and the presence of occasional shell artifacts throughout all four sequences, that the formation of midden stratigraphy occurred predominantly through human action and that cave occupation was largely associated with their formation. The very low incidence of 'micro mollusc species' <5mm in size, which only start to appear in sub-tropical forest soils during periods of long term vegetation stability, suggests that significant parts of the record of human occupation at these sites was associated with disturbed habitats.

The Tràng An massif contains evidence of human occupation across and between the last three major marine transgressions in northern Vietnam; the Quang Xuing (2600-1500 cal. BP), Dong Da (7000-4000 cal. BP) and Vinh Phuc (59,000-30,000 cal. BP). Analysis of archaeomalacological assemblages from these sites offers us a reliable, independent palaeoenvironmental dataset that can be associated directly with their geoarchaeology and chronostratigraphy, enabling the reconstruction of conditions across much of the last 40,000 years, and helps to elucidate the impact that marine transgressions had on ecology of this landscape as well as the humans living there.

Spatial distribution of mass movement processes in tropical mountains: Implication for geohazard assessment based on examples from Colombia and Peru.

Aleksandra Tomczyk¹, Marek Ewertowski¹, Ramón Pellitero²

¹Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznan, Poland, ²Department of Geography, National Distance Education University, Madrid, Spain

Abstract

Recent climate changes and land-use/land-cover changes can control geomorphic dynamics in many tropical mountain areas. Observations and simulations suggested a substantial role of land use changes in the intensification of hazardous debris flows and landslides (Figure 1); however, this has yet to be fully recognised. Moreover, the quantitative aspect of recent geohazards related to land-use and climate changes remains also largely unknown despite being critically important due to their potentially substantial impact on numerous human communities. This study employed field-based and remote sensing observations to quantify and compare the geomorphic sensitivity of tropical mountain landscapes to direct anthropogenic influence in two key locations in the Andes characterised by different socio-economic and environmental conditions: Eje Cafetero, Colombia and The Cordillera Vilcanota, Peru.

We mapped the distribution of mass movement processes based on their traces detectable in high-resolution satellite imagery. Mapped features included landslides, debris flow channels, erosional rills, and rockfall deposits. Time-series of imagery allowed us to study temporal changes in the occurrence of hazardous geomorphological processes and their potential impact on human communities and infrastructure. Mapped areas were also ground-checked during the fieldwork, and detailed topographical data were collected for several key locations using repetitive unmanned aerial vehicle surveys.

Studied sites comprise reasonably small areas (~500-1000 km²); hence, the global factors (like climatic conditions, tectonic activity, indirect global human impact) were more or less uniform in any given area. As such, it allowed us for investigation of local factors and their correlation with mass movement activities. Four main groups of factors were tested: (1) topographic properties (slope, curvature, slope length, size-dimension-orientation of valleys); (2) geology (type of rock, pre-existing rock conditions); (3) local climate (exposition, potential amount of solar energy); (4) direct human impact (changes in land-use, occurrence of roads, mining sites, and other types of infrastructure). Statistical analyses were performed to assess the influence of individual factors (and their groups) on the distribution and intensity of mass movement processes. Based on the results we proposed a conceptual model presenting the development of modern-day mass movements in mountain areas affected by different degrees of direct human impact.

The research was funded by the Polish National Science Centre, Poland (Project number 2015/19/D/ST10/00251)

Paleoclimatic reconstitution of the Monte Cristo Cave, Minas Gerais, Brazil, through Phytolith analysis

Heloisa Helena Coe^{1,2}, Karina Chueng², Alessandra Vasconcelos³, Joël Rodet⁴

¹Universidade do Estado do Rio de Janeiro, São Gonçalo, Brazil, ²Universidade Federal Fluminense, Niterói, Brazil,

³Universidade Federal dos Vales do Jequitinhonha e Mucuri, Diamantina, Brazil, ⁴Université Rouen-Normandie, Rouen, France

Abstract

The study area is part of the project known as "Environmental Dynamics and Biogeoclimatic Evolution in Karst Environments formed in Carbonatic and Siliciclastic Rocks at the Western Edge of the Southern Espinhaço Range" in the state of Minas Gerais, Brazil. The project aims to contribute to the understanding of paleoclimatic variations in karst environments throughout the Quaternary. In the present study, results are presented on the Monte Cristo Cave, formed in quartzite. The objective is to contribute to the understanding of paleoclimatic variations in the region during the Holocene, evaluating how the caves respond as a paleoenvironmental analysis environment using phytoliths as proxy. Phytoliths are microscopic particles of biogenic opal, which are formed through precipitation of amorphous silica between and within cells of several living plants, as a result of silicic acid absorption of the soil solution by plants. Previous studies carried out in the region using phytoliths as indicators of climatic variations in areas of "cerrado" (savannah) formations have shown promise for inferences on vegetation and climate. Two profiles were collected, the first being an Organosol outside the cave and the second consisting of mostly sandy sediments inside the cave, in layers that vary in color between light and dark tones. The results showed that both profiles present a high stock of phytoliths, with very similar observed morphotypes, which follow the pattern of decreasing with the depth. The phytoliths are well preserved; with a predominance of globular echinate and globular granulate types, produced respectively by Arecaceae and woody dicotyledons, besides the presence of bulliform cuneiform, cross, bilobate, rondel and trapeziform types, produced by Poaceae. The tree density index (D/P) is low in both profiles (between 0.19 and 0.36), indicating open vegetation. The mean values of the Bi% index (32.8 to 53%) indicate moderate water stress, similar to the results found in previous studies in nearby regions. The Ic (climatic) index showed variation in plant adaptation at lower temperatures, with a predominance of C3 grasses, while the Pa/P index (palm tree density) indicated the presence of palm trees along both profiles. The ages obtained by ¹⁴C-AMS in the organosol were from 4440/4230 to 2740/2430 years cal BP, and the sediment samples within the cave from 1000/920 to 660/550 years cal BP. The vegetation type remained stable during the analyzed period, characteristic of rupestrian fields with the presence of woods in more humid environments. The phytoliths found inside the cave have an allochthonous origin indicating that the material is alterite, not sediment, it probably having been carried by flooding in periods under different hydrogeomorphological conditions. The results were promising for the paleoenvironmental understanding of the region.

Palaeoclimatic reconstruction of areas of the Caatinga Biome, Northeast Brazil

Heloisa Helena Coe^{1,2}, Raphaella Dias², Sarah Ricardo³, Leandro Sousa⁴

¹Universidade do Estado do Rio de Janeiro, São Gonçalo, Brazil, ²Universidade Federal Fluminense, Niterói, Brazil,

³Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, ⁴Universidade Federal Rural do Semiárido, Mossoró, Brazil

Abstract

The *Caatinga*, a typical biome in Northeast Brazil, is composed of a mosaic of dry forests and steppe vegetation with enclaves of moist montane forest and savannah. Despite this, it is the Brazilian biome with the second lowest number of protected areas in its domain and with very few paleoenvironmental studies. The current prevailing climatic conditions are semi-arid, and their intensification has affected economic and social development. In order to contribute to the discussion on the paleoenvironmental evolution of this biome, the objective was to investigate if there have been changes in the vegetation linked to climatic variations during the Holocene. Twenty soil samples were collected in four profiles in the states of Rio Grande do Norte and Ceará. In this study phytolith analyses are used, complemented by pedological and carbon isotope studies. Phytoliths are microscopic opal particles that are formed by precipitation of amorphous silica within or between the cells of living plants. The amount of organic carbon and phytoliths in the soil present a normal trend in all the profiles, decreasing with depth, except for some horizons with a higher stock of phytoliths, which is probably due to the finer grain size or organic matter accumulation. In all the profiles the phytoliths are well preserved, with the classified percentage decreasing with depth. The predominant phytolith types in all the profiles were those of grasses (bulliform and acicular), in some cases with the presence of saddle type, characteristic of dry environments. For the period being studied (between 10000 and 500 years cal BP), the tree density index (D/P) always presented low values, Profile 1, which has the driest environment, being that which presents greater anthropic changes in vegetation and soil use. The climate in the Northeast has undergone changes during the Holocene, for example there are records of a moister climate and/or moister environments than the current at around 3000 years cal BP. In all the profiles, there is a tendency of decreasing D/P and increasing water stress towards the surface, indicating that tree coverage was denser in the past, suggesting a more humid environment than the current. This increase in aridity may be due to natural causes of variations in the regional climate, but one cannot ignore the hypothesis that this natural tendency is aggravated by the anthropic influence on the vegetation of the present *Caatinga*, since the region is historically and erroneously associated with low diversity and drought, and thus has few affirmative actions of preservation and conservation. Phytoliths have been shown to be promising for vegetation studies in this biome, because they are well preserved in the soils, especially since this is an area lacking suitable environments for the use of other proxies.

Pyromagnetic enhancement of an Anthropogenic Dark Earth from Amazonia

Giancarlo Scardia¹, Filippo Stampanoni Bassi², Luigi Jovane³, Igor Carrasqueira³, Giliane Rasbold⁴

¹Universidade Estadual Paulista (UNESP), Rio Claro, Brazil, ²Museu da Amazonia, Manaus, Brazil, ³Universidade de Sao Paulo, Sao Paulo, Brazil, ⁴Universidade Estadual de Maringa, Maringa, Brazil

Abstract

In the Amazon basin, paleoindian occupation and land use are associated with a dark, organic-rich soil, known as *Terra Preta do Índio* or Amazon Dark Earth (ADE). Although the anthropic origin of ADE is currently accepted, it is not clear yet if it resulted as by-product of daily human activity or it is an allochthonous sediment intentionally deposited to improve the fertility of the latosols. Rock magnetism analyses have been carried out on samples from the Bom Socorro archeologic site (Itacoatiara, Amazonas), where the ADE occurs over an area of 6 ha at the rim of the fluvial terrace of the Urubu River. From top to bottom the site stratigraphy consists of ADE (30–50 cm-thick), a transitional horizon (50–60 cm-thick), and the lateritic soil. Radiocarbon chronology indicates that ADE experienced a polyphasic development through two different moments of anthropic occupation at 385–535 cal yr AD and 1460–1635 cal yr AD, respectively. Magnetic susceptibility values show a ten-fold increase from the lateritic soil to the ADE, associated to the occurrence of low-coercivity magnetic mineral, interpreted as maghemite on the base of thermomagnetic curves and FORCs. Unmixing analysis of the IRM acquisition spectra indicates goethite as main magnetic mineral in the lateritic soil, with a minor amount of hematite. The distinctive magnetic properties of the ADE are interpreted to have been originated by fires related to the daily anthropic activity at the settlement, including both ceramics production and waste burning. Formation of maghemite, primarily responsible for the magnetic enhancement of the ADE, is directly linked to burning in the presence of organic matter. Temperatures of about 200–300 °C allowed the conversion of iron (oxyhydr)oxides from the lateritic soil to magnetite, which eventually transformed into maghemite by low-temperature oxidation. Magnetic enhancement of the ADE with respect to the underlying lateritic soil may be used as discriminant physical property for future large-scale prospections, considering that the total extent of the ADE in the Amazon basin is still largely unknown.

University of Bergen, Bergen, Norway

Abstract

Vegetation dynamics-inferred climate change, changing sedimentation regimes, and evolutionary history of the North Andean flora during the Quaternary have been remarkably well monitored in high-resolution pollen records from deep sedimentary basins. Here we present a composite pollen record from three high-Andean lakes jointly reflecting the full Quaternary in over 6000 pollen spectra. Records from Funza09 (2550 m alt., from 2250 to 128 ka; 1200 years resolution), Fúquene-9C (2540 m alt., from 280 to 14 ka, 60 years resolution), and La Cocha (2780 m alt., last 14 ka, 30 years resolution) show a stunning record of glacial-interglacial cycles, millennial-scale climate variability, and numerous events of rapid climate change (mostly 2-4°C, up to 10°C at Pleistocene Terminations). Temporary disappearance of biomes due to differences in upslope migration speed, immigration of Northern Hemisphere arboreal taxa, and suites of no-analog vegetation types are also shown. Grain-size analysis documents periods with riverine and lacustrine environmental settings and allows improved interpretations of long continental pollen records.

This unprecedented documentation of *temporal* change provides insights to understand better the *spatial* dynamics of high mountain biomes. Reconstructed changes in the pollen-based upper forest line positions were used to estimate quantitatively changing páramo distribution and extent during the last million years. Highly variable periods of fragmented and connected páramo areas reflect the extremely dynamic history of this archipelago of 'paramo sky islands'. The stunning high rates of speciation of the páramo flora during the Quaternary (shown by molecular phylogenetic studies) are now better understood in the context of this extremely dynamic system of páramo 'islands' fuelling connectivity (gene flow and hybridization), isolation (speciation), and fragmentation (allopatric speciation). Remarkably, numerical analysis of pollen composition of the last 10 interglacial periods during the last million years shows a high resilience of floral composition. No significant difference is observed in North Andean upper montane forests among the last 10 interglacial periods. Indeed, connectivity of the montane forest appeared to be extremely high during most of the Quaternary as cool and cold glacial conditions prevailed c. 75% of the time. Plant populations migrated maximally over 1500 m vertical distance with low risks of species loss as a consequence.

Long-continental pollen records are now contributing to a new field of geo-ecological research and allow quantifying the conditions which stimulated an unprecedented rate of speciation in the North Andean páramo biome.

Vegetation changes in the catchment of Lake Alaotra, Madagascar

Nils Broothaerts¹, Vao Fenotiana Razanamahandry¹, Liesa Brosens¹, Benjamin Campforts¹, Liesbet Jacobs¹, Tantely Razafimbelo², Gert Verstraeten¹, Steven Bouillon¹, Gerard Govers¹

¹KU Leuven, Leuven, Belgium, ²University of Antananarivo, Antananarivo, Madagascar

Abstract

To understand the driving processes for changes in tropical landscapes and its related problems such as soil degradation, it is crucial to gain insight in the relative importance of human disturbance and natural variation in these environmental changes. Madagascar is known for its particularly high erosion rates in the central highlands, yet the role of human disturbance versus natural processes are not well understood. Recent studies have challenged the traditional view that the observed erosion processes and sediment fluxes in Madagascar are mainly driven by recent large-scaled deforestation. However, at present almost no quantitative data is available to couple vegetation dynamics and sediment fluxes over time in Madagascar. This study aims to provide more insight in landscape changes (vegetation changes, sediment mobilization and deposition) in central Madagascar, and in the specific role of human disturbance versus natural drivers. The study focuses on the 1800 km² catchment of Lake Alaotra, located ca 200 km northeast of Antananarivo, Madagascar's capital. Lake Alaotra is formed in a graben system in the highlands of Madagascar, and is the largest freshwater lake of the country (400 km²). A pollen record from Lake Alaotra was used to reconstruct regional vegetation changes. Radiocarbon dates of extracted pollen provide a detailed chronostratigraphic framework. The pollen record provides an overview of natural vegetation dynamics and increasing human impact on the vegetation throughout the Late Holocene. Multivariate statistical analysis of the pollen data (cluster analysis and non-metric multidimensional scaling) was used to semi-quantify human impact on the vegetation. The organic carbon concentration in the lake record varies between 10 and 20 %. $\delta^{13}\text{C}$ data on the organic carbon shows an increase towards present (from -21 to -15 ‰). Overall, this study provides a spatial and temporal integrated reconstruction of vegetation changes in the catchment of Lake Alaotra and provides a better understanding of landscape changes in central Madagascar.

Reconstructing tropical wetlands and Maya agroecosystems in northwestern Belize

Samantha Krause, Timothy Beach, Sheryl Luzzadder-Beach
The University of Texas at Austin, Austin, USA

Abstract

Wetlands are threatened and critical components of tropical systems globally. The geomorphology and ecology of these systems were once limited areas of study, but are now growing disciplines that scholars are embracing to meet the challenges of the Anthropocene. Further, Neotropical wetlands are proving to have played an intensive role in agriculture among the ancient Maya. These wetland agroecosystems were spatially and temporally complex, and served different purposes across the Maya world depending on groundwater quality and spatial arrangement. Here we present our recent research within forested fluviokarst wetlands along the Belize/Guatemala border. Through LiDAR and other remote sensing efforts, field survey, and excavation, and we now recognize that wetlands in this region have undergone extensive anthropogenic modification in the form of agricultural field building and channelization during the Maya Classic (1650-1050 years before present) with use possibly extending into the early Maya Postclassic (1050-700 years before present). Through many field seasons of study, we have developed a chronosequence for paleosols and a temporal understanding of human management within this wetland environment. Here we characterize soil profiles, present new geochemical (ICP-MS) and isotopic ($\delta^{13}\text{C}$) analysis of these buried soils, and refine our understanding of soil development and sedimentation within the system, as well as explore the lines of evidence for and against an anthropogenic burn layer throughout the system that could represent wide scale clearing during the Maya Terminal Classic. By synthesizing soil geochemistry as well as micro and macrocharcoal records from wetland sediment cores, we consider anthropogenic forest clearing and cultivation, as well as natural patterns of tropical fire sequences to better understand how these factors control long term wetland development and geomorphology. The spatial and temporal patterns of charcoal variability within these sequences enhance our understanding of both long term anthropogenic impacts on fire regimes as well natural drought cycles and environmental change within the region. This research demonstrates the complexity of human engineering and modification during culturally significant periods of ancient Maya occupation in this region, provides new chronologies of soil development and wetland genesis, and provides a case for the succession and recovery of tropical wetlands after intensive anthropogenic manipulation terminates. Further, this research enhances our understanding of the direct and indirect benefits of tropical wetland agroecosystems, and can be synthesized with ongoing research on tropical watershed and wetland ecology, modern use and restoration, and long-term environmental change.

Vegetation history and sea level changes at the terminals of the Gorgan and Tammisheh Walls (SE Caspian Sea)

Suzanne Leroy^{1,2}, Francois Demory¹, Francoise Chalie¹, Jebrael Nokandeh³, Hamid Omrani Rekavandi⁴, Eberhard Sauer⁵

¹Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, , Aix-en-Provence, France, ²Aix Marseille Univ, CNRS, Minist Culture, LAMPEA, UMR 7269, Aix-en-Provence, France, ³National Museum of Iran and Research Institute of Cultural Heritage and Tourism, Tehran, Iran, Islamic Republic of, ⁴Iranian Cultural Heritage, Handcraft and Tourism Organisation of Golestan Province, Gorgan, Iran, Islamic Republic of, ⁵School of History, Classics & Archaeology, University of Edinburgh, Edinburgh, United Kingdom

Abstract

In northern Iran, the Walls of Gorgan (c. 200 km, W-E) and Tammisheh (12 km N-S) were built to protect the Sasanian rural and urban populations from the northern nomad attacks. They were built of fired mudbricks around the 5th century AD. The Tammisheh Wall ends below the present-day water level of the Caspian Sea in the Gorgan Bay; while the former wall is covered by marine sediment at its extremity close to the sea.

A series of cores were taken at the known ends of the walls by the sea or in the sea in order to link the timing of the wall construction to sea level change and vegetation history. The Caspian Sea level has fluctuated widely in the last millennia with a highstand around 600-300 BC (the likely ground on which the wall was constructed), the Derbent lowstand (Late Antiquity-early Middle Ages) when the walls were constructed, and finally the Little Ice Age highstand long after the walls had been abandoned.

The vegetation history reflects on the one hand human activities such as agriculture and arboriculture, and on the other hand the extension and contraction of the Alder carr along the coast. Other microfossils contribute to establish the palaeosalinity of the water.

P-3402

Micro disseminated noble metals in Pleistocene sediments of the South Caspian oil-gas basin

Dadash Huseynov, Elmira Aliyeva

Geology and Geophysics Institute of Azerbaijan National Academy of Sciences, Baku, Azerbaijan

Abstract

The geochemical testing of the fault zones within the oil fields in the South Caspian sedimentary basin revealed the significant gold-oil paragenesis. The faults' thickness is more than 100 m. Preliminary testing of one of such zones within distance of 80 m across the strike of the fault showed hurricane concentrations of gold (0,3 to 0,9 g/t), palladium (0,2-0,7 g/t), corresponding to the lower boundary of commercial (cutoff grade) amounts, as well as indicators of Carlin type epithermal gold mineralization - arsenic on average 1665 g/t, antimony – 30g/t and barium - 1794 g/t, which are exceed clarks 1700, 250-1000 and 170 times respectively. There have been also determined abnormally high contents as related to the clark of the following elements: iron-10-15 times; manganese and nickel - up to 100 times, copper - 10 times. Zink and lead exceed the clark up to 2 times. Contrary to the above mentioned metals, silver and uranium in the investigated zone are tens times below the clark.

As a result of statistical work, we can conclude that in the mineralized zone there have been determined three associations of elements: I-Fe-Cu-As-Ba-(Mn); II-Cr-Ti-Zr; III-Au-Pd-Pb. Elements from associations I and III negatively correlate with elements from association II, and do not correlate or weakly correlate with each other. This indicates that Fe, Cu, As, Ba, Mn, Au, Pd and Pb have been supplied to the fault zone and control balance of Cr, Ti and Zr, which are components of stable in situ accessory minerals of the enclosing sandstones. Superimposed character of the mineralization is confirmed by microscopic investigations of samples from the fault zone.

A visible gold has not been determined. Absence of correlation of gold, palladium and lead (association III of elements remobilized from oxidation zone) with iron excludes their accumulation in iron hydroxides. At the same time, the strong correlation and high contents of elements from association Fe-Cu-As-Ba-Mn are caused by their accumulation in the zone of hypergenesis and iron hydroxides. It is very important, that abnormally high amounts of gold and palladium were recorded in calcareous highporous sandstones with extremely low amounts of clay minerals, organic matter (OM) and bitumen, which are main sorbents, and concentrators of noble metals in stratiform deposits of Carlin type. This enables to make a conclusion about the existence of commercial concentrations of gold and palladium in the sediments with a high amount of pelitic material and OM, such like shales, silts, silty sandstones, muddy sandstones, which constitute most of the Quaternary sections in the study fields. By the analogy with gold epithermal deposits in Nevada and Alberta, we can make a conclusion about the initial concentration of gold in pyrite in the South Caspian basin as well.

P-3403

Unraveling lake level changes through bottom sediment of the Lake Urmia (NW Iran)

Hamid A.K. Lahijani¹, Rostamabadi S.², Tudryn Alina³

¹Iranian National Institute for Oceanography and Atmospheric Science, Tehran, Iran, Islamic Republic of, ²Iran Water and Power Resources Development Co., Tehran, Iran, Islamic Republic of, ³Univ. Paris-Sud, CNRS, Université Paris-Saclay, Orsay, France

Abstract

Lake Urmia Lake (LU) is a low-lying area; its watershed is of ~ 50000 km². The climate of the region is cold semi-arid with average annual precipitation of 380 mm. Water and sediment are supplied to the LU through 40 rivers with 4 km³ and 4 mil ton respectively. The LU itself is a shallow water brine basin. Its water depth has changed from maximum 13 meters to a few meters during instrumental measurement time. The surface area fluctuated between 2000 and 6000 km². The last lake level drop happened during the past two decades.

A total of 12 cores have been taken with maximum penetration of 20 m; four were located in the area covered by water in the extreme low stand, 8 others were excavated around the LU with average one meter depth. Two cores have been XRF scanned and *Artemia* counted along the cores sub-samples. Here we present preliminary results of two cores for unraveling past lake level impacts, they cover the last lake level fall.

Comparison of pair elements could highlight the role of detrital and chemical/biochemical material in the sediment composition. We identified several groups. The first, detrital fraction group, is represented by Si, K, Ti, Fe, Rb and Mn. This fraction is more abundant towards the bottom of core. The second group is carbonate/gypsum fractions shown by Ca and Sr. High intensity of Sr, probably displays aragonite content in the sediment. Some Ca peaks below 400 cm coincide with S peaks, suggesting gypsum occurrence. The third group possibly related to pore-water and salt, is shown with Cl and Br. The elements are more abundant at the shallower depth in the core. Cl, possibly related to salt, strongly dilutes other mineral such as detrital and carbonate phases at depth shallower than 400 cm. Below 400 cm, the carbonate/gypsum and detrital fractions are major phases and dilute each other. *Artemia* cyst has been counted along the core; in the top salt part of the core almost does not have any cyst. The cyst number in the muddy part varies from 20 to 800 per sample. Surface salt deposit encircled the LU since 2001 with rapid drop of the lake level. The salt deposits are unevenly distributed. In the northern part of the LU, it is ~ 3 m thick; it decreases toward the south, with ~ 70 cm in the middle part and to negligible amount on the southern shores adjacent to the river mouths. Detrital, chemical and biological components of the sediment that cover late Pleistocene and Holocene represent different lake level changes. However current salt deposition never discovered through sediment cores; that could be attributed to the both climate change/variation and intensive human interventions.

P-3404

Urmia Lake's Upper Quaternary Deposits Analysis - New Data and Interpretation

Mohammad Lankarani¹, Seyed-Hani Motavalli-Anbaran², Mohsen Ranjbaran¹, Alina Tudryn³, Piotr Tucholka³, Hesam Ahmady-Birgani⁴, Seyed-Jasser Motavalli-Anbaran²

¹School of Geology, University-College of Science, University of Tehran, Tehran, Iran, Islamic Republic of, ²Institute of Geophysics, University of Tehran, Tehran, Iran, Islamic Republic of, ³GEOPS, Univ. Abstract

Urmia Lake, NW Iran, has been a focus for many geologists during the past years because of its critical condition. The condition is deeply rooted in considerable lowering of its water level in a relatively short time span, mainly caused by great decrease in the water inflow to Lake Urmia. Our French-Persian research group is one of the teams recently involved to study sedimentology, geophysics, hydrology, and hydrogeology of the lake for the purpose of paleo-environmental and paleo-climatic reconstruction for the Holocene time. Current study, as a part of that comprehensive project, focused on sediment analysis of the lake substrate and cores obtained from the upper parts of the lake deposits in order to indicate evidences of the lake level fluctuations.

Reconnaissance studies of many coastal areas of the lake have led to selection of the Golman-Khaneh district, at the vicinity of the city of Urmia, for coring and detailed sediment sampling. Seven sediment cores have been obtained from recently dried out parts of the lake in Golman-Khaneh. The core sediments (up to 12 m thick) are dated as 5.2 Kyr or younger. Detailed sediment analysis of the upper Quaternary deposits of the Golman-Khaneh area (based on field observations and laboratory studies) has been done. The sedimentary succession consists of great amounts of sand with intercalations of organic matter rich clayish/silty deposits, and some horizons of marl and marly clay. The upper (thin) part of the succession, which is exposed at the surface, comprises some 10 to 15 cm of well cemented hard crust of sandy carbonates. To investigate this hard crust in detail, some oriented samples were collected. Standard thin sections were prepared from those samples for petrographic and facies analyses. All of the rock constituents (allochems, cement, matrix, detrital grains and porosity) were determined. Classification and nomenclature of carbonates were on the basis of Dunham (1962). Identified facies were compared with standard facies from well known sedimentary environments (Flügel, 2004).

The mentioned studying processes have led to recognition of an oolitic carbonate hardground (beachrock) in the most recent parts of the basin. The beachrock unit covers a thick column of siliclastic deposits and generally overlies unconsolidated sands and muds. From facies analysis viewpoint, this hardground comprises sandy ooid grainstone and peloid (fecal pellet) grainstone facies. Occurrence of carbonate/mixed siliclastic-carbonate facies on the overwhelmingly siliclastic environment indicates reduction in sediment influx from the land and considerable lake level drop during the latest Holocene, which has finally led to the subaerial exposure of saline beach. Thinness of the carbonate strata in the studied columns is attributed to shortness of this period or some subsequent erosional phases. Available data suggest that the long term lake level changes responded mainly to climate oscillations.

Abrupt climatic events during the Early and Middle Weichselian - the pollen record at the Dzierniakowo site, NE Poland

Mirosława Kupryjanowicz

University of Białystok, Institute of Biology, Department of Palaeobotany, Białystok, Poland

Abstract

The response of Central Europe environment/vegetation to rapid global climate changes during the Last Glaciation, including Early Weichselian (MIS 5d-5a) and Middle Weichselian (MIS 4) was assessed by pollen and geochemical analyses, and by radiocarbon AMS dating of palaeolake sediments from the Dzierniakowo site, NE Poland. This record is the one of the longest Late Pleistocene sequences both in Poland and throughout Central Europe. The dominance of open communities and their considerable diversity were the most characteristic features of the vegetation during the first stadial of the Early Weichselian (MIS-5d). At that time, the lake in Dzierniakowo lay near the northern forest boundary. During the Brørup interstadial (MIS-5c), the expansion of birch forest, as the first response to the warming, was interrupted by a brief cold oscillation, after which birch woods returned, and then birch-pine forests developed. The northern forest boundary moved north of Dzierniakowo. Then, during the second stadial of the Early Weichselian (MIS-5b), tundra and cold steppe communities spread again. During Odderade interstadial (MIS-5a), after a brief birch phase the development of boreal pine forests took place. The boundary between Early and Middle Weichselian (MIS5a/MIS-4) was put above the Odderade interstadial. Within the Middle Weichselian (Pleniweichselian; MIS-4) part of the Dzierniakowo profile, which contains 13 local pollen assemblage zones, it has been assumed that increases in AP values correspond to climatic variation of interstadial rank, while falls in AP and increases in NAP correspond to periods of poorer climatic conditions, i.e. stadials. Seven stadials and seven interstadials were determined in the studied profile. However, low AP frequency, both during stadials and interstadials, shows that the lake in Dzierniakowo was situated outside the northern line of closed forest throughout the Pleniweichselian. The high degree of completeness of studied sequence allows its correlations both with Greenland ice cores and with sea-surface temperature records from the North Atlantic. Interstadials registered in the Dzierniakowo profile well correspond to 18-24 Greenland interstadials, while recorded here stadials, and cooling within the Brørup to 18-25 North Atlantic stadials. Cooling noted in the middle part of the pine phase (E7) of the Eemian Interglacial is equivalent of the 26 North Atlantic stadial, and warming at the very end of this phase is equivalent of the 25 Greenland interstadial.

Provenance of terrestrial materials and paleoenvironmental reconstruction in northwestern continental shelf of South China Sea

Shaohua Yu, Xia Jing, jingpeng Zhang , Hongjun Chen, Shun Li
Guangzhou Marine Geological Survey, Guangzhou, China

Abstract

The north-western continental shelf of South China Sea has deposited a series of terrestrial materials since the late Pleistocene, which has recorded the paleoenvironmental changes of the coastal areas during the glacial-interglacial periods. In this study, high-resolution pollen analysis has been utilized in the core ZBW with 100.65 m in this area. The main results have showed that the pollen assemblages of percentage and concentration has presented a significant zoning characteristic. When pollen concentration is low, the diversity of pollen assemblages is simple, mainly *Pinus* and *Quercus*, indicating the transport distance is further during this period, and the core site is far from the pollen source and estuary of rivers, mainly transported by wind and ocean currents, as a result, the sea level during this period is relatively higher. *Quercus* is a dominated species of evergreen trees in the South China, therefore, the pollen source in this period is mainly from the South China.

When pollen concentration is higher, the diversity of pollen assemblages is rich, and the lowland tropical pollen content increases significantly, indicating the transport distance is close, and core site is nearly with the estuary of rivers in the tropical areas. In addition, alpine trees as well as the deciduous broad-leaved trees has also increased significantly, meaning the pollen source is from the mountain as well. For example, there is Wuzhi Mountain in the nearby Hainan Island, and the island is close to the drilling location and belongs to the tropics. It is speculated that pollen deposition in this period is mostly from the barely shelf area in the lower sea level period as well as the Hainan Island.

According to the seismic data, there was formed a Hainan Delta during the transition period of MIS4-3 stage, and the pollen concentration has undergone a lowest-high-moderate process according with pollen zone 3-2, 4-1, 4-2. The source of pollen has also experienced a transition from further mainland to nearer delta frontier. During this period, the climate is relative warmer and humid according the pollen assemblages. Increasing discharge of rivers in the Hainan Island has brought amounts of sediments into the continental shelf to deposit. Therefore, there is a stable source of sedimentation from the Hainan Island to the near shelf in the MIS3 stage and eventually form a delta.

Heinrich Event Instability as an Example of Self Organized Criticality

Jesse Velay-Vitow, Richard Peltier, Gordan Stuhne
University of Toronto, Toronto, Canada

Abstract

We investigate the possibility that Heinrich event one (H1), which occurred during the most recent glacial-interglacial transition, may be an example of the phenomenon known as Self-Organized Criticality (SOC), in which a dynamical system has a critical point as an attractor. Heinrich event instabilities were responsible for triggering the Dansgaard-Oeschger mode of climate variability that dominated such variability during Marine Isotope Stage 3 of the last glaciation cycle (Peltier and Vettoretti, GRL, 2014). The most recent Heinrich event (H1) was similarly responsible for the related Bolling-Allerod warming transition. In our model, the instability is triggered and thereafter continuously forced by the tides until the ice loss proceeds up the strait to Nottingham Island or beyond over a period from 500 to 1000 years. We find that the amplitude of the dominant M2 semi-diurnal tide reaches its maximum when Hudson Strait is filled with grounded ice that extended to the shelf break, and it is important to note that following H1, tidal amplitude falls precipitously throughout the North Atlantic. It is equally important that during the instability an extremum of tidal amplitude tracks the retreat of the grounding line up the strait. As the strait deglaciates, the up strait paleobathymetry begins to rebound due to Glacial Isostatic Adjustment until the ice stream stabilizes and reforms. At this point, the resonance in the North Atlantic is re-established, M2 reaches a maximum and the conditions for a subsequent Heinrich event are created.. For the purpose of this investigation, we have employed a discontinuous Galerkin method to solve the shallow water equations on the sphere using a non-uniform icosahedral grid. The model was fully described in Salehipour, Stuhne and Peltier (OCMOD, 2012) where it was benchmarked against the standard aquaplanet suite as well as modern altimetric observations of the main tidal constituents.

Heinrich events recorded in annually laminated sediments in Maar Lake Sihailongwan, northeastern China

Zeyang Zhu^{1,2}, Jens Mingram³, Guoqiang Chu¹, Jing Wu¹, Qiang Liu¹, Jiaqi Liu¹

¹Institute of Geology and Geophysics, Beijing, China, ²University of Chinese Academy of Sciences, Beijing, China, ³GFZ German Research Centre for Geosciences, Potsdam, Germany

Abstract

Heinrich events are widely observed in North Atlantic marine sediments cores, ice cores, loess and Chinese caves, however, few paleo-temperature time series extend to these events. Here, we present a branched glycerol dialkyl glycerol tetraether (GDGTs) based temperature reconstruction from annually laminated sediments in Maar Lake Sihailongwan, northeastern China. The reconstruction was weighted towards the warm-season (April to October) when the lake is ice-free. The branched GDGTs-based temperature suggested the ice sheet collapses were coupled with the atmospheric summer temperatures.

The warm season temperatures in Sihailongwan northeastern of China varied between 10.8°C and 16.2°C during 50-8.7 ka. Our records mentioned five obvious Heinrich events (H5-H1) which are consistent with ice core $\delta^{18}\text{O}$ records at about 46.0 ka (12.8°C), 39.4 ka (12.3°C), 31.2 ka (13.2°C), 23.1 ka (11.8°C) and 15.8 ka (11.9°C), respectively. The most rapid and biggest temperature decrease occurred in the YD and H1 events, however, H2-H5 showed a slight temperature drop, which was different slightly with East Asian Summer Monsoon signals in the stalagmite $\delta^{18}\text{O}$ records. Our brGDGTs records suggest that the climate in northeast China were impacted by the ice sheet collapse in North Atlantic, while the warm season temperature and EASM intensity exhibited deviations in Heinrich events.

Evolution of the Cantabrian Mountains maritime glaciers during the latest Heinrich Stadials and coupled response with the Atlantic thermohaline circulation

Laura Rodríguez-Rodríguez¹, Vincent Rinterknecht¹, Valery Guillou², Saúl González-Lemos³, Didier Bourlès², Georges Aumaître², Karim Keddadouche²

¹Laboratoire de Géographie Physique (UMR 8591, CNRS), Meudon, France, ²Centre Européen de Recherche et d'Enseignement des Géosciences de l'Environnement, Aix-en-Provence, France, ³Universidad de Oviedo, Oviedo, Spain

Abstract

Ice sheet melting during the Last Glacial Termination or Termination-I triggered important changes in thermohaline circulation which caused changes in atmospheric circulation and seasonality. The comparisons made between marine and terrestrial records in the Northern Hemisphere suggest synchronous but heterogeneous responses of both environments in Southern Europe during Heinrich Stadial 1/Oldest Dryas (HS1/OD). Focusing on the Iberian Margin, which is under the direct influence of the North Atlantic Drift current, vegetation variations recorded in core MD03-2697 indicate a climate signal during HS1/OD event with three distinctive phases: extremely cold/relatively wet (HS1-a), cool/dry (HS1-b), and relatively warmer/increasing precipitation (HS1-c) (Naughton et al., 2016).

Here we focus on reconstructing the evolution of maritime mountain glaciers in the Cantabrian Mountains of Northern Spain (43°N). This deglaciated mountain chain reaches elevations of up to 2648 m a.s.l. running parallel to the Cantabrian Coastline, westward of the Pyrenees and all along the northern margin of the Iberian Peninsula. Its short distance to the North Atlantic Ocean, less than 100 km, makes it ideal to study the coupled response between marine and terrestrial archives during the latest Heinrich Events (HS1 and HS0).

Our previous studies based on ¹⁰Be surface exposure dating of 20 boulders from moraines and rock glaciers in the Monasterio valley revealed progressive recession and thinning of glaciers between 18.1 ka (glacier front at 1150 m) and 16.7 ka (glacier front at 1170 m), during HS1a and HS1-b (Rodríguez-Rodríguez et al., 2017). The last stagnation of the glacier front ended at a minimum age of 14 ka (marked by a cirque moraine located at 1540 m), during the Oldest Dryas (OD). The stagnation age obtained at the foot of a rock glacier nested within the OD moraine suggests that the Monasterio valley was fully deglaciated during the Allerød. The Monasterio valley lacks a glacier response to the HS0 event (also known as Younger Dryas) probably due to the modest elevation of the source area (2022 m a.s.l.). Here we present 64 new ¹⁰Be and ³⁶Cl surface exposure ages from boulders taken from similar landforms sampled in nearby valleys. Landforms selected are distributed at similar (1560 m) to higher elevations (up to 2100 m) than those from the Monasterio valley in order to better reconstruct how glaciers responded to the HS1 and HS0 events in the Cantabrian Mountains, and what the distribution of equilibrium lines was with regards to paleoclimate conditions.

Geomorphological and geoarchaeological impacts of Heinrich stadials in central Portugal

Michael Benedetti¹, Jonathan Haws²

¹University of North Carolina Wilmington, Wilmington, USA, ²University of Louisville, Louisville, USA

Abstract

Due to its position at the southwestern extremity of Europe, Portugal was strongly influenced by abrupt climatic reversals during Heinrich events of the Late Pleistocene. Proxy records from the Portuguese margin demonstrate large environmental responses to Heinrich stadials (HS) including cold/arid climate, reduced sea surface temperature, changes in upwelling intensity, and reduced forest cover. Records from caves in the Estremadura region of central Portugal support these observations, with evidence for reduced soil moisture and chemical weathering during HS, in some cases leading to hiatuses in speleothem growth. Climate fluctuations (including HS and D-O cycles) and their ecological impacts have also been implicated as triggers of Paleolithic cultural transitions in Iberia, with various authors linking these to the start or end dates of the Mousterian, Gravettian, Solutrean, and Magdalenian phases.

Our coastal geoarchaeological survey in central Portugal presents numerous examples of HS-driven geomorphic change. The evidence comes from stabilized dunes, fluvial terraces, deep valley fills, and eroding coastal bluffs in the Estremadura region surrounding Nazaré. Intense landscape instability in this area between 11-70 ka is indicated by sandy aeolian, fluvial, and colluvial deposits with OSL ages that cluster around HS1, HS2, HS3, HS4, and HS6. The cessation of extreme climate fluctuations at the end of the Pleistocene corresponded with a period of prolonged forest expansion and an overall reduction in geomorphic activity, including transitions from braided to meandering river channels in the study area. The Early and Middle Holocene were instead marked by geomorphic stability and pedogenesis, as evidenced by a well-developed spodosol soil profile that is found today on undisturbed parts of the landscape. In places, the spodosol is buried beneath Late Holocene aeolian and fluvial deposits associated with anthropogenic landscape disturbance. Surface and buried exposures of this paleosol are valuable indicators of Pleistocene-aged geomorphic surfaces that often preserve Paleolithic archaeological evidence.

These observations are consistent with a biogeomorphic response model first proposed for fluvial contexts by Knox (1972). The model suggests short-lived episodes of severe hillslope erosion and sediment yield after a transition from arid to humid climate as vegetation cover adjusts to the new climatic regime. We argue that such conditions occurred at the end of each HS in our study area, and that the concept may be more broadly applicable to unglaciated extratropical regions. Given the adjustment time required for forest expansion and soil formation following an arid phase, the occurrence of HS at 5000-7000 yr intervals (along with higher frequency D-O cycles) during the Late Pleistocene may have precluded formation of mature soils and favored geomorphic instability throughout MIS 2, 3, and 4.

The millennial-scale climatic variability in central Asia during last glacial

Jia Jia^{1,2}, Youjun Wang², Qu Chen¹, Lidong Zhu¹, Wei Ye¹

¹College of Geography and Environmental Science, Zhejiang Normal University, Jinhua, China, ²College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China

Abstract

In the North Atlantic and the surrounding region, more than 20 rapid millennial-scale climatic fluctuations occurred during the last glacial-interglacial cycle (Dansgaard *et al.* 1993). These oscillations, known as Dansgaard-Oeschger (D-O) and H-events. Simulate studies suggest that the millennial-scale climatic signals can spread to a wide area by atmospheric and oceanic circulations. However, it lacks of such record in central Asia which is climatically characterized by arid and sensitive to climate change.

Here, we present the record of millennial-scale fluctuations from loess deposits in Tajikistan in central Asia. The frequency dependent magnetic susceptibility (c_{fd} , a moisture proxy) record in the Darai Kalon (DK) section (38°23'4"N, 69°50'1"N, 1561 m) can be readily matched with the NGRIP oxygen isotope curve, especially during the interval from 60-30 ka in which typical D-O cycles and H-events are well developed (Fig. 1). Most of the long-lasting D-O cycles in Greenland, e.g., D-O 8, 12, and 14, are also evident in the Tajikistan loess. Similarly, the short-duration D-O cycles in Greenland, e.g., D-O 6, 7, 9, 10 cycles, have their damped counterparts in the Tajikistan loess. However, some significant differences in detail can be observed between the two records. The most distinct difference occurs in the case of last D-O cycle, which includes the well-documented Oldest Dryas (OD or H1), Bølling-Allerød (BA), and Younger Dryas (YD or H0) events, which are not clearly present in the c_{fd} curve.

Figure 1

The magnetic results support that the climate is humid in interstadials and dry in stadials in central Asia. And, the variation of humidity is much more remarkable in central Asia than in Chinese Loess Plateau which is climatically dominated by Asian Monsoon. It exhibits the humidity in central Asia is sensitive to millennial-scale climate oscillations during last glacial. The comparison results further indicate propagations of millennial-scale climatic signals were different between these two regions. We assumed the former one is the Westerlier which can directly

and effectively force the millennial-scale climatic variability in central Asia, and latter one is thermohaline circulation and Asian Monsoon, the complex propagation weakened the millennial-scale climatic variability Northern China.

This work was supported by the National Science Foundation of China (Grant No. 41771213).

Figure 1. Correlation of millennial-scale climate variations recorded by the DK section (red curves) and the NGRIP Greenland ice core (pink curve) (NGRIP members, 2004) and SPECMAP curve (blue) (Lisiecki & Raymo, 2005). Numbers (i.e., 1, 2, 3) indicate D-O events, and W1, W2, W3, etc., indicate humid events recorded by the DK section; H-events are indicated by i.e. H1, H2.

³Universidad del Norte, Barranquilla, Colombia, ⁴University of Florida, Gainesville, USA, ⁵EAWAG, Dübendorf,
Switzerland, ⁶University of Minnesota, Duluth, USA

Abstract

A seesaw existed in precipitation between the northern and southern Neotropics during the last glacial period related to the migration of the Intertropical Convergence Zone in response to changes in North Atlantic heat transport. During stadials, and especially those containing Heinrich events, aridity increased in the northern Neotropics at the same time as rainfall increased in the southern Neotropics. Lake Peten-Itza at 17°N in northern Guatemala contains an exceptional record of millennial and centennial climate variability during the last glacial period that is marked by alternating clay and gypsum deposits, reflecting relatively wet interstadial and dry stadial conditions, respectively. New high-resolution XRF data from Peten Itza sediment cores reveal a complex structure during each stadial period when rapidly changing hydrologic conditions occurred on centennial time scales. The distinct patterns of centennial variations within each of the stadial stages may provide a means for locating the short-lived Heinrich events within the longer period of stadial conditions and for correlating records and refining age models. As a case study, we will report on internal variations in temperature and rainfall/humidity that occurred during Heinrich stadial 1, which includes Heinrich Event 1.

Abstract

Lakes have the potential to hold long records of climate. Previous studies have used various techniques to access these records, primarily through coring the inferred deepest part of the sediment sequence. Cores have been analyzed for microfossils (pollen, diatoms, chironomids) as proxies for hydroclimate, temperature and ecological structure. Water levels have been inferred from macrofossils of plants that have specific depth ranges. This work is time consuming and may not yield desired results. Ground penetrating radar (GPR) has been employed in lacustrine situations to evaluate sediment thickness and palaeoshorelines. The capacity of GPR to image subsurface architecture is directly applicable to accessing climate records from lakes and can substantially augment the information gained from sediment records.

North Stradbroke Island, the world's second largest sand island, is home to numerous lakes and wetlands. Previous and ongoing studies have used these environments to reconstruct the climate from pollen and stable isotopes at several sites that date to the LGM and one site that extends to the previous interglacial.

New work employing high-definition, high-resolution digital dual frequency (160 and 670 MHz) GPR equipment has recently been completed as a test case at Swallow Lagoon (SL). SL is a high-altitude (~150 m above sea level), perched terminal lake within a small interdune depression. GPR lines were collected around the lake on the terrestrial margins and over the lake using an inflatable raft. As a part of previous research to elucidate the climate of NSI, SL was cored and a basal radiocarbon date of 11.5 kyBP was recovered from 4.8 m below the lake floor above a sand-rich layer (Tibby et al., 2017). The core site was imaged on several GPR crossings.

GPR imagery shows there may be twice as much sediment accumulated in the basin as has been recovered previously and numerous submerged and emergent shorelines. The dataset allows for correlation of lake levels with core chronology. The terrestrial GPR lines revealed palaeoshorelines at elevations of 5 m above present lake level with numerous palaeoshoreline complexes buried beneath the present regressive surface.

Further analysis of GPR data using techniques of sequence stratigraphy will allow for an understanding of previous lake levels on a relative time scale. GPR data will be used to target key horizons and units to provide detailed chronology for lake levels. The result will ultimately be a lake level curve that can be used to infer regional climate and in combination with planned lake hydrological modelling, these data have the potential to provide quantitative hydroclimate reconstructions from the Holocene and beyond.

Towards a reconstruction of high-resolution environmental and sedimentary records spanning the last glacial cycles from Orakei Maar, Northern New Zealand.

Benjamin Laeuchli

University of Auckland, School of Environment, Auckland, New Zealand

Abstract

Precise linkage of thin-section observations and high-resolution elemental data produced by micro-XRF scanning of corresponding epoxy resin-impregnated sediment slabs can significantly improve our ability to detect abrupt shifts in climatic forcing, as well as identification of short to long-term changes in seasonality. Located within the Auckland Volcanic Field, Orakei Maar's well-laminated and continuous lake sediments are very suitable for the application of this integrative approach in New Zealand. Compared to its northern counterpart, long, high-resolution mid-latitude terrestrial paleoclimate archives from the Southern Hemisphere are few and suffer from age controversies. Consequently, we propose that our ongoing work will substantially reduce the existing gap in paleoclimate data from the New Zealand sector of the Southern Hemisphere spanning the last glacial cycle.

During a recent drilling campaign, ~73.5 m of mainly laminated lacustrine sediments were retrieved from Orakei Basin with nearly 100 % sediment recovery achieved with two overlapping sediment cores. The main objective of the present study is to apply the integrative approach of high-resolution micro-XRF scanning on impregnated Orakei Maar Lake sediments with observations made on corresponding thin-sections to thoroughly identify and examine micro-facies transitions. Using this approach, we can identify and document of shifts in environmental and climatic conditions, as well as short to long-term changes in seasonality at very high precision. Supplementary Laser Ablation-ICP-MS measurements carried out on the impregnated sediments allow precise calibration of the micro-XRF data time series. In addition, automated grain size analysis application 'RADIUS' (=Rapid Particle Analysis of digital images by ultra-high-resolution scanning), is being applied to establish an event stratigraphy, identified via sub-mm scale, aeolian dust records contained in the Orakei core. This supports the identification of phases with cooler and drier conditions that are either related to a shift of the Southern Westerly Winds over the last glacial cycle as well as sub-decadal alterations in the El-Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO).

Palaeoenvironmental changes since the late Pleistocene revealed by ostracodes record to the east of Bangong Co, western Tibet

Gao Song, Hailei Wang

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China

Abstract

A 4.9 m section (BG-1), located 45 km to the east of Bangong Co, west Tibetan Plateau, provides a continuous climate records from the Late Pleistocene to the mid-Holocene, on the basis of ostracodes assemblages and shell trace elements. Results show five distinct climate changes in the east Bangong Co area from 23.4 to 4.9 ka based on U-series dating. It remained extremely cold till 13.0 ka due to the influence of LGM, as indicated by very few ostracodes and no snail occurring in this stage. After that, the temperature increased gradually meanwhile the paleolake (Dagutuqiong) enlarged with well developed ostracodes, though the dominance of cold water species and low Mg/Ca of ostracodes shells indicate the climate was still cool. More glacier melting waters in relatively warming climate into the lake, as suggested by the high U/Ca and Mn/Ca of ostracodes shells, led to a high lake level in this stage, which was also verified by the low Sr/Ca values. The warming climate was interrupted by a transient extreme event during 11.5-11.1 ka, which was attributed to the Younger Dryas event. It was characterized by rapid drop of temperature at the beginning and slow warming thereafter, with little lake level variations. The temperature was recovered and the climate remained cool and wet till 10.3 ka. In 10.3-6.23 ka stage, it was still cool as indicated by low Mg/Ca of ostracodes shells. However, it dried substantially during this stage with saline water ostracodes dominating at the beginning and then disappearing in the middle due to higher salinity of lake water. At the end of this stage, few saline water ostracodes appeared again suggesting that the climate become wet again. It was a transitional stage toward a warm and wet climate. The 6.23-5.25 ka stage was the optimum period throughout the section. The climate was warm and wet and the paleolake enlarged. Thereafter, the temperature continued to rise, resulting in an increasing evaporation and extremely dry climate, as indicated by sharply high Mg/Ca and Sr/Ca of ostracodes shells during 5.25-4.9 ka. The paleolake shrank rapidly and dried up at some time after 4.9 ka. The extremely dry climate after 5.25 ka, especially after 4.9, was responded by the records from other lakes in west Tibetan Plateau, suggesting a large scale drought event. The eastern Bangong Co likely closed and separated from the Dagutuqiong paleolake during this stage.

The paleoclimate recorded by phytolith in Anguli-Nuur Lake since the mid-late Holocene

Linjing Liu¹, Chang'an Li², Dongmei Jie³, Xin Mao¹, Gaolei Jiang¹

¹Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences, Shijiazhuang, China, ² Faculty of Earth Sciences, China University of Geosciences, Wuhan, China, ³School of Geographical Sciences, Northeast Normal University, Changchun, China

Abstract

Bashang area of Hebei Province, Northeastern of China, is located in the East Asian monsoon-margin region and the ecotone between agriculture and animal husbandry. East Asian monsoon variability significantly affects the development of human civilization within its area of influence. In order to reconstruct the climate changes in Bashang area and understand the interactions between past climate and human civilization, a continuous 120-cm sediment profile was recovered from Anguli-Nuur Lake based on phytolith and pollen analysis. The results showed that, the climate in this region is gradually becoming cold and dry during the last 5000 years, which is related to the weakening of East Asian monsoon produced by gradually of solar radiation. However, the climate is relative wet during the periods of 5030~3074 cal. a BP. On the centennial scale, Anguli-Nuur has experienced seven obvious cold and dry events, which occurred during ~4500 cal. a BP、 4100-3800 cal. a BP、 ~3500 cal. a BP、 ~3000cal. a BP、 ~2100 cal. a BP、 ~1100 cal. a BP和800-270 cal. a BP. The cold and dry events are consistent with weakening stage of the East Asian monsoon that is probably affected by high latitude climate and the solar activities. In this region, the development of human civilization is sensitive to climate change. Agriculture civilization is relatively developed during warm and humid stage, and grassland civilization appears during cool and arid stage.

Abstract

Lake Chatyr Kul is located in arid central Asia at 3530 m a.s.l. in the Tian Shan/ South Kyrgyzstan. Present day climate conditions are controlled by the Westerlies and the Siberian High. To disentangle processes and consequences of changes in dominating atmospheric circulation patterns on a freshwater system throughout the Holocene, high resolution records are needed.

We present a sediment record of ~6.25 m length, which is the first in this region showing seasonal laminated sediments almost throughout the entire late Pleistocene-Holocene. Sediment cores were retrieved in 2012 and 2017 with piston corers from ~20 m water depth. Two independent dating methods have been applied: (1) Varve counting between 63 and 623.5 cm composite depth with a mean counting uncertainty of ca 3.8% and (2) Radiocarbon dating including 22 AMS ¹⁴C ages from wood, other plant remains, *Daphnia*, TOC Bulk and *Ruppia maritima* seeds. BACON has been applied for reservoir corrections. The floating varve chronology has been anchored to the absolute time scale at 990 cal a BP as adopted from modelled radiocarbon BACON ages. The resulting ages for the sediment record base for the varve chronology (~12,230 cal a BP) and the radiocarbon age model (~12,700 cal a BP) are within uncertainties in good agreement. Based on ¹³⁷Cs, ²⁴¹Am and ²¹⁰Pb profiles, the uppermost 20 cm homogeneous sediments were radiometric dated.

The late Pleistocene deposits contain well preserved clastic-pyrite varves with sporadically occurring aragonite and vivianite sublayers. The Early to Mid-Holocene comprises changing intercalations of clastic-organic, calcite-clastic and diatom varves, with decreasing varve qualities until ~2,000 cal a BP and mean varve thickness (mvt) of 0.39 mm/a. The Late Holocene exhibits again well preserved clastic-organic varves with highest mvt of 1.55 mm/a. Changing microfacies structures are accompanied by variations of varve thickness, species assemblages and of the proxy data (μ XRF data of Ca/Ti and geochemical data of TOC, $\delta^{15}\text{N}$, $\delta^{18}\text{O}$) mainly mirroring changing intensities of erosional processes.

The synthesis of all available data documents highly variable environmental conditions with a prominent transitional change at ~4,300 cal a BP possibly related to a declining Indian Monsoon influence. Distinct periodicities in varve microfacies, mvt and Ca/Ti ratios of ca 100 years between 11,700 - 8,700 cal a BP, and 200 years in the period from 8,700 - 4,300 cal a BP possibly reflect De Vries solar cycles. The abrupt change from organic-clastic varves (0.39 mm/a) to clastic varves (1.55 mm/a) at 2,000 cal a BP suggests a combined control on depositional patterns by climate and human impact. Comparison with other regional records (Lake Son Kul, Uluu Too Cave Stalagmite) suggests a dominance of westerly influence for the mid-late Holocene.

This is a contribution to the BMBF-funded project CAHOL.

Past land-use in Russia Karelia: The pollen record of Lake Lavijärvi

Fatemeh Ajallooeian^{1,2}, Mischa Haas², Nathalie Dubois²

¹University of Helsinki, Helsinki, Finland, ²Eawag Institute, Dübendorf, Switzerland

Abstract

Paleoclimate and paleolimnology studies done on the Northern boreal zone remain scarce (Alenius et al., 2013). As this area covers an important body of water, Lake Ladoga, the need to understand the vegetation and land-use dynamics of this region has advanced. Here, based on 21 pollen and spore types identified in a window of ~3000 years, the results of vegetation, land-use reconstruction of Lake Lavijärvi located in western Karelian Russia are presented. These data helped to understand major land-use shifts and climate pattern of the area. The pollen diagram of Lavijärvi was divided into 4 zones determined by the main vegetation changes: Zone A (750 BC to 550 AD) representing a consistent arboreal forest; Zone B (550 to 1300 AD) demonstrating a transition from forest to forest-steppe vegetation; Zone C (1300 to 1940 AD) illustrating fluctuations of vegetation patterns; and finally, Zone D (1940 to 2016 AD) showing the recent post-war relaxation of land-use. *Pinus*, *Picea*, *Betula*, *Alnus*, *Chenopodiaceae* and *Poaceae* are among the major pollen types. Throughout the core changes in vegetation patterns and slash and burn cultivation are well represented. The Medieval Warm Period and the Little Ice Age are also moderately present in the pollen frequency and variety. The anthropogenic effects of farming are displayed by large abundances of *Poaceae* and *Cerealia* pollen especially in Zone C, eutrophication of the lake and the absence of *Picea* pollen due to fires. Today, the lake's surrounding is mainly pasture with arable farming taking place moderately. The climate of Lavijärvi appeared to have had long winters with excessive snow cover especially in the early stages (2600 to 1000 cal BP or 650 BC to 950 AD) and a moderately dry temperature due to *Chenopodiaceae* growth though maintaining enough soil moisture for cultivated plants. Lake Lavijärvi is a good example of shifting from dense arboreal forest to steppe-like vegetation and finally pasture throughout a window of 3000 years.

Abstract

The fertile and densely populated floodplains of river Ganga host many oxbows and meander cut-offs, offering the possibility of obtaining high-resolution paleoclimatic data. Few of these lakes have previously been studied for their climatic history but are constrained by a lack of robust chronology. To gain insights on the role of local and/or regional climate forcings, an oxbow lake in the Central Ganga Plains was studied using multiple biotic proxies to obtain a well resolved Holocene paleoclimatic record. Broadly, four climatic phases (Phase 1 to 4) were identified. Phase 1 (~13.0 to 10.6 kyr BP) shows relatively higher net rate of sediment accumulation, which declines by 28% in phase 2 (10.6 to 7.8kyr BP). Only a slightly lower net rate of sediment accumulation (23-24%) was observed in phases 3 (7.8 to 2.9kyr BP) and 4 (2.9 to 1.1 kyr BP). This indicates a high fluvial input during phase 1 that drastically reduced in Phase 2, and finally the sediment succession indicates a lower sediment input due to the formation of the ox-bow lake in phases 3 and 4.

Palynological results show a drastic increase in arboreal pollen (AP) by 60% in phase 3 as compared to 9.9%, 21.1% and 7.9% in phases 1, 2 and 4, respectively. The ratio of AP and NAP (non-arboreal pollen) is therefore, 0.07, 0.5, 0.2 and 0.8 in phases 1-4, respectively. Thus, the stabilization of the lake ecosystem and nearby floodplain resulted in the establishment of forest accompanied by conducive warm and humid environment with moderate seasonality during phase 3. The aquatic pollens show an ascending trend from phase 1 to 4. Relatively, the maximum was observed in phase 4 (60%) with high percentage of prostrate running *Polygonum serrulatum* suggesting highly disturbed shallow water body. Contrastingly, phase 2 shows moderate percentages of *Myriophyllum* and *Nymphaea* pollen suggesting relatively deeper water column in the lake. Phases 1 and 2 show increased pollen of *Typha* indicating swampy periphery of the water body. The highest percentage of planktonic and benthic siliceous diatoms and freshwater sponge spicules were recorded in phase 3 indicating warm and humid climate with high gammoscleres of sponge spicules that are formed by reproductive bodies only during water scarcity. During phase 4 an abrupt decrease in diatoms and abundance of megascleres/ microscleres indicate permanent water and intense illumination in water column. It is concluded that decrease in vegetation, bilobed graminaceous phytoliths and diatoms along with the chlorophyllous algal content indicate an overall transition from wetter to drier climatic conditions since 13kyr BP; also the local fluvial dynamics in the Ganga Plain played a major role in the development of the succession of the lake ecosystem.

Late Pleistocene (~20-60 ka) hydroclimatic variabilities in arid north-west China: geochemical evidence in Balikun Lake, eastern Tianshan

Yongtao Zhao^{1,2}, Chengbang An²

¹Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, Lanzhou, China, ²Key Laboratory of Western China's Environmental Systems (Ministry of Education), College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China

Abstract

Reconstructing the environmental and hydrological response to millennial-scale fluctuations of mid-latitude, climate-sensitive areas, such as the arid areas of Central Asia (CA), is crucial to understand Late Pleistocene climate in terrestrial inland regions. We use sedimentologic and geochemical analyses of a sediment core (BLK11A) obtained from Balikun Lake, eastern Tianshan Mts., to elucidate variations in sedimentation, water-chemistry and watershed weathering intensity of the Late Pleistocene interval. The record documents high-frequency oscillations and alternating hydrological patterns in this region on (multi-) millennial timescales. Balikun Lake changes from nearly fresh to brackish and finally to hypersaline, with evaporate minerals varying from carbonate to sulfate and finally halite. Specifically, the stadials (MIS4 and MIS2) are characteristic of low lake level and weak chemical weathering, reflected by coarse grain size and high Rb/Sr value, respectively. The onset of MIS3 at Balikun Lake is featured by abrupt increase in carbonate and chemical weathering intensity, suggesting warm and wet climate conditions. This optimal episode facilitated regional vegetation and bio-productivity. Halite sedimentation took place from the middle to late MIS3, and it indicates a gradual drying trend that reduced in the lake area and vegetation cover, as well as weakened of chemical weathering in the watershed. These new interpretations challenge the idea of climate amelioration with highest lake level and wettest conditions prevailed in most areas of north-west China during the late MIS3, indicating a possible westerlies-dominated Late Pleistocene climate in Xingjiang area.

Sedimentation dynamics in multi-millennial lacustrine record: varves and slumps in Lake Szurpiły (NE Poland)

Małgorzata Kinder¹, Wojciech Tylmann¹, Michał Rzeszewski², Bernd Zolitschka³

¹University of Gdansk, Gdańsk, Poland, ²Adam Mickiewicz University, Poznań, Poland, ³University of Bremen, Bremen, Germany

Abstract

Annually laminated (varved) sediments and inserted mass-movement deposits of Lake Szurpiły track sedimentation dynamics since the Late Glacial and relate to natural and anthropogenic forcing. The chronology of this study is based on varves for the last 8400 years and extends back to the Allerød applying radiocarbon dating and pollen stratigraphy. In addition, the age-depth model was validated by cryptotephra findings. In annually laminated sections before 850 BC, when anthropogenic influence was limited. Gleissberg (88-yr) and Suess (208-yr) solar cycles are detectable in varve thickness data. Additionally, 22-yr and 11-yr sunspot cycles are detectable in the light-to-dark laminae thickness-ratio. Decreases in varve thickness between AD 1500-1800 correspond to Spörer and Maunder solar minima and reflect climatic conditions with reduced human impact during the Little Ice Age. In-between finely laminated sections, different mass-movement deposits were identified including one major turbidite and 85 minor slumps. In the Late Glacial section, highly minerogenic event layers represent increased runoff related to a poor vegetation cover. The major turbidite of 6400 ± 100 BC could have been triggered by an earthquake or very late thawing of permafrost and related transformations of groundwater circulation. Slumps with silt caps indicate humid conditions during the Atlantic. Human activities, as well as flood events or snow melting could have been responsible for slump events since the Subboreal. Despite regional seismic inactivity, deformation of varves could have been caused by an earthquake observed in AD 1803. With the analysed multi-millennial sediment record we demonstrate the complexity of events recorded by lacustrine sediments.

Is the present the key to the past? Diatom-based lake-level reconstruction of Lake Kinneret (Israel)

Hannah Hartung¹, Thomas Litt¹, Jane M. Reed², Jeffery Stone³

¹Institute of Geosciences and Meteorology, University of Bonn, Bonn, Germany, ²School of Environmental Sciences, University of Hull, Hull, United Kingdom, ³Department of Earth and Environmental Systems, Indiana State University, Terre Haute, USA

Abstract

Uniformitarianism is a key concept in palaeoecological research. Based on the assumption that ecological preferences remain constant, a better understanding of the modern lake environment can strongly improve palaeoenvironmental interpretation derived from analysis of fossil datasets preserved in lake sediment archives. In palaeolimnology, the analysis of modern diatom communities and their subfossil death assemblages is a good example. Diatoms (single-celled siliceous algae) are highly useful palaeoenvironmental indicators due to their specific ecological preferences and the long-term preservation of their silica valves in lake sediments.

Meso-eutrophic Lake Kinneret is the largest natural freshwater body in Israel and, by water extraction, a major source of drinking and irrigation water for the region. Although the lake is currently the subject of extensive aquatic monitoring programmes, knowledge of the spatial distribution and habitat preferences of modern diatom assemblages is rather limited.

Twenty-eight surface sediment samples were collected from Lake Kinneret, covering a range of different water depths and habitat areas, to investigate the composition of diatom death assemblages and their distribution within the modern lake system. A quantitative diatom-inferred water-depth model based on simple linear regression between modern diatom assemblages and water depth is presented in this study, as a tool for semi-quantitative calibration of Holocene lake-level change. The new calibrated lake-level reconstruction fits well to palaeo-shoreline measurements and appears to display greater sensitivity to minor lake-level variation than a simple Plankton/Benthos-ratio approach. A close similarity between Lake Kinneret and the Dead Sea is observable, indicating that they were subject to similar regional fluctuations in moisture availability. Our results confirm that the investigation of modern diatom death assemblages can be helpful to understand and calibrate the limnological history of lakes.

Estimated chronology in a continuous lake sediment sequence from Kai Iwi Lake, New Zealand using MIS boundaries as age markers

Gianna Evans¹, Paul Augustinus¹, Patricia Gadd², Atun Zawadzki², Amber Ditchfield¹

¹University of Auckland, Auckland, New Zealand, ²ANSTO, Sydney, Australia

Abstract

It is a common problem in paleoclimate research to have long sediment sequences that are difficult to date due to the ~50 ka age limitation of ¹⁴C dating. A possible solution where other laboratory methods are not available is to approximate the chronology using Marine Isotope Stages (MIS) as age markers via robust interpretation of environmental proxy data. A 9.3 m lake sediment core obtained from dune impounded Kai Iwi Lake in Northland, New Zealand provides a nearly continuous record of environmental changes in multi-proxy and μ -XRF data estimated to MIS 5d. Chronology for the upper 3 m of the core is well established until ca. 45 ka via ²¹⁰Pb, ¹⁴C and tephrochronology. To identify patterns in the μ -XRF proxy data associated with environmental change, principal component analysis (PCA) and cluster analysis were performed on a data set including nine common elements in lake sediments (P, S, Fe, Ti, K, Ca, Si, Al, and Zr) and six element ratios (Sr/Ca, Br/Cl, Mn/Fe, (Fe+Ti)/K, Ti/K, and Inc/coh). PCA indicates that Component 1 represents the detrital fraction, and Component 2 is associated with nutrient influx and biological productivity. The elements and ratios in the Component 2 μ -XRF variables also indicate a wind component to the data as P, Mn/Fe, Fe, Ca and S are also indicators of anoxic/oxic conditions as a result of wind driven mixing in the water column. The cool periods of MIS 2 and 4 are well-defined in the μ -XRF data as having increased detrital influx (Ti, K, Si, Al), less thermal stratification in the water column (P), and more sea spray (Br/Cl, S). Warm periods are identified by high P variability, less detrital influx and increased organic productivity (Inc/coh). MIS 5b is estimated from similar changes in the data as MIS 2 and 4, however the difference between MIS 5c and 5d is not as evident and so the alignment of the cluster analysis of the μ -XRF proxy data was used as the definition of this boundary. These environmental interpretations define a framework of age markers from the MIS boundary ages and allow an age/depth profile estimated from a sediment accumulation rate to be calculated in addition to the age profile established via ²¹⁰Pb, ¹⁴C and tephrochronology. Since MIS 2 has a slower accumulation rate in the Kai Iwi Lake chronology and the proxy data profile for MIS 2 is similar to MIS 4, it may also be possible to further refine the estimated chronology for MIS 4 by adjusting the accumulation rate for that section of the core.

P-3424

Mineralogical record for climatic change in Lake Qinghai sediments since the marine isotope stage 2

Yongui Song

Institute of Earth environment, Chinese Academy of Sciences, Xian, China

Abstract

Lake Qinghai, the largest inland lake on the northeastern part of the Tibetan Plateau, lies in the critical semi-arid zone between the eastern humid and the western arid areas, and is extremely sensitive to climatic changes. A 18.5m long drilling core (1Fs) from the depo-center of southwest-sub basin of Lake Qinghai provides new information of the climatic dynamics of Asian semi-arid areas since 32ka BP. We applied X-Ray diffraction analysis to determine the content of quartz, aragonite, dolomite and calcite. Based on the characteristics of mineral assemblages, together with sedimentary facies, we divided the 18.5m long core into three distinctive stages at the depth of 11.65m and 4.8m indicating three climate stages. The analysis results indicate that the 18.5m long core recorded three paleoclimate stages: Cold-dry period (32-25.5 ka BP), tempered cold-dry period (25.5-11.6 ka BP), and warm-humid period (11.6-0 ka BP), and the third period can be further divided into three periods: Climatic oscillation period, The Holocene Climatic Optimum and cool-dry period. Quartz content is correlated well with humid and dry climate, high quartz content reflects dry climate, while low content reflects humid climate. During last glacial period, 1F core deposited little aragonite, from the time of deglaciation, aragonite deposited steadily and reach the top value during Holocene. High aragonite content reflects warm-humid climate, while low aragonite content reflects cold-dry climate, and can be reasonably correlated with delta ^{18}O record of stalagmite in Dongge cave. Quartz and aragonite assemblages may well represent paleoclimate variation in the lake Qinghai.

Late Oligocene Warming Event on the Tibetan Plateau: evidence from a sporopollen record

Fuli Wu^{1,2}, Yunfa Miao^{2,3}, Qingquan Meng⁴, Xiaomin Fang^{1,2}, Jimin Sun^{2,5}

¹Key Laboratory of Continental Collision and Plateau Uplift, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China, ²CAS Center for Excellence in Tibetan Plateau Earth Sciences, Beijing, China, ³Key Laboratory of Desert and Desertification, Cold and Arid Regions Environmental and Engineering Institute, Chinese Academy of Sciences, Lanzhou, China, ⁴School of Earth Sciences, Lanzhou University, Lanzhou, China, ⁵Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

A large number of studies have been carried out on the causes and mechanisms of events occurred in the Quaternary, and research on events prior to the Quaternary has been relatively low. Especially, few terrestrial records have yet been employed to verify the *Late Oligocene Warming Event* and investigate its associated driving forces. The Nima Basin, located in the central Tibetan Plateau contains thick Oligocene sediments, allowing its ecological record to be used as verification of the LOWE. Here, we used the reconstructed vegetation record from the Nima basin in the 1,100 m thick DZC section (27.5-22.4 Ma). Sporopollen analysis revealed that the dominant taxa throughout the whole section were conifers (over 85%), including *Piceapollis*, *Pinuspollenites* and *Abietpollenites*. One notable feature is that the broadleaved trees (e.g., *Quercoidites*, *Meliaceoidites*) increased obviously (averaging from 0.9% to 6.6%, max 41.2%) after 25.6 Ma. This change could be interpreted as a response to late Oligocene global warming, which changed the forest line and corresponding plant species composition. The mean average precipitation of 400-850 mm and 800-1,000 mm, respectively inferred from the above vegetation types in the Nima Basin, both exceed the present 150 mm. It indicates that the LOW event accompanied the global warming.

Fire history during the mid- to late Holocene based on black carbon records inferred from Jingpo Lake, Northeastern China

Rong CHEN, Ji SHEN

Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

Climate change is likely to alter wildfire regimes, but the significance of climate-driven factors in regional fire regimes over extended temporal scales is poorly understood. Comparison of the reconstructed fire dynamics from lake sediments with modern active fires may provide clues about the drivers of wildfire activities, and help us validate models of fire activity for both the past and the future. The results of black carbon (BC) indicates that the patterns in fire activity history observed in Jingpo Lake region during the mid- to late Holocene are consistent with the climate change inferred from paleoclimate proxies. Furthermore, both the BC content and BC mass sedimentation rate (BCMSR) display a close relationship with the percentage of herb pollen from the same sediment core, suggesting that regional vegetation type would be a factor controlling the intensity of fires. Low BC content and BCMSR level during the period of ~5100–3500 cal. yr BP imply low fire episodes and are consistent with wet climate conditions. Limited fuel availability (limited herbs content) inferred from the pollen data also likely reduced intensity of fires. During the period of ~3500–2000 cal. yr BP, the large increase in BC content and BCMSR level indicates that the increased intensity of fires, and are consistent with the climate was cold and dry and more herbs vegetation covered the Jingpo Lake region. The subsequent dramatic changes in intensity of fires during the period of ~2000–150 cal. yr BP was consistent with climate change and also with changes in intensity of human activities. After ~150 cal. yr BP, BC content and BCMSR reach very high levels. The sources of black carbon during this period shift from biomass burning to a combination of biomass and fossil-fuel combustion products, partly reflecting the industrialization of China during the latter half of the 20th century. Moreover, a strong positive relationship is found between $\delta^{13}\text{C}_{\text{BC}}$ data from surface soils in northeast China and temperature of the warmest month. The general features of the $\delta^{13}\text{C}_{\text{BC}}$ values are generally consistent with inferred herbs content changes. Therefore, we conclude that the $\delta^{13}\text{C}_{\text{BC}}$ values in the Jingpo Lake sediments may serve as a reliable proxy for climate change.

P-3427

Palaeoenvironment variations recorded by sedimentary organic moleculars in Lake Nanyi from the middle–lower Yangtze region since the last deglaciation

Jianfang Hu, Fenghao Liu

Guangzhou Institute of Geochemistry, Guangzhou, China

The compositions of GDGTs and *n*-alkanes as well as the specific stable carbon isotopes of *n*-alkanes ($\delta^{13}\text{C}$) in a sediment core taken from the Lake Nanyi, middle–lower Yangtze region were investigated. The chronology of the sediment core was established according to the ^{14}C -AMS data of TOC and terrestrial leaves from the core sediments. This study reconstructs the paleovegetation and paleoclimate change from 16.0 ka B.P. to present. The East Asian summer monsoon was discussed.

The results show that from 16.0 to 8.0 ka B.P., the undetected sporopollen and long-chain *n*-alkanes ($n\text{C}_{27}$ – $n\text{C}_{33}$) suggested that the *n*-alkanes were mainly derived from algae and aquatic plants. The MAT (mean air temperature) which reconstructed by brGDGTs showed that the temperature was low and the climate was dry and cold in this area.

From 8.0 to 4.8 ka B.P., the *n*-alkanes were mainly consisted of $n\text{C}_{27}$ – $n\text{C}_{33}$. The low Paq values suggested that the *n*-alkanes were mainly derived from terrestrial higher plants. Sporopollen records, the increased $n\text{C}_{27} / n\text{C}_{31}$ ratios and decreased ACL (average chain length) values indicated that herbaceous plants were reduced, and woody plants were increased. Depleted $\delta^{13}\text{C}$ values of $n\text{C}_{27}$ – $n\text{C}_{33}$ indicated the surrounding vegetation was dominated by C_3 plants. The MAT showed that the temperature was high, suggesting that the climate was more humid and warmer in this area and the East Asian summer monsoon was stronger.

From 4.8 to 2.4 ka B.P., the high Paq values and the declined contents of $n\text{C}_{27}$ – $n\text{C}_{33}$ suggested that contribution of terrestrial plants decreased. The lower ACL of *n*-alkanes and the higher ratios of $n\text{C}_{27} / n\text{C}_{31}$ indicated that the woody vegetation was dominated. The $\delta^{13}\text{C}$ values of $n\text{C}_{27}$ – $n\text{C}_{33}$ were between -33.5‰ and -29.1‰ , indicating that C_3 plants were dominated. However, contribution of C_4 plants increased. The MAT showed that the temperature was low, suggesting that the East Asian summer monsoon weakened relatively.

After 2.4 ka B.P., the decreased Paq values and the slightly increased $n\text{C}_{27}$ – $n\text{C}_{33}$ suggested that the contribution of terrestrial plants increased. The decreased $n\text{C}_{27} / n\text{C}_{31}$ ratios and increased ACL values indicated that the grass vegetation was dominated. The $\delta^{13}\text{C}$ values of $n\text{C}_{27}$ – $n\text{C}_{33}$ were between -33.9‰ and -28.0‰ and changed rapidly. The MAT showed that the temperature was high, suggesting that the climate tended to be warm and humid. The rapid changes of these indexes might be related to the gradual increase of human activity in the Yangtze River basin since 2.4 ka B.P. All these indexes show that the East Asian summer monsoon was weakened when the summer solar radiation in the northern hemisphere decreased.

Biomarker investigations in Lake Van sediments of the penultimate interglacial/glacial cycle

Typhaine Guillemot¹, Mona Stockhecke², Achim Bechtel³, Carsten J. Schubert¹

¹Eawag, Kastanienbaum, Switzerland, ²Eawag, Dübendorf, Switzerland, ³Montanuniversität Leoben, Leoben, Austria

Abstract

Paleoclimatic changes on interglacial/glacial time scales in the Near East are not very well resolved especially going back in time beyond the last glacial. To better identify reasons for changes in this region, we quantified source-specific biomarkers in Lake Van sediments during the penultimate interglacial/glacial cycle. Long chain *n*-alkanes, long chain alkenones (LCAs), and sterols, produced by terrestrial vegetation and aquatic algae, respectively were investigated. Stable hydrogen isotopic measurements ($\delta^2\text{H}$) on *n*-C₂₉ alkanes and on MeC37:3 LCA revealed three wetter periods interrupted by two drier intervals during the MIS 7 interglacial. On the contrary, during the MIS 6 glaciation, a more stable and generally drier climate was predominant. During warmer and wetter periods of MIS 7, a higher input of aquatic OM vegetation and algae to Lake Van sediment was recorded by higher concentrations of mid-chain *n*-alkanes, LCAs and dinosterol and brassicasterol. Inputs of freshwater and terrestrial element like silica in the lake water column might have boosted the aquatic productivity. On the contrary, during cooler and drier episodes of MIS 7 and MIS 6, only high concentrations of long chain *n*-alkanes were measured in sediments, revealing sustainable terrestrial vegetation when the climate was getting harsher. Generally, in the Mediterranean realm, a wetter interglacial interrupted by drier episodes followed by a dry glaciation was the common feature observed during the penultimate interglacial/glacial cycle. In comparison to the last interglacial/glacial cycle, the extreme dry glaciation registered from MIS 5d to 2 was apparently unique around Lake Van, not preceded by a similar event during the last 250 kyrs.

P-3429

Developing a regional approach to palaeoflood reconstruction using lake and reservoir sediments for the British Isles.

Hazel Phillips, Richard Chiverrell, Neil Macdonald
University of Liverpool, Liverpool, United Kingdom

Abstract

Flood hazard management requires precise estimates of extreme flood magnitude and frequency to better inform estimates of future risk, but are challenged by a paucity of data that often fails to capture rare high magnitude events. Data on flood magnitude and frequency in the UK before 1900 are sparse in nature and regionally variable. River gauging station time series in the UK are typically short in duration (<50 years). Records of rainfall and other related meteorological series whilst longer, rarely exceed ~200 years with restricted spatial coverage. Historical reconstructions have been used to augment river gauging station data, but also fail to present a full picture of past flooding with records increasingly fragmentary with time. The duration of flood time series can be extended by incorporating additional extreme events from sedimentary palaeoflood archives.

The palaeoflood data from British lakes have only recently begun to be accessed. A challenge in developing a regional database of palaeolimnological flood series is that lakes are not ubiquitous. In Britain they are numerous in the north and west, but few occur in the south and east. Reservoirs conversely have a broader distribution with many constructed during the nineteenth century. Flood histories have rarely been generated from reservoirs despite the associated instrumental data on water levels and flows. Here, we extend the number of palaeoflood records, with new data from both lakes and reservoirs. A ~200 year sedimentary record has been developed from Thirlmere Reservoir (NW England) in the River Derwent catchment, which can be contrasted to nearby lacustrine palaeoflood series. The repeatability of reservoir palaeoflood records is explored using three adjacent reservoirs draining the western Pennines towards the River Tame catchment near Manchester. Further east across the Pennines, lacustrine palaeoflood data from Semer Water in the River Ouse catchment provide a basis for comparison with the Manchester reservoir records.

Together these archives extend the range and character of sedimentary archives used to understanding past flooding in Britain. The palaeoflood data for each sequence has been interpreted from high resolution particle size analyses and geochemical ratios diagnostic of variations in sediment grain size. Our aims are 1) to explore how reservoir palaeoflood records differ from those preserved in lakes; 2) to build new palaeoflood time series for the Derwent, Tame and Ouse catchments for comparison with existing instrumented and historical palaeoflood data.

Abstract

High-resolution pollen records obtained from well-dated lake sediments are exceptional proxies for palaeoenvironmental and palaeoclimate reconstructions. The availability of modern pollen-climate calibration datasets and the application of numerical techniques to the high-resolution paleoecological records allow the quantitative reconstructions of past climate parameters. Here, we present pollen-inferred summer temperature series for the last 200 years in northern Italy obtained from two published pollen records, Lago di Lavarone (Arpenti and Filippi, 2007) and Lago Grande di Avigliana (Finsinger et al., 2006), provided with good chronological control and sub-decadal sample resolution. The direct comparison between pollen-inferred temperature and site-specific instrumental series enables to discuss methodological issues and validates the pollen-based climate estimates. We find moderate to good correlation during the whole 200 years interval. The pollen-based temperatures capture the general warming of the last centuries and its intensification occurred in the last decades recorded in the instrumental series. Thanks to the sub-decadal resolution of the pollen records, the pollen-based reconstructions detect a short colder interval around 1910 AD and a warmer interval around 1940-1950 AD recorded in the instrumental data. Differences and shifts between the pollen-based temperatures and the instrumental series are discussed in relation to human activities and methodological issues, such as the choice of the numerical method used to develop the pollen-climate calibration models. The pollen-based temperatures provide the base for direct comparison with other proxy-based climate reconstructions (e.g. tree-rings, chironomids).

The story of two lakes: high-resolution landscape changes during the last 1300 yrs in central Italy

Irene Tunno¹, Scott Mensing², Leonardo Sagnotti³, Fabio Florindo³, Paula Noble², Claire Archer², Susan Zimmerman¹, Gianluca Piovesan⁴

¹Lawrence Livermore National Laboratory, Livermore, USA, ²University of Nevada, Reno, Reno, USA, ³INGV, Rome, Italy, ⁴Università degli Studi della Tuscia, Viterbo, Italy

Abstract

The Mediterranean area has been deeply affected by natural and human-induced changes during the last 10,000 years, resulting in a complex interaction between societies and the environment. These mutual influences deeply marked the landscape and drove the response of the vegetation to the changes, especially during the last millennium.

We reconstruct the history of landscape evolution of the Rieti basin, in the central Apennines during the last 1300 years based on a multiproxy approach. We compare stratigraphic records of pollen, non-pollen palynomorphs (NPP), microcharcoal, palaeomagnetism and rock magnetism, sedimentology, and geochemistry from Lago Lungo and Lago di Ripasottile sediment cores. The two lakes are remnants of an older, bigger lake named *Lacus Velinus* that periodically filled the plain until the late 1500s, as shown by ancient maps recovered from historical archives. The records from both lakes show a sudden decrease in forest taxa percentage during the Medieval period (900-1400 CE) and a rapid increase during the early modern time starting around 1450 CE. The Lungo cored sequence spans 2700 years in 14.37 m while the Ripasottile sequence represents 1300 years in 12.40 m - a higher sedimentation rate.

Despite the proximity and periodic connection of the two lakes, the sediments record different information about the practices of the local population. In particular the disturbance taxa, mostly related to agricultural and grazing activities, reveal a different human impact on the lakes. A higher percentage of chestnut pollen in Ripasottile than Lungo suggests a greater influence of the fluvial sediments and pollen transported by the Velino River into the lake from the surrounding mountains. Ripasottile also shows a high percentage of grass and disturbance taxa (e.g. hemp) throughout the entire sequence, whereas the Lungo sequence shows phases dominated by woodland and phases dominated by grass and disturbance taxa, particularly during the Medieval period.

Comparing the sedimentary records from Lungo and Ripasottile at high-resolution contributes to interpretation of the dynamics and responses of the vegetation to natural and human-induced changes in the landscape of a central area of the Mediterranean region during the last millennium. These results underscore the value of multiple study sites at the local scale to capture the spatial variability of human activity in changing the environment.

Abstract

The sediment record from Boundary Lake (unofficial name, Melville Island, Nunavut) provides a new continuous Holocene paleoenvironmental record from the western Canadian High Arctic, thus contributing to the geographically distributed network of reconstructions from the Arctic. Changes in watershed and lake characteristics are assessed through physico-chemical properties of the lake since the last deglaciation as well as the potential link to climatic and glacial influences over the Holocene. Boundary lake (74°56N – 109°48W) is located 7 km northwest of Cape Bounty Arctic Watershed Observatory (CBAWO). Unlike most of published studies, Boundary lake is a high elevation site for the region (100 m a.s.l.), thus isolated from marine incursion and long-term base level adjustments. It has a low-relief and small catchment area (8.2 km²), which leads to slow accumulation rates (0.15mm/yr).

A 160-cm long sediment sequence was recovered and analyzed at 1 cm resolution for total carbon-nitrogen-sulfur (CNS), visible near infrared reflectance spectroscopy (VNIRS), Chlorophyll-*a* content (Chl-*a*), and particle size. The other core half was also scanned for XRF data. The sediment age-depth model is derived from 15 samples analyzed for ²¹⁰Pb and ¹³⁷Cs combined with ¹⁴C AMS dating from 7 macrofossil layers, dating the basal of the core to 10,000 cal yrs BP. The sediment sequence consists of long intervals of laminated sediments interrupted by non-laminated sequences, with the best preservation conditions of the laminations coinciding with the highest Chl-*a* content. Following regional deglaciation, Boundary lake watershed remained under sea-spray influence (high Cl/K content) with the absence of substantial lake productivity until 8,000 BP. Within the following millennium, enhanced lake productivity was reflected by a pronounced increase in Chl-*a* along with slightly higher VNIRS-inferred lake-water total organic Carbon (TOC) levels, as well as greater Mn/Fe values suggesting increased oxygen depletion. These favorable conditions remained stable over approximately three millennia during the Holocene climate optimum.

Finally, the largest change in sedimentation occurred at 3,500 cal yr BP with a clear shift towards an erosion-based system, analogous to present day conditions. Higher mass accumulation rates are reflected by the occurrence of discrete sand-sized events, and an increase in lake-water TOC that is decoupled from Chl-*a*. This suggests enhanced catchment inputs through colder and wetter conditions. This record from Boundary Lake will help better understand the spatial pattern of paleoenvironment and paleoclimate changes of the Arctic region.

Comparing highly-resolved records of abrupt climate oscillations from the last deglaciation: testing the coincidence of the Gerzensee Oscillation and GI-1b.

Christine Lane¹, Stefan Engels², Richard Staff³, Amy McGuire¹, Rebecca Kearney⁴

¹Department of Geography, University of Cambridge, Cambridge, United Kingdom, ²Department of Geography, Birkbeck University of London, London, United Kingdom, ³Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom, ⁴Research Laboratory for Archaeology and the History of Art, University of Oxford, Oxford, United Kingdom

Abstract

Palaeoclimatic records of the last glacial to interglacial transition (LGIT) from across the North Atlantic region show consistent evidence for a series of abrupt climate oscillations. The similarity in form of the climate record in the Greenland ice cores with those from terrestrial archives across Europe and the northern American continent implies climate teleconnections operating on sub-centennial scales. Frequently the characteristic abrupt transitions of the LGIT are used as tie-points for tuning records with poor chronological control to the exceptionally well-dated Greenland ice core stratigraphy. Tuning is typically based on the undemonstrated assumption of synchronicity between proxy signals, which may in fact be sampling very different climatic or environmental phenomena. It has already been shown, using volcanic ash (tephra) isochrons and working with annually-resolved ice core and lake sediment records, that not all abrupt climatic transitions are recorded synchronously, even within the same continent (Lane et al., 2013).

In this study, we explore the timing of the Gerzensee Oscillation (GZO), a short-lived cooling event that interrupted the Allerød interstadial, prior to the onset of the Younger Dryas, using high resolution lake core records and tephra correlations to the Greenland ice cores. The GZO was described initially within $\delta^{18}\text{O}$ records from a series of carbonate lakes on the Swiss Plateau by Lotter et al. (1992). Since then, the GZO has been correlated to concomitant events (including the Killarney Oscillation and the Intra Allerød Cold Period) recorded in lake and marine records across much of the North Atlantic region. The GZO occurs in the same stratigraphic position as Greenland Interstadial 1b (GI-1b), a 212 year long isotopic downturn that terminates precisely 203 GICC05 (ice core) years prior to the onset of Greenland Interstadial 1 (GS-1). It is widely assumed that these two isotopically-defined events are manifestations of the same climatic change. We set out to test this assumption using an independent dating approach, combining tephra, annual layer counting and new radiocarbon dates. Our results raise questions about the accuracy of age models for well-known European LGIT records, key climatic transitions and volcanic eruption events.

Fade of superparamagnetic particles during catchment-to-lake transport – an important factor for interpreting magnetic properties of lacustrine sediments as paleoclimate proxy

Qi Zhang¹, Shouyun Hu², Longsheng Wang³, Erwin Appel¹

¹University of Tübingen, Tübingen, Germany, ²Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China, ³Coast Institute of Ludong University, Yantai, China

Abstract

The lacustrine sediments in Heqing basin (SW China) are a research hotspot for studying monsoon evolution in the Quaternary. Rock magnetic properties have been used as proxies to interpret less and more humid phases in the record of a 168m-deep core (HQ) drilled in the basin. In order to support the significance of magnetic proxies in this record that covers ca. the last 0.9 Ma, our study focuses on understanding the magnetic properties of catchment materials and their changes during sediment transport into the paleolake and after deposition. For this, we investigated a series of magnetic parameters of red soil samples from the catchment and samples from sediments of a small modern lake in the basin. The soil was likely providing the main source material delivered to the Heqing paleolake. It is strongly magnetic due to a large fraction of ultrafine superparamagnetic (SP) magnetite (and maghemite) that is likely an extracellular product of bacterial activity. The soil also contains larger multidomain (MD) magnetite particles inherited from weathering of the prevalent limestone bedrock around the basin. Additionally, hematite is observed which might be an oxidation product of magnetite and maghemite. The SP fraction is evidenced by very high frequency dependence of magnetic susceptibility (χ_{fd} %) of ~15-20%, and the presence of MD magnetite and hematite are indicated by thermal demagnetization of isothermal remanent magnetization (IRM) and end-member modeling of IRM acquisition curves. In contrast, as a most remarkable result, barely an SP fraction was observed in the lacustrine sediments of the HQ core (χ_{fd} % <4%). Our new results from the sediments of the modern lake indicate that during the transport process the portion of the SP fraction is partly reduced, probably by dissolution or oxidation. This is mainly evidenced by a lower χ_{fd} % (~10%) and higher relative hematite content compared to soil samples, and magnetic property changes after CBD treatment. The studied properties of the modern lake samples are rather similar throughout the sampled ~0.5 m thick sediment layer. Although no dating of these sediments is available, we can estimate that they comprise a period of several 100 years or more. Therefore the ultrafine SP magnetite fraction of the soil did not only largely survive during transport from the catchment into the lake but was also relatively little decreasing during hundreds of years while residing in the lake sediment. We thus conclude that the almost complete extinction of SP magnetite particles observed in the HQ drill-core must have been a longer (>1 kyr) lasting process or a diagenetic effect that occurred at deeper levels in the sediment column.

P-3435

Early middle Holocene climate oscillations indicated by a multi-proxy analysis of a sediment core in Hangjiahu Plain, southeast China

Wei YE, Qu CHEN, Lidong ZHU
Zhejiang Normal University, Jinhua, China

Abstract

Hangjiahu Plain is located in southeast China. The East Asian monsoon dominates the climate. During the Holocene, the study area underwent transgression and regression for many times. A Neolithic culture flourished and neolithic sites were widely distributed. In recent years, geographers have debated the climatic conditions existing at the time of the Neolithic cultures. This study reconstructed the sedimentary environment between 11.30 and 4.17 cal ka BP based on a multi-proxy analysis of a 14.3 meter sediment core, drilled in Beihuqiao, Zhejiang Province, China. The results show: (1) The climate was getting warm between 11.50 and 8.77 cal ka BP. Grain size became finer from the bottom to the top layer, accompanied by an increase in the chemical index of alteration (CIA), Mg/Sr ratio, the percentage of clay, pollen concentrations, and a decrease in SiO₂/Al₂O₃ ratio, and the value of bases–alumina (ba), as well as other trace elements. (2) Between 8.77 and 7.99 cal ka BP, the sediment is composed of gray-yellow and gray silt. The percentage of CaO and the ratio of CaO + Na₂O + K₂O to Al₂O₃ is much higher. The pollen concentration sharply decreases. The climate was cold and dry in the early stages of this period, but became relatively warmer and wetter in the later stages. (3) The Holocene Climatic Optimum occurred at 7.99–5.68 cal ka BP. Higher contents of clay, total Fe₂O₃, Al₂O₃, CIA, the chemical proxy of alteration, pollen concentration, evergreen pollens, and high values of Mg/Sr are observed at this stage, coinciding with a lower SiO₂/Al₂O₃ value, (CaO + Na₂O + K₂O)/Al₂O₃ ratio, and an obvious reduction in silt/clay, and SiO₂ and CaO concentrations. (4) During the period 5.68–4.17 cal ka BP, the temperature in the study area declined in a stepwise fashion. The grain size became finer, and the Mg/Sr ratio decreased gradually. As the Liangzhu cultural site is prominent in the study area, a significant increase in the pollen of cultivated *Oryza* in the sediments may reflect a increase in human activities. We propose that cool and dry climate may have led to the declining level of groundwater that was conducive to human activities and cultural prosperity in the area. Supplementary color and environmental magnetism investigations of the BHQ core are consistent with the results. The multiple proxy study of the BHQ core offers a reconstruction of the early middle Holocene environment in southeastern China. The climate conditions vary significantly between 11.30 and 4.17 cal ka BP.

Hydroclimatic changes during lake-level fall from last deglaciation Dead Sea sediments

Daniela Müller¹, Ina Neugebauer¹, Rik Tjallingii¹, Markus J. Schwab¹, Yoav Ben Dor², Yehouda Enzel², Achim Brauer¹
¹GFZ German Research Centre for Geosciences, Section 'Climate Dynamics and Landscape Evolution', Potsdam, Germany, ²The Fredy and Nadine Herrmann Institute of Earth Sciences, Hebrew University of Jerusalem, Jerusalem, Israel

Abstract

The Dead Sea is a terminal lake of the largest hydrological system in the Levant, which covers the boundary between the sub-humid Mediterranean and the hyper-arid Saharo-Arabian climate zones. Due to the strong precipitation gradient in this region, small shifts in the distribution of these climate zones can be documented in the Dead Sea lake sediments. Particularly, the lake level of the Dead Sea is sensitive to climate changes, showing substantial drops and rises that are directly linked with the amount of precipitation in the drainage basin. Increased drying in the Dead Sea watershed is marked by a major drop in lake level during the last deglaciation.

Core 5017-1-A of the ICDP Dead Sea Deep Drilling Project obtained a unique sediment record from the deepest part of the northern Dead Sea Basin. In this study, we analyze the annually laminated sediments of this core between 88.5-99.2 m core depth. This interval records the transition from the last Glacial to the Holocene (ca 16.5-11 ka), when the lake level dropped by ca 160 m. The laminated sediments were investigated using detailed microfacies analyses in combination with XRF element core scanning.

Microfacies analyses reveal alternating lithological facies of aad (alternating aragonite and detritus), greenish aad, gd (massive gypsum deposit within marl), native sulfur concretions (associated with greenish colored aad), mtd (typically graded mass-transport deposits) and homogenites consisting of clay to silt. Element ratios of Ti/Ca and S/Ca are examined and utilized as proxies for relative variations in detrital input (Ti/Ca) and gypsum occurrence (S/Ca). Further, the sediments are correlated to the Lisan Formation of the more distal Masada outcrop, using distinct marker gypsum layers, potentially indicating periods of pronounced lake level drop. A significant drop in lake level exposed the Masada section at around 14.5 ka, but the deep core 5017-1-A records this succeeding lake level drop into Holocene levels. The deep core sediments comprise gypsum layers and gypsum-rich deposits with higher S/Ca ratios. In addition, flood layers have been identified that might indicate severe precipitation events associated with specific eastern Mediterranean synoptic systems.

This study was funded by the German Science Foundation (DFG Grant BR 2208/13-1/-2). Further, it is a contribution to the Helmholtz Association (HFG) climate initiative REKLIM Topic 8 "Rapid climate change derived from proxy data".

Abstract

Climate-change induced thawing of Arctic soils is rapidly changing both the quantity and the quality of carbon (C) entering lakes. Lake sediments offer long-term records to probe the influence of rapidly changing landscapes, and the relative roles of climate, vegetation and lake characteristics, on aquatic C sequestration.

Here we focus on quantitative and qualitative changes in sediment organic C accumulation in four lakes along the same catchment at the boreal-subarctic ecotone in Finland. We reflect past C accumulation against present-day C flux dynamics and catchment characteristics. The four study lakes have had the same climatic forcing over the Holocene, but different positions, morphology, and vegetation development in their respective close catchments. High-resolution C accumulation rates were calculated for the past ca. 9500 years for each core. Elemental and isotopic concentrations of C and nitrogen (N), C:N ratios, and visible-near-infrared spectroscopy (VNIRS) and diatom analysis were used to infer relative changes in terrestrial and aquatic C inputs.

In their present-day state, the four lakes were placed along clear and parallel upstream-to-downstream gradients in sub-catchment peatland abundance (0–30%) and CO₂ flux (from a slight uptake to 27 mmol m⁻²d⁻¹). Spatial pattern of CH₄ effluxes varied from 1 to 1.7 mmol m⁻²d⁻¹. Furthermore, long-term average C accumulation rate over the Holocene (from 3 to 13 g m⁻²yr⁻¹) followed the elevation, peatland abundance and CO₂ efflux gradients, highlighting the role of peatlands as a key source of lacustrine organic carbon. Rapid fluctuations in C accumulation took place over the Holocene with differing between-lake patterns. Carbon quality changes followed overall Holocene climate development, but again with significant between-lake differences in the magnitude and direction of change.

We suggest that the major shifts in C accumulation and source were associated with water level fluctuations, peatland development and aquatic macrophyte abundance. Despite their location in the same catchment, the four basins faced a unique combination of changes in these factors over the Holocene, and thus presented highly individualistic responses to large-scale climate forcing. We propose that multi-lake data are essential when interpreting landscape modulation of external forcing. Together with increasing the number and geographical coverage of high-resolution datasets, multi-lake data will be pivotal when defining critical ecosystem thresholds in the Arctic.

High resolution climate and environmental reconstruction from lake sediments in Lake Comedero, NW Argentina: preliminary results.

Paula Vignoni^{1,2}, Rik Tjallingii¹, Francisco Córdoba³, Achim Brauer¹

¹GFZ German Research Centre for Geosciences, Section 4.3 Climate Dynamics and Landscape Evolution, Potsdam, Germany, ²Universität Potsdam, Potsdam, Germany, ³Instituto de Ecorregiones Andinas, CONICET, San Salvador de Jujuy, Argentina

Abstract

The Andes forelands of NW Argentina cover the climatic transition zone between the South American Monsoon System and the Pacific Westerlies, which are the two main meteorological precipitation systems of southern South America. Therefore, this region is sensitive to shifts in climatic transition zones due to climate changes and a key region for past climate reconstructions. However, only sparse information on past climate variability is available for this area. Here we present a more than 10 m long sediment record from Laguna Comedero (24° 06' 54.7" S - 65° 29' 7.2" W, 2100 m asl, 5 m deep), located in the Provincial Park Lagunas de Yala, NW Argentina. Preliminary results reveal a clear change in sedimentation from detrital brown layers in the lower part of the core to an alternation of gray clastic and black organic-rich intervals with abundant plant debris in the upper 3.5 m. Below this sediment depth we find low values for TOC, C/N and S in combination with high Si, Ti and K values, revealing no variation of detrital sediments and low amounts of organic matter. However, TOC, C/N and S values strongly increase above 3.5 m. TOC values in the upper 3.5 m ranges from 0.1 to 20.5%, while organic C/N atomic ratio reaches values up to 17, suggesting a substantial contribution of allochthonous organic matter in some layers. These intervals also show low values in elements indicative of detrital input (e.g. Si, Ti) and high Mn/Fe that indicate periods of reducing conditions at the lake bottom. Changes recorded in Laguna Comedero sediments reveal that the deposition in the lake varied strongly. Further analysis needs to be done and a detailed chronology is still required to reveal the link between this sediment record and a climate and environmental reconstruction for this region.

P-3439

Climate-driven changes in seasonal and interannual variability in diatom assemblages, productivity and deposition in Lake Tiefer See, Germany

Ieva Grudzinska-Elsberga^{1,2}, Sylvia Pinkerneil¹, Birgit Plessen¹, Achim Brauer¹

¹GFZ German Research Centre for Geosciences, Section 'Climate Dynamics and Landscape Evolution', Potsdam, Germany, ²University of Latvia, Institute of Biology, Salaspils, Latvia

Abstract

Climate change clearly is affecting aquatic ecosystems. One of climate-induced detrimental effects is alteration of the phenology of biological events. It is expected that climate change alters rates of primary production of algae; thus, causing significant consequences for aquatic ecosystems. Particular attention is paid to the lake productivity and factors affecting it. Diatoms contribute substantially to the total primary productivity of temperate lakes, as Ott et al. (2017) observed that extended periods of lake productivity in the northern-central European Lowland appear in the occurrence of thick monospecific diatom layers. The seasonal succession and productivity of diatoms differ among lakes depending on factors, such as stratification, temperature, length of ice-cover, nutrients. Recently, it has been demonstrated, that timing of spring warming and mixing duration can be crucial factors as well (Kienel et al., 2017). Hence, to permit more reliable interpretations of sedimentary diatom assemblages, it is vital to understand which factors are dominating and how climate change and anthropogenic impact affect lake ecosystems.

The aim of this study is to improve the understanding of the link between the seasonal climatic variation and biological processes in the lakes and their catchment area and to distinguish proxies that most accurately reflect the lacustrine life cycle and changes in the lake environment. We combine the proxy data of trapped lake sediments with instrumental data of weather stations, hydrogeological and limnological monitoring and analyse this comprehensive data set by multivariate statistical methods.

The study comprises a comprehensive monitoring program (sediment trapping, limno-hydrological and weather monitoring) at Lake Tiefer See, which is a part of the larger regional monitoring program the Northeast German Lowland Observatory (TERENO-NE). Since 2012, GFZ has monitored lake water and recent sediment formation using continuously measuring sensors, sediment traps with bi-weekly and monthly resolution at different water depths (50 and 12 m), and a weather station installed on a platform on the lake (Heinrich et al. 2018). Lake Tiefer See was selected as an intensive monitoring site because its sediments consist of seasonally formed laminations that are an ideal tool for the high-resolution reconstruction of climate changes. In the poster, we have provided an overview of the monitoring setup in Lake Tiefer See and preliminary results covering recent 5-6 years.

Reconstructing climate variables from microfossil proxies with machine learning – thoughts on model assessment and selection

J. Sakari Salonen¹, Mikko Korpela¹, John W. Williams², Miska Luoto¹

¹University of Helsinki, Helsinki, Finland, ²University of Wisconsin-Madison, Madison, USA

Abstract

A range of reconstruction algorithms are commonly used to infer palaeo-environmental variables from microfossil proxy datasets. Here, we test several quantitative approaches as reconstruction tools for North American and European fossil pollen data. We use the classical weighted averaging (WA) and weighted averaging-partial least squares (WA-PLS) transfer functions and the modern analogue technique (MAT), as well as machine-learning approaches based on regression tree ensembles and artificial neural networks.

Our special focus is on the reconstruction of *secondary* climate variables, as their comparatively small ecological influence presents special challenges to palaeo-reconstructions (Juggins 2013). We use July temperature as the primary reconstructed variable, while the secondary variable is water balance in North America and January temperature in Europe. These variables were chosen for their ecological significance and their low correlations to the primary variables (0.05 in North America and 0.28 in Europe).

We test our methods using a novel and comprehensive cross-validation (CV) approach. We run a series of h -block CV's (Telford and Birks 2009) using h values of 100–1500 km. This CV method has important strengths. First, the effect of spatial autocorrelation is minimized. Second, at large h values the CV approximates the challenges faced in palaeo-reconstructions with poor modern analogues available. Third, in some cases we find the model performance to change abruptly with small changes in h , revealing a sensitivity of the reconstruction model to small data variations.

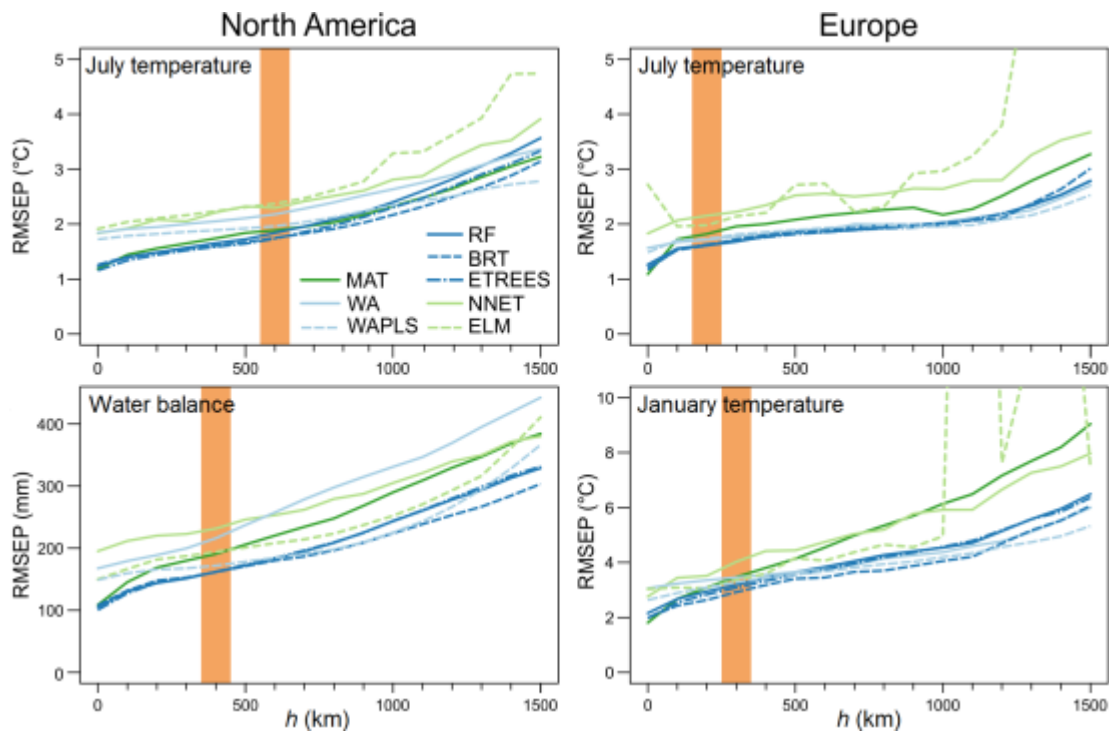

Figure 1. CV errors for North American and European pollen–climate models. Results are shown for h -block CV runs using a range of h . Orange bars indicate the h values suggested to provide neutral performance estimates.

In our CV results (Fig. 1), we find boosted regression trees (BRT) to provide the overall most robust performance, with a small advantage in root-mean-square error of prediction (RMSEP) over other tree ensemble methods (extraTrees (ETREES) and randomForest (RF)) and a more significant advantage in maximum bias. Among neural network models, the Extreme Learning Machine (ELM) generally outperforms the classical implementation (NNET). The overall performance of the best reconstruction models is strong, with errors under 10 % of calibration data gradients for both primary and secondary variables. Palaeo-reconstructions prepared from fossil pollen datasets (example in Fig. 2) show major independent features for the primary and secondary variables, consistent with identified forcings and supporting multi-proxy data.

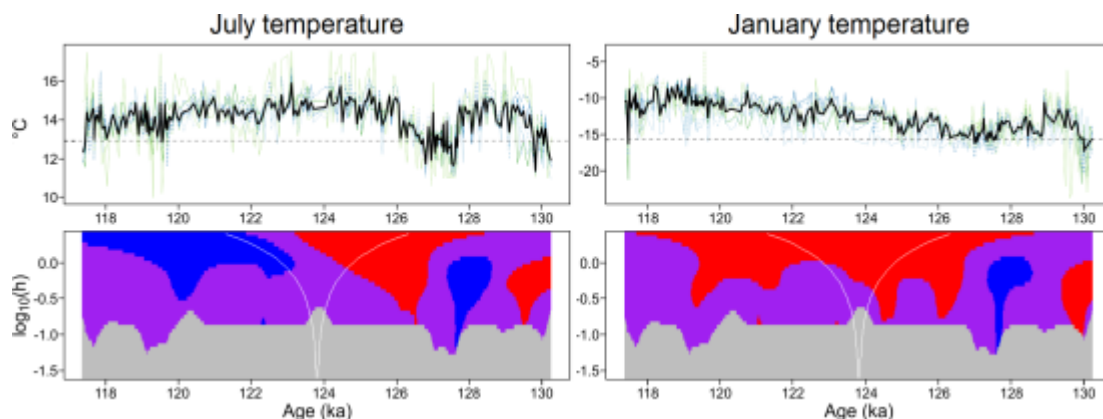

Figure 2. July and January temperature reconstruction from a Last Interglacial fossil pollen dataset from Finland (Salonen et al. 2018). SiZer maps (Chaudhuri and Marron 1999) are shown to illustrate independent features.

Principal curves in ecological data: insights into palynological shifts in response to abrupt climatic change during the Last Glacial-Interglacial Transition

Ashley M. Abrook, Ian P. Matthews , Alice M. Milner, Ian Candy, Adrian P. Palmer

Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London , Egham , United Kingdom

Abstract

Vegetation change during the Late Quaternary is often inferred to reflect either dynamic equilibrium (autogenic migratory or successional lags, population dynamics and seed dispersal) or disequilibrium variability (allogenic climatic forcing). For longer term millennial-scale vegetation development a combination of the above parameters define vegetation present at any given location. However, at the centennial-scale vegetation shifts are likely a response to abrupt climatic change and systemic feedbacks therein. The Last Glacial-Interglacial Transition (LGIT; 16-8 ka BP) is one period containing a suite of centennial to decadal-scale climatic oscillations where palynological responses to these abrupt climatic shifts are poorly constrained. However, where available highly-resolved palynological studies demonstrate increased complexity with variable responses across Britain and continental Europe. To explore this complexity, ordination techniques (Principal Components or Correspondence Analysis) are frequently applied with the first axis of variation used to define phases of change. However, this approach may only explain <40 % of the total variation within the data due to the existence of multiple environmental and ecological gradients during the LGIT. Principal Curves (PrC) may help elucidate this complexity whilst maximising the potential of palynological data.

PrCs are defined as smooth one-dimensional curves fitted via regression through an m -dimensional data space and have applications in palaeoecology. We present palynological research from sites across a north-south climatic gradient within the British Isles and apply PrCs. The PrCs perform well with the extracted gradient routinely capturing greater than 70 % of the variability within the original datasets. Subsequent palynological scrutiny reveals that the gradient defined by the data has open ground taxa and woodland as each end member permitting assessments of landscape change with shifts in PrCs. Broadly coeval shifts in PrC and climatic indices suggest that at each site the PrC can assist in delineating palynological responses to abrupt climatic change.

The PrC data presented here facilitates an understanding of the magnitudes of palynological responses to abrupt climatic changes during the LGIT. These data, and the re-analysis of key palynological sequences from Britain and Europe alongside summer-temperature isotherm maps demonstrates two major findings: 1) for the early Lateglacial climatic oscillation (a broad correlative of the GI-1d climatic event) the magnitude of the PrC shift is greater in continental Europe, despite climatic forcing being most strongly felt in Britain; and 2) for the later Lateglacial climatic oscillation (a broad correlative of the GI-1b climatic event) the magnitude of the PrC shift is greater in Britain despite climatic forcing being most strongly felt in continental Europe. This finding indicates that different vegetation sensitivities exist between Britain and Europe and/or that additional climatic parameters drive palynological change across abrupt climatic transitions.

Abstract

Rhythmical lamination is preferentially formed in deep lakes with small surface areas without bioturbation in wind protected basins. A contrasting setting characterizes present mountain lacustrine basins of Eastern Cordillera, at the Argentinean Central Andes. In this semi-arid area, seasonal (December-March) precipitation is below 400 mm yr⁻¹, mostly supplied by the South American summer Monsoon (SASM). Under these climatic conditions few shallow ephemeral lakes can be found at high-altitudes (>4000 m a.s.l.). Laguna Salada Grande (LSG) (23°S/65°W, 4100 m a.s.l.) is a small (5.8 ha) shallow (approximately 1 m depth), intermittent closed-lake. The presence of a laminated section from ~47 ¹⁴C kyr and ~22.3 cal kyr BP underlying massive sediments, together with paleoshorelines situated several meters above the present lake level, provided the basis for a high-resolution study of the Late Pleistocene paleoenvironment in this area. Using high-resolution techniques, the laminated section of a short core has been analyzed in detail with magnetic susceptibility, XRF scanning and micro-XRF mapping, and dated with AMS. The application of automated scanning electron microscope, QEMSCAN™, in impregnated thin sections was explored to picture differential mineralogical distributions. Grain size analysis in discrete laminae have shown that mixed laminae are formed by alternation of silty sands with carbonate shells, white carbonate muds, siliciclastic (illite) clays and yellow ochre Fe-rich clays. The elemental mapping of Ca/ Fe ratios indicates changes in detrital input to the lake pointing towards runoff, slope wash and rainfall processes controlling the development of lamination. Biogenic sediments also indicate seasonal changes in productivity. Ochre laminae indicate variable redox conditions and subsequent diagenetic processes. The combination of XRF geochemistry, mineralogy and image analysis at different scale resolution allows establishing a high-frequency event stratigraphy for this high-altitude lake system during a deep perennial paleolake stage. Differences within the laminated sequence suggest a shift at ~34 ka from productive conditions in a relatively deep perennial productive paleolake with water column stratification to more variable lake-stands in a smaller paleolake. These stages can be regionally correlated in time with Late Pleistocene wet cycles on the Altiplano/Puna plateau tied to the SASM activity.

Sedimentological and high-resolution pollen and aquatic microfossil analysis of Middle Pleistocene lakeshore deposits of paleolithic site Schöningen 13 II-4, Germany

Mario Tucci¹, Kim J. Krahn², Brigitte Urban¹, Antje Schwalb²

¹Leuphana University, Institute of Ecology, Subject Area Landscape Change, Lüneburg, Germany, ²Technische Universität Braunschweig, Institute of Geosystems and Bioindication, Braunschweig, Germany

Abstract

The internationally well-known Lower Paleolithic site of Schöningen is located within an open-cast lignite mine in Lower Saxony, Germany. This site is outstanding due to the finding of the world's oldest wooden hunting spears as well as large quantities of excellent preserved flint artifacts and faunal remains. The embedding sediments originate from a remarkably complete Middle Pleistocene sequence, locally named the Reinsdorf Interglacial, which is correlated with MIS 9. In order to characterize the paleo-lakeshore environment and its final transitional sedimentation cycle of lake marl (level 13 II-4c) into organic mud (level 13 II-4b) containing the spear find horizon, geochemical and high resolution palynological and aquatic microfossil analyses were undertaken on small sediment sections distributed along the shoreline of archeological site Schöningen 13 II-4. Palynological analyses focused on both taxa percentages and pollen concentrations, the latter providing additional information on conditions of sediment accumulation. Carbonate content of the horizon underlying the archeologically significant horizon is generally very high while carbon and nitrogen increase with higher biomass production and stronger silting tendencies in the upper horizon. Pine (*Pinus sylvestris*) and particularly birch (*Betula* sp.) are the dominant tree species. Based on pollen concentration, pine pollen is considered to have been transported over longer distances. At higher topographical locations and in greater distance from the lakeshore pollen concentration of aquatic taxa declines and heliophytes such as *Centaurea* sp. and *Helianthemum* sp. increase, indicating dryer and more open vegetation conditions. Pollen records of *Picea*, that most of the spears are made from, are extremely rare in both analyzed horizons which clearly indicates that the raw material was not locally derived and the spears were not manufactured close to the place of deposition. Ostracod and diatom analyses indicate shallow water at the study site with higher salinities and rich aquatic vegetation. Mesorheophilic ostracod species along with tychoplanktonic diatom taxa point to small streams at the lakeshore, presumably originating from springs on nearby highlands. A progressive terrestrialization from horizon 13 II-4c to 13 II-4b is supported by considerably decreasing microfossil concentrations and increasing proportions of benthic taxa. According to their position in relation to the paleo-lakeshore, the samples show a diverse vegetation pattern including small patches of local birch forest and species favoring wet and nitrogen rich loamy soils as well as submerged areas indicated by the occurrence of aquatic taxa. Other samples of this transitional phase point to very dry, also partly saline, terrestrial locations indicated by plants of dry grass, meadow or steppe vegetation.

Boom and bust on different scales – Neolithic and Bronze Age examples from northern Central Europe

Walter Doerfler, Ingo Feeser, Stefan Dreibrödt

Institute of Prehistoric and Protohistoric Archaeology, Kiel University, Kiel, Germany

Abstract

Linking lake records enables for a high resolution comparison of environmental records and for a comparison of the course of settlement and abandonment phases. If we are able to interlink our records, we can identify over-regional patterns of boom and bust but also local peculiarities. Thus behind the palaeo-environmental data a reliable chronological framework is necessary for a good probability of synchronism or asynchronism of events. As pollen stratigraphic connection may involve the danger of circular reasoning, an independent dating based on ¹⁴C-determination – ideally of land plants – and interlinking tephra-layers is necessary. In the frame of a collaborative research center about 'Scales of Transformation' (CRC 1600), supported by the German Science Foundation, we were able to produce high resolution palaeo-environmental records from lake sediments along a transect from Northern Germany to Greater Poland. The poster will show examples of common trends and events and of transformations that differ from site to site. This regards to boom and bust phases in the Neolithic as well as in the Bronze Age.

High-resolution quantitative reconstructions of abrupt cooling events during the Lateglacial Interstadial – Spatial trends across the British Isles.

Christopher P. Francis¹, Ian Candy¹, Stefan Engels², Ian P. Matthews¹, Adrian P. Palmer¹

¹Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom, ²Department of Geography, Birkbeck, University of London, London, United Kingdom

Abstract

The IPCC predicts that Northwest Europe will become increasingly susceptible to abrupt cooling events (ACEs) in the near future, triggered by fresh meltwater pulses into the North Atlantic originating from the Greenland ice sheet. The Lateglacial Interstadial (c. 14.7-12.9 kyr ago), a relatively warm period at the end of the last glaciation, was punctuated by several centennial-scale ACEs. These ACEs, commonly referred to as GI-1d, GI-1cii and GI-1b, are thought to have been in the order of several degrees cooling in magnitude and provide useful analogues to investigate such key research priorities. The ACEs of the Lateglacial Interstadial have been intensively studied in Britain and Ireland; however, qualitative rather than quantitative techniques have largely been utilised and have generally been applied at a low temporal resolution only. This restricts our understanding of the magnitudes and rates of climate change associated with the ACEs and their impact on the local environment. The application of quantitative techniques will enable ACEs to be fully quantified and further improve our knowledge.

Chironomid-inferred temperatures and Oxygen-isotope analysis are powerful tools for palaeoenvironmental reconstructions, as they provide quantitative inferences of past climate. As both methods require little sediment, very high-resolution datasets can be generated that are decadal, and even sub-decadal, in scale. To date, however, these techniques are rarely applied at sufficient stratigraphic resolution for the full magnitude and structure of centennial-scale ACEs to be adequately resolved. Another issue is the strong sampling bias towards certain regions, particularly the North of England, Central Scotland and the Swiss Alps. This poor, uneven spatial coverage of sites further means the spatial expression and complexities of ACEs are not properly defined across large continental scales.

This study aims to explore the requirements needed to fully investigate and characterise ACEs including: 1) the minimum number of samples needed to adequately represent past ACEs, 2) the selection of an appropriate training set(s), and 3) the geographical position of sites. To this end, we present new data from Crudale Meadow, Orkney, and Llangorse, South Wales, showing the ACEs of the Lateglacial Interstadial in near-decadal resolution, greater detail than any published site to date. The application of very high-resolution sampling has enabled their full magnitude to be identified. Our results furthermore show that ACEs, like the Lateglacial Interstadial cold events, can be easily overlooked when a more conventional sampling strategy is employed. Finally, this new data shows GI-1d is of greatest intensity in the North of the British Isles whilst GI-1b is most strongly expressed in the South.

Climate and environmental changes during the last 3000 years on Barentsøya (E-Svalbard)

Wim Hoek¹, Lineke Woelders^{2,3}, Keechy Akkerman^{1,4}, Stan Schouten¹, Friederike Wagner-Cremer¹

¹Department of Physical Geography, Faculty of Geosciences, Utrecht University, Utrecht, Netherlands, ²Department of Earth and Environmental Sciences, K.U. Leuven, Leuven, Belgium, ³Department of Atmospheric and Oceanic Sciences, University of Colorado Boulder, Boulder, USA, ⁴Department of Geography, Loughborough University, Loughborough, United Kingdom

Abstract

The Svalbard archipelago is positioned at the northern limb of the Atlantic Gulfstream and, therefore, highly sensitive to climate changes related to changes in ocean circulation. At present, a strong climate gradient from SW-NE Svalbard illustrates the Atlantic influence. While from Spitsbergen (W-Svalbard) several palaeoclimate records are available, palaeoclimate records from Barentsøya and Edgeøya (E-Svalbard) are lacking.

During the 2015 NWO-SEES expedition (<http://www.sees.nl/>) the first lake sediment records from Barentsøya and Edgeøya (E Svalbard) have been collected. The lakes, formed in isolation basins on intrusive dolorite plateaus, were selected based on their elevation above current sea-level. Based on published isostatic rebound values, the lakes became disconnected from the sea around 3000 years ago. Since then the lakes recorded biological production changes which are clearly reflected in the lithology of the cores. The presence of abundant plant macro fossils including *Salix polaris* leaf remains allows for plant palaeophysiological paleoclimate estimates, which together with pollen and diatom analysis provides a high detail palaeoenvironmental reconstruction for the last 3000 years. Age assessment of the sediments is based on Pb-210 and AMS C-14 dating on botanical macrofossils, while indications for the presence of Icelandic tephra opens up the potential for additional tephrochronological time-control.

The first results on a shallow gravity core from Lake Andsjøen, Barentsøya have been published recently and show a strong increase in organic production during the last decades. This increase in organic production appears to be the result of temperature rise and prolonged ice-free period rather than eutrophication (Woelders et al., 2018). Here we focus on the deeper part of the core where more subtle changes in organic production after the initial isolation are recorded. It appears that these organic changes reflect natural climate changes which seems to be comparable to the Roman Warm Period, Dark Age Cold Period, Medieval Climate Optimum and Little Ice Age. The recent climate warming trends seem to be out of range compared to the natural climate and environmental changes during the last 3000 years in this vulnerable area.

Sedimentary record of the Naleshwar Lake (India): a witness of climate change and human activity during the last 100 years

Dorota Czerski¹, Thierry Adatte², Sumedh K. Humane³

¹Institute of Earth sciences (IST), University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Canobbio, Switzerland, ²Institute of Earth Sciences, Faculty of Geoscience and Environment, University of Lausanne (UNIL), Lausanne, Switzerland, ³Post Graduate Department of Geology, Rashtrasant Tukadoji Maharaj Nagpur University, Nagpur, India

Abstract

In the present study a multiproxy approach including sedimentological, mineralogical and geochemical analyses was carried out on two cores sampled in the Naleshwar lake (Maharashtra, central south India). The small reservoir lake is located on a basement of metamorphic sedimentary rocks. Forest and small villages surround the area and the local people main livelihood consists in animal breeding, fishing and agriculture activities. The semi-arid climate affected annually by the monsoon causes important yearly water level fluctuations.

The study aimed to provide a reconstruction of the recent history of the lake. First, the sedimentary record was analyzed, in order to correlate the weathering of the catchment and the detrital supply due to climate variations, seasonal or over a larger scale. Secondly, the anthropogenic influence on the lake sedimentation regime was evaluated. A precise chronostratigraphy was carried out for the first time on central India lakes using the method of ¹³⁷Cs activity within the sediments.

The dating showed that studied sediments approximately cover the last seventy years, with sedimentation rates of 1.7 cm/year. The data revealed very fine sediments with cyclical variations between a silty and clayey deposit, which could be mainly related to climate and seasonal variation (magnetic susceptibility, granulometry, mineral fraction (%)). In the upper part a positive excursion of clay minerals, iron and phosphorus is observed. Suggesting that some change in sedimentation or supplies is registered, this could be natural or human induced.

The record shows an allochthonous source of organic matter to the lake. However, the increase of phosphorus in the upper part of the core reflects an eutrophication of the basin, with a resulting increment of primary productivity in the lake. TOC (%), N_{tot} and the organic carbon isotope increase towards the top of the core, the combined higher HI reflects an enhancement of the algae proliferation in the basin. Additionally, a uranium rich layer corresponding to the increase of primary productivity suggests the setting of anoxic/suboxic conditions in the lake basin. This observation is coherent with the resulting depletion of phosphorus towards the top of the core. Finally, the main weathering product of the catchment is kaolinite. This clay mineral is very common in warm and humid regions and is often a product of quartzitic rocks. The clay minerals as well as the CIA (around 85%) remain constant all over the record.

To conclude, the recorded eutrophication could result from human activity and the surrounding cultivated fields. But except this, the sedimentological record seems to be related to natural variations as climate. Nevertheless, the sedimentary record shows a decrease of the organic carbon isotopic composition from bottom to top of the cores. This could be the result of the global and human induced environmental change.

Lake Gorgana paleolake – New insights in the mid-Holocene evolution of the Lower Danube valley, southern Romania

Dirk Nowacki¹, Carolin Langan¹, Annette Kadereit², Anna Pint³, Jürgen Wunderlich¹

¹Department of Physical Geography, Faculty of Geosciences, Goethe University Frankfurt, Frankfurt/Main, Germany,

²Institut for Geography, Heidelberg University, Heidelberg, Germany, ³Institut of Geography, University of Cologne, Cologne, Germany

Abstract

Geoarchaeological studies in the periphery of the archaeological site Măgura Gorgana, one of best studied settlements representing the transition from Neolithic times to Copper Age, uncovered the environmental situation in this area to contribute to a better understanding of human-environment interactions during this period.

Within the framework of sedimentological research using a multi-proxy and a regionalisation approach, it was proven for the first time that the Lower Danube valley was covered by an extensive lake from the 8th millennium BC to the beginning of the 2nd millennium AD. The analyses of the sediments of the so called 'Lake Gorgana' also provided valuable insights into the lake's paleoecology, which changed within the course of lake evolution. These new findings that will be presented are of great importance for archaeology as they shed a completely new light to the prehistoric settlement in the Lower Danube region. From a geoscientific point of view, the lake sediments also represent an extremely valuable geoarchive that allows conclusions to be drawn about changes in the lake ecology, the paleoclimate, and the human influence on the landscape on various spatial and temporal scales.

Early Holocene ecosystem dynamics: a palaeontological approach from the annually-resolved record of Diss Mere, UK

Amy A. Walsh, Alice M. Milner, Simon P.E. Blockley, Celia Martin-Puertas

Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, United Kingdom

Abstract

Understanding the resilience and sequence of change in different components of an ecosystem is a priority research area in ecology, especially during periods of environmental instability. Testing the sensitivity of ecosystems to external forcing (i.e. climate and human impact) and assessing rates of change requires records on longer timescales (decadal to millennial scales) than those typically addressed in contemporary ecological studies. Combining ecology and palaeoecology, therefore, provides crucial data to refine our understanding of ecosystem change, yet, the integration of the two is often limited by the temporal resolution.

The use of annually-laminated (varved) lake sediments provides a unique means to analyse multiple biological indicators (pollen, plant macrofossils, diatoms) at an annual to seasonal resolution. Diss Mere is a small lake in East Anglia (UK), that provides a 17-m annually-laminated (varved) sediment record spanning much of the Holocene. New cores were retrieved from the deepest part of the lake (6 m) in 2016 and an independent chronology established, based upon varve counting, radiocarbon dating and tephrochronology. This study presents new data from the early Holocene portion of the record (ca 10.6-8 ka BP) with high-resolution, decadal-scale pollen analysis. The earliest sediments within the laminated sequence are characterised by an increasing dominance of the temperate woody taxon *Corylus*. The *Corylus*-dominated woodlands transition through a successional sequence towards a mosaic of deciduous forests with stands of *Quercus*, *Ulmus*, *Tilia* and *Alnus*. Given that the early Holocene in Britain is known to be one of low level, pre-agricultural human occupation and thus major anthropogenic influence is thought to be minimal, the varved sediments of Diss Mere allow us to present an insight into the landscape sensitivity to major rapid climatic oscillations identified during the early Holocene (i.e. the 10.3, and 9.3 ka BP climatic events).

Investigating meromixis dynamics in varved lake sediments of Lake Jaczno, Poland using high-resolution hyperspectral imaging and XRF data.

Stamatina Makri¹, Wojciech Tylmann², Hendrik Vogel³, Martin Grosjean¹

¹University of Bern, Institute of Geography & Oeschger Centre for Climate Change Research, Bern, Switzerland,

²University of Gdansk, Faculty of Oceanography and Geography, Gdansk, Poland, ³University of Bern, Institute of Geological Sciences & Oeschger Centre for Climate Change Research, Bern, Switzerland

Abstract

Lake ecosystems are very sensitive to environmental changes, of both climatic and human induced origin. Eutrophication and meromixis can occur naturally as part of the lake evolution or much faster due to external forcing, leading to altered biogeochemical cycles and anoxia. Yet, not much is known about events of paleoproductivity, meromixis and hypoxia in the past due to analytical difficulties and lack of effective proxies. The assessment of the causes and dynamics of such changes require long term, high-resolution data.

The varved lake sediment record of meromictic Lake Jaczno has so far been analyzed for the last 1700 years, revealing its great potential for a long-term assessment of the causes and dynamics of meromixis and hypoxia [1]. Here we analyze a 12-meter sediment record utilizing recent developments in novel hyperspectral imaging (HSI) techniques combined with XRF scanning. This study completes a series of applications across Europe (Greece, Switzerland, and Poland). The aim is to show how and when meromixis/hypoxia established and vanished over Holocene time scales and which where the forcing factors (erosional input, land use change, climate). For this, we perform HSI scanning at very high spectral (3 nm) and spatial (40 μm pixel size) resolution, able to detect sedimentary pigments at sub-millimeter scale. We use hyperspectral indices to infer quantitatively {Chl a and chlorins} as an indicator for aquatic primary production and Bacteriopheophytin a (Bphe a) as an indicator for meromixis [2]. Bphe a is a diagenetic product of Bacteriochlorophyll a, produced by anoxygenic phototrophic bacteria in the chemocline. Pigment compositions are inferred from sets of spectral indices, such as the Relative Absorption Band Depths (RABD). Indices are calibrated with absolute pigment concentrations of selected samples of the sediment sequence as measured by HPLC, using linear regression models (e.g average RMSEP of 9% or 200 $\mu\text{g g}^{-1}$). Chronology is based on radiocarbon dating of terrestrial plant microfossils. In addition, we measured relative changes in sedimentary element composition by high resolution XRF scanning and the organic matter and carbonate content by LOI/CNS analysis. Preliminary results show a strong link of the lake mixing regime with catchment processes. Meromixis is present during periods of a closed and more stable landscape around the lake (i.e. without human disturbance). Remarkably, meromixis is interrupted mainly by the presence of an open landscape around the lake during periods of intense deforestation and soil erosion in the catchment.

Potential keystones to paleoenvironmental studies: characteristic phytoliths in Norway spruce needles

Zsuzsa Lisztes-Szabó¹, Botond Buró¹, Attila Csík², Petr Kuneš³, Mihály Molnár¹, Mihály Braun¹

¹Isotope Climatology and Environmental Research Centre, Institute for Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary, ²Laboratory of Electron Spectroscopy and Materials Science, Institute for Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary, ³Department of Botany, Faculty of Science, Charles University, Prague, Czech Republic

Abstract

Phytoliths (also known as silica bodies or plant opals) are preserved in soils and sediments as well as have taxonomic relevance, therefore phytoliths can be fingerprints of the vegetation of the period from which they originated. Comparative phytolith studies are essential for finding phytolith morphotypes with taxonomic relevance. These are used to build reference collections for future paleoecological and archaeobotanical studies.

Biogenic silica extracted by dry ashing method from six woody species commonly occurring in temperate climate plant communities were examined (*Corylus avellana* L., *Fagus sylvatica* L., *Quercus robur* L., *Abies alba* Mill., *Picea abies* [L.] H.Karst, *Pinus sylvestris* L.). Elemental analysis of phytoliths was conducted by scanning electron microscopy (Hitachi S4300-CFE) using Energy Dispersive X-ray Fluorescence. The phytolith taxonomic diagnostic potential of element content was tested by discriminant analysis. The anatomical position of the silicon accumulation was examined by X-ray element mapping.

High concentrations of aluminium and magnesium in phytoliths are associated with two of three conifer species. *Abies alba* and *Pinus sylvestris* could be differentiated statistically on the basis of elemental content. An inventory of phytolith types with anatomical origin was provided and type-frequencies were assessed. The most important finding is that a characteristic cubical phytolith morphotype ("*Picea* – cubic type") originating from transfusion tissue was described as a distinct layer encompassing the central cylinder of the needle.

To make sure that these characteristic cubical phytoliths are preserved in the fossil needles of *Picea abies*, a 4 m long sediment section was retrieved at the deepest point of Černé Lake, Bohemian Forest, Central Europe (1028 m a.s.l.), with a modified Kullenberg type piston corer. Subsamples of sediment were taken contiguously, over 1 cm depth intervals, and fossil *Picea abies* needles were sorted out. Phytoliths were identified in situ position in the fossil tissues on the longitudinal and cross sections of leaves cut by blade using stereomicroscope. Microphotos of phytoliths were also taken in situ position, the element content of phytoliths was analysed by SEM EDX. Radiocarbon dating of bulk and fossil needle samples were completed at the Hertelendi Laboratory of Environmental Studies, Debrecen, Hungary. There was not any significant difference between the fossil phytoliths (oldest are 7680–8023 cal yr BP) and the recent ones in the element content and ultra structure of surfaces, thus there was no any traces of corrosion. Consequently, *Picea* – cubic type phytoliths allow comparative, *in situ* studies to provide the possibility to find further measurable proxies. Moreover, our findings provide the possibility to identify the taxa based on phytoliths from soils and sediments.

The research was supported by the European Union and the State of Hungary, co-financed by the European Regional Development Fund in the project of GINOP-2.3.2.-15-2016-00009 'ICER'.

Late Holocene aridification in the Indian subcontinent: Myths versus reality

Sayak Basu, Prasanta Sanyal, Anoop Ambili

Indian Institute of Science Education and Research Kolkata, Mohanpur, India

Abstract

Isotope-based records, pollen, and productivity data suggest that variations in Northern Hemisphere summer insolation affected Indian summer monsoon (ISM) precipitation during Late Holocene. The subsequent gradual decrease of summer monsoon precipitation has also been linked with regional (reduced convection, a shift in moisture source) and remote (SST change in Pacific Ocean) climatic factors. In contrast to well explored ISM variability, no detailed study has evaluated the influences of these factors on its boreal winter counterpart-Northeast monsoon (NEM), despite observing an inverse relationship between modern ISM and NEM precipitation. In boreal winter months (October to December), southern peninsular India receives dominant fraction of annual precipitation from NEM while ISM contributes only about 25% of the total precipitation. Understanding the variability of the relative contribution from each monsoon to the annual precipitation cannot be resolved by studying the fluvial architecture or elemental concentrations in sediment. In the absence of monsoon-source specific climate records from southern peninsular India, the onset and causal factors of the anti-phase relationship between two monsoonal precipitations remain elusive.

Here, leaf-wax hydrogen isotopic composition ($dD_{n-alkane}$) from the pit sediments retrieved from now-dry Lake Ennamangalam, southern peninsular India has been used to understand precipitation change during the last 5000 cal yr BP. Isotopic compositions of modern precipitation and vegetation served as the basis for interpreting climatic signals retained in lacustrine archive. The monthly amount-weighted oxygen ($d^{18}O_{prec}$) and hydrogen (dD_{prec}) isotopic composition at nearby station (Chennai) varied from $\pm 1.5\text{‰}$ to $\pm 7.4\text{‰}$ and $\pm 12.0\text{‰}$ to $\pm 52.0\text{‰}$, respectively. More positive dD_{prec} values ($\pm 19\text{‰}$ to $\pm 9.7\text{‰}$) were associated with precipitation sourced from Arabian Sea during ISM while more negative dD_{prec} values ($\pm 37.4\text{‰}$ to $\pm 14.7\text{‰}$) were related to precipitation derived from Bay of Bengal during NEM. Therefore, more negative isotopic excursions in geological archives in southern peninsular India would correspond to high NEM precipitation. The most prominent feature of the $dD_{n-alkane}$ curve is the gradual lowering since the last 3000 cal yr BP, which reflects an increase in NEM precipitation over southern peninsular India. Intensification NEM precipitation was related to southward migration of Intertropical Convergence Zone and subsequent higher frequency of El-Nino events. However, the same mechanisms were responsible for the reduced summer monsoonal precipitation in the Indian subcontinent, and thus established an inverse relationship between two monsoonal precipitations. The present study also identifies that enhanced cold season NEM precipitation favored C_3 plants in the study site after 3000 cal yr BP. Our findings on precipitation-vegetation interaction are expected to improve crop-management policies, especially when increasing El-Nino activity is predicted under warmer climate.

P-3453

The Island of Amsterdamøya: A key site for studying past climate in the Arctic Archipelago of Svalbard

Jostein Bakke

University of Bergen, Bergen, Norway

Abstract

Due to its location near the interface of oceanic and atmospheric systems source from Arctic and Atlantic regions, Amsterdamøya is a key site for recording the terrestrial response to marine and atmospheric changes. We employed multi-proxy approaches on lake sediments, integrating physical, biogeochemical, and isotopic analyses to infer past changes in temperature, precipitation, and glacier activity. The results comprise a series of quantitative Holocene-length paleoclimate reconstructions that reveal different aspects of past climate change. Each of the four papers addresses various facets of the Holocene climate history of north-western Svalbard, including a reconstruction of the Annabreen glacier based on the sedimentology of the distal glacier-fed lake Gjøavatnet, a reconstruction of changing hydrologic conditions based on sedimentology and stratigraphy in Lake Hakluytvatnet, reconstruction of summer temperature based on alkenone paleothermometry from lakes Hakluytvatnet and Hajeren, and a hydrogen isotope-based hydrological reconstruction from lake Hakluytvatnet. We also present high-resolution paleomagnetic secular variation data from the same lake, which document important regional magnetic field variations and demonstrate the potential for use in synchronizing Holocene sedimentary records in the Arctic. The paleoclimate picture that emerges is one of early Holocene warmth from ca. 10.5 ka BP interrupted by transient cooling ca. 10-8ka BP, and followed by cooling that mostly manifested as two stepwise events ca. 7 and 4 ka BP. The past 4ka were characterized by dynamic glaciers and summer temperature fluctuations decoupled from the declining summer insolation.

P-3454

A multi-proxy lacustrine record to understand role of global teleconnections in triggering extreme events in Indian Monsoon realm

Ankit Ankit¹, Bulbul Mehta¹, Praveen K Mishra², Anoop Ambili¹, Parth Shah³

¹Indian Institute of Science Education and Research, Mohali, India, ²Wadia Institute of Himalayan Geology, Dehradun, India, ³Indian Institute of Science Education and Research Mohali, Mohali, India

Abstract

We aim to develop a comprehensive picture of late Holocene climate variability over the North-Eastern India to address the existing large spatial gaps in paleoclimate data coverage in Indian subcontinent. This region receives precipitation only from the Indian Summer Monsoon (ISM) and lies in the region sensitive to the impact of various teleconnections (e.g., El-Niño, North Atlantic oscillations and Indian Ocean Dipole). A multi-proxy approach involving elemental concentration, isotopic geochemistry ($\delta^{13}\text{C}_{\text{org}}$, $\delta^{15}\text{N}$), pollen as well as biomarker (*n*-alkane) investigations have been performed on short sediment cores (ca. 1.0 m long) retrieved from Shilloi Lake, Nagaland, NE India (25° 35' 44" N, 94° 47' 33" E) to decipher climate vis-à-vis vegetation dynamics in the region.

The chronology of the core sediment is based on the 8^{14}C dates derived from bulk organics, charcoal and organic fragments. The $\delta^{13}\text{C}_{\text{org}}$ values from the core sediments ranges from -34‰ to -23‰ with a sharp excursion of ~8‰ observed during 1000 cal yr BP. The grain size parameters (D[4,3]- De Brouckere Mean Diameter) also demonstrate enhanced ISM precipitation from 1000 cal yr BP. Furthermore, pollen and *n*-alkane indices also provide evidences of vegetational shift corresponding to the changes in the rainfall variability. The present work will provide an improved picture of the ISM variability and helps to identify the possible teleconnections responsible for the changes in regional paleoclimate during the late Holocene.

P-3455

Which different sources drive the distribution of biomarker lipids (brGDGTs) in lacustrine sediments?

Cindy De Jonge¹, Yuki Weber², Timothy Eglinton¹

¹ETH, Zurich, Switzerland, ²Harvard, Cambridge, USA

Abstract

Branched glycerol dialkyl glycerol tetraethers (brGDGTs) are membrane-spanning bacterial lipids that show a large structural diversity in the environment. In lakes the lipid fingerprint, i.e. the fractional abundance of all 15 brGDGT compounds, has been shown to correlate with the surface temperature of modern lakes (Russell et al., 2018). The interest of the paleoclimate community in using lacustrine sediments to reconstruct continental climate stems from the limited bioturbation (especially in anoxic sediments) and absence of wind erosion, which allow the development of continuous geological archives, often with an annual resolution. BrGDGT compounds are thus recovered from lacustrine sediments formed in lakes of different sizes, in different climates and at different time scales. For example, Holocene temperature records have been based on a Maar lake in subtropical China (Hu et al., 2015) and changes since the late Pleistocene have been reconstructed based on East African lakes (Loomis et al., 2015).

However, at all these sites the use of brGDGTs relies on a major assumption: that the brGDGT encountered in the lake sediments are sourced from a single source: the lake surface water. However, brGDGTs are produced in high abundance in soils and transported with surface run-off, they are produced within the rivers that drain the watershed (Buckles et al., 2014a; De Jonge et al., 2014), within the lake water column (Buckles et al., 2014b; De Jonge et al., 2015) and within lake sediments (Tierney et al., 2012). Also inflowing and outflowing rivers, and deep water layers compared to surface water layers are characterized by different brGDGT signatures (De Jonge et al., 2015: Lake Baikal; Buckles et al., 2014b: Lake Challa; Buckles et al., 2014a: Loch Lomond, Weber et al., 2018: Lake Lugano).

In this presentation I will show how the changing contribution of different brGDGT sources is observed in modern ecosystems, using examples from literature (i.e. Weber et al., 2018). Secondly, I will show a long-term database of high temporal resolution sampling in the Swiss Sihl river watershed, to illustrate how the different run-off regimes are reflected in the lipid signatures in modern aquatic systems. As brGDGTs remain very powerful tools to reconstruct climate change in lacustrine sediments, I will introduce a method to identify those lacustrine archives in which brGDGTs can be used with confidence.

Atmospheric dust loading, sediment geochemistry and East Asian summer monsoon linkages since the last interglacial of Lake Xingkai, northeast China

Ji SHEN, Weiwei SUN

Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

A 336-cm-long sediment core spanning the last 130 ka was recovered from Lake Xingkai on the northeastern margin of the East Asian summer monsoon domain to reveal the linkage between lacustrine depositional processes and environmental changes. Bayesian end member modeling analysis was conducted to partition and interpret the grain-size distributions of Lake Xingkai sediments. Our results suggest that the sedimentary system is characterized by three end members (EMs). EM1 and EM2, with a modal value of 13 and 10 μm , respectively, indicate the variation of local hydraulic conditions. EM3, with a modal value of 5 μm , reflects the background atmospheric dust loading. Major elemental analyses on lacustrine samples and sand samples from Lake Xingkai and the surrounding sandy ridges in northeast China indicate that their abundance varied in relatively narrow ranges. The samples had only undergone the primary stage of chemical weathering. Similar Ti/Al and K/Al ratios between the lacustrine samples from Lake Xingkai and the loess-paleosol samples in north China were observed, which suggests that they come from broadly similar desert sources. Due to the significant dependence on grain-size and influence of sediments recycling, Chemical Index of Alteration of the lacustrine sediments could not be regarded as sensitive indicators of source regions' weathering on the glacial-interglacial timescale. Alternatively, the geochemical proxies of the lacustrine sediments could be linked to the Asian summer monsoon through the development of runoff and physical erosion in the catchment.

In summary, high atmospheric dust concentration generally occurred during Marine Isotope Stage (MIS) 5d, MIS 4, and early MIS 3, when the climate in the Asian dust source region was cold and dry. In contrast, low dust concentration prevailed during MIS 2, likely due to the southward shift of the westerlies driven by maximum ice volume in the high latitudes. However, weakened Asian summer monsoon caused more fine particles transported to the lake basin by reduced runoff in the last glacial period. In contrast, coarser and less-weathered detritus are transported into the lake accompanying strengthened Asian summer monsoon during the warm periods. Our results suggest that the BEMMA and Chemical Index of Alteration method represents a powerful tool for indicate erosion in the lake catchment and unmixing of the polymodal grain-size distributions of lacustrine sediments, which, in turn, deepens our understanding of the sedimentary processes of clastic materials in lake systems and the environmental conditions of the catchment during the geological past.

Ltd., Kyoto, Japan, ⁷Department of Chemistry, Faculty of Science, Gakushuin University, Tokyo, Japan, ⁸Geochemical Research Center, Graduate School of Science, the University of Tokyo, Tokyo, Japan

Abstract

The Early-Middle Pleistocene Transition (EMPT) is characterized by the change in climatic pacing from precessional variations to glacial-interglacial cycles with a quasi-100 kyr frequency, which has been clarified from many marine and terrestrial sediments, and Antarctic ice cores. The EMPT includes two important chronostratigraphic horizons of the Jaramillo Subchron (1.07-0.99 Ma) and the Matuyama-Brunhes boundary (MBB; around 0.78 Ma). During the geomagnetic reversals, short cool climatic events were reconstructed within the warmer interglacial intervals from the marine sediment core (Higashinada 1700-m core) from Osaka Bay, southwestern Japan. It is suggested that the cooling was caused by weakening of geomagnetic intensity through an umbrella effect. However, the cooling event during the MBB has not recognized in the marine facies of the Early-Middle Pleistocene Kokumoto Formation exposed in the Boso Peninsula, eastern Japan. To confirm the cooling event and its mechanism, along with the clarification of high-resolution climate changes in the early half of the EMPT, we focus on the Katata Formation of the Kobiwako Group outcropping in the hilly area west of Lake Biwa, southwestern Japan. Lacustrine sequences predominate in the formation, with intercalated less fluvial beds and some widespread volcanic ashes named the Kisen, Biotite-1 (Bi-1) and Biotite-2 (Bi-2) volcanic ashes in ascending stratigraphic order. The MBB was detected approximately 10-m above the Bi-1 by previous researchers. The Kisen and Bi-2 volcanic ashes are correlated with the Azuki (0.86-0.85 Ma) and Hakkoda-Kokumoto (0.76-0.75 Ma) tephra layers, respectively, which are contained in the Kokumoto Formation. The Higashinada 1700-m core also includes the Azuki and Bi-1 tephras. Sixty one zircon crystals are collected from Bi-1 and used for the LA-ICP-MS U-Pb dating. After removing one broken crystal and correcting the non-equilibrium effect, we determine the concordant U-Pb age of the Bi-1 to be 0.80 ± 0.01 Ma (error in 2-sigma) based on 7 grain results. Thus, these three marker tephras can chronostratigraphically correlate the marine and fluvio-lacustrine sediments among these localities, providing the comparable palaeoclimatic records during the early phase of the EMPT. We have obtained an 84.5-m long core from the Katata Formation in late 2018. It covers the horizons below the Bi-2 tephra possibly with the Kisen and Bi-1 tephra horizons and includes oriented all-core samples about 60-m long. We will present the precise horizon of the MBB in this core and the preliminary results of palaeoclimatic reconstruction based on pollen and diatom analyses.

Abstract

Cladocera (Crustacea: Branchiopoda) constitute a major component of the planktonic and benthic fauna of the high-latitude lakes. They are tolerant to extreme environmental conditions and are one of very few groups of aquatic animal that are not only able to persist in cold thermokarst lakes but to build up viable populations. Subfossil Cladocera investigations in northern Siberia have the potential to reveal Holocene environmental variations, which likely have consequences for global climate change because of the strong high-latitude feedback mechanisms. Here, we present results of subfossil Cladocera analyses of a lake sediment core from the southern Taymyr Peninsula (northern Siberia) covering ~7100 cal years BP to present.

In total, 24 Cladocera taxa from five families were identified in the core, consisting mainly of Chydoridae. The distribution of the most common Cladocera taxa across the depth gradient showed heterogeneity among the samples. For the lowest part of the lake sediment sequence, we hypothesise initial thermokarst refers to a suite of landscape processes associated with the thawing of ice rich permafrost, or melting of massive ground ice, which modify the local topography. During that time, high temperatures and high humidity together with poor drainage may have promoted the formation of a small water-filled depression at the study site lasting for around 500 years. Our subfossil Cladocera data from the period following the initial lake formation from 6550 until around 5100 cal years BP are closely linked in to the processes of a deepening water body. An increase in the abundance of phytophilic and cold-water taxa ca 5100–2150 cal years BP indicates the ongoing development of a macrophyte belt in the shore area. The reconstructed conditions were close to the modern after 2150 cal years BP. Our results confirm earlier investigations from north-eastern Siberia using pollen and/or macrofossils analyses (Andreev et al 2011; Klemm et al 2015).

This work was funded by the Russian Government Program of Competitive Growth of Kazan Federal University, by the subsidy allocated to Kazan Federal University for the state assignment in the sphere of scientific activities and supported by RFBR (projects 18-05-00406, 18-05-60291 Арктика). The part of this work concerning microscopy of Cladocera was supported by grant from Russian Scientific Foundation (project 16-17-10118).

Using varved lake sediments to reconstruct eutrophication and recovery in Lake Vesijärvi, Southern Finland

Sarianna Salminen¹, Saija Saarni¹, Tom Jilbert², Eeva Haltia¹

¹University of Turku, Turku, Finland, ²University of Helsinki, Helsinki, Finland

Abstract

Lake Vesijärvi in Southern Finland experienced strong anthropogenic eutrophication and hypoxia in the mid 20th century, principally due to the discharge of municipal and industrial waste waters from the adjacent city of Lahti. Comprehensive rehabilitation actions, including improved waste water treatment, removal of fish, and most recently aeration, have led to a recovery of water quality in recent decades. Due to spatial and temporal gaps in water quality monitoring, varved sediments in the Enonselkä basin of Vesijärvi may provide the most complete record of the evolution of hypoxia in the lake. Sediments in the Enonselkä basin of Vesijärvi have previously been reported to exhibit varve formation during periods of hypolimnetic hypoxia.

Here we study the occurrence of varved sediments along water-depth transects in the Enonselkä basin. Varve preservation started in the 1950s, reflecting the growing anthropogenic influence on the lake at this time. This result contrasts Vesijärvi with other Finnish lakes with varved sediments, whose varve preservation started thousands of years ago due to natural vulnerability to stratification. Varve thickness and continuity are greatest in the deepest stations, due to focusing of organic material and strongest oxygen depletion in these areas.

The results suggest that varve formation persisted beyond the improvement in waste water treatment (late 1970s), implying continued deep water oxygen stress, although varve thickness declined at this time due to lower organic matter flux to the sediments. Varve formation was terminated by lake aeration since 2009, indicating that this restoration action had the single most dramatic impact on bottom water oxygen conditions.

Climatic oscillation cycles modulating the Río de la Plata fluvial discharge into the adjacent continental shelf, during the Late Holocene

Laura Perez¹, Carolina Crisci¹, Till Hanebuth², Felipe García-Rodríguez¹

¹CURE, UdelaR, Rocha, Uruguay, ²Department of Coastal and Marine Systems Sciences, South Carolina, USA

Abstract

The Río de la Plata estuary (RdIP) and adjacent inner continental shelf exhibit complex hydrological processes, resulting of the highly variable continental discharge and associated terrigenous supply, primarily controlled by regional climatic forcing in interaction with the oceanographic system. This study aims to analyze the cyclicity in the continental supply and the associated climatic oscillation behind it over the past 1,000 years. To achieve this, we used a 10-m-long sediment core GeoB13813-4 retrieved from the RdIP mud depocenter, which exhibits an extremely high sedimentation rate, with a mean of 1.1 cm yr⁻¹. We analyzed Fe/K, Ti/Al, Fe/Ca, Ti/Ca and Si/Al XRF element ratios considered as regional proxies for inferring fluvial supply and freshwater and marine diatom indicative groups, and performed time series analysis (Lomb periodograms and wavelet analyses).

The most significant cyclicities occur at 2- 8, 35, 37, 47, 49, 100, 115, 192 and 215 yr recurrence times. The long-term cyclicity is persistent throughout the whole record and it is most probably related to solar forcing, i.e. the 200 yr Vries/Suess cycle, which determines the activity of the South American Monsoon System activity. In addition, the shorter climate-related cyclicities (<100 yr) were assigned to the Atlantic Multidecadal Oscillation (AMO), the Pacific Decadal Oscillation (PDO) and the El Niño Southern Oscillation (ENSO) climatic modes.

This study provides new evidence that both tropical Pacific and Atlantic SSTs and solar forcing are the main drivers of changes in rainfall over Southeastern South America on inter-annual to decadal, multi-decadal and centennial scales, and thus modulates the RdIP river discharge.

¹LPB-HNB, La Paz, Bolivia, Plurinational State of, ²ISEM-IRD, Montpellier, France, ³MNHN-LPB, La Paz, Bolivia, Plurinational State of, ⁴Institute of Geography, University of Bern, Bern, Switzerland, ⁵LMI-EDIA, IRD, Montpellier, France

Abstract

The Beni region is located in the southern Amazonian foreland basin and exhibits numerous lakes and rivers at the rainforest forest–cerrado ecotone. Geomorphological, paleoenvironmental and archeological studies showed subregion-specific responses to past environmental changes. Our study is located in the Northern Beni and aimed to improve our knowledge on regional landscape changes during the Holocene. We performed pollen and charcoal analyses on an 8600-yr sediment core collected on the margins of one of the largest lake of the area, the Ginebra Lake. Gallery forest and lacustrine sediment were observed from 8645 cal yr BP until 3360 cal yr BP. After 1700 cal yr BP the coring site changed from a lacustrine to a swamp environment. The Cerrado-like landscape with a *Mauritia* swamp on the lake margins became installed 1000 years ago. During the last 1000 years BP anthropogenic disturbances are attested first by fire activity and cultivated plant taxa. Then, after 540 cal yr BP, the absence of fire and the increase in maize and in the Cerrado tree taxa suggest the development of the raised field cultivation. Our results evidence a west-east climatic gradient with the persistence of the rainforest throughout the whole Holocene on the western side and the presence of the Cerrados until the late Holocene on the eastern side. The influence of the Andes on the western Amazonian lowlands mitigated the insolation-linked SASM variability along a west-east gradient. In the last 1000 years Pre-Columbian population around Lake Ginebra initially performed agriculture using fire but then switched to no-fire agriculture on raised fields

Verification of wavelet analysis interpretation of μ -XRF paleoclimate data from lake sediments using PCA, cluster analysis and empirical climate data

Gianna Evans¹, Paul Augustinus¹, Patricia Gadd², Atun Zawadzki², Amber Ditchfield¹

¹University of Auckland, Auckland, New Zealand, ²ANSTO, Sydney, Australia

Abstract

Reliable interpretation of annual resolution climate proxies for wind, precipitation, and detrital influx are a necessity for understanding the onset and periodicities of climatic events. In particular, verification of individual climate proxies in a μ -XRF time series data set is essential for the evaluation of inter-annual, decadal, and centennial periodicities driven by shifting positions of the South Westerly Winds (SWW) and subsequent storm belts associated with the Southern Annular Mode (SAM) and El Niño Southern Oscillation (ENSO) using wavelet analysis. Chronology for the Late Holocene section of lake sediment cores from Lake Kanono, Northland, New Zealand indicate an annual to sub-annual accumulation rate at a 500 μ m Itrax μ -XRF scanning resolution. This fast accumulation rate provides the opportunity to produce quasi-annual μ -XRF time series data. Here we present twelve ca. 2200 year long elemental and element ratio μ -XRF time series including P, S, Ti, Ca, K, Si, Fe, Mn/Fe, (Fe+Ti)/K, Sr/Ca, Br/Cl, and Inc/coh. These twelve variables were interpreted as environmental proxies using a combination of principal component analysis (PCA) and cluster analysis, then verified with comparison to regionally averaged empirical rainfall and wind climate station data from Northland. Our results show that the wavelet patterns align with the PCA results allowing the μ -XRF time series to be classified into: Group I (detrital) and Group II (biological productivity and normalized climate proxies). The normalized Group II μ -XRF time series wavelet analyses displayed periodicities in the 2-16 year frequency, likely associated with ENSO, from ca. 237 BCE – 1330 CE. The data shows clear evidence of from both Polynesian and European settlement phases in this part of northern New Zealand as increased detrital influx. There is indication that Polynesian settlement impact was coeval with changes in ENSO intensity and a phase shift in SAM ca. 1350 CE, however European settlement is less associated with climatic shift. The Medieval Climate Anomaly (MCA) and the Little Ice Age (LIA) appear in the μ -XRF time series data as separate clusters. This data shows that the MCA is associated with windy/dry conditions with intermittent storms. During the LIA, the 2-16 year periodicity associated with ENSO decreased and centennial length periodicities increase, which may be an indication of an underlying SAM signal within the data. The combination of the methods of PCA, cluster analysis, and wavelet analysis indicates that sediment loading after ca. 1330 CE may be accentuating the climate signal in the Group I (detrital) proxies, and so interpretations after this time must be made with caution.

P-3464

Evidence for increased expression of the Amundsen Sea Low over the South Atlantic during the late Holocene

Abstract

The Amundsen Sea Low (ASL) plays a major role in the climate and environment of Antarctica and the Southern Ocean, including surface air temperature and sea ice concentration changes. Unfortunately, a relative dearth of observational data across the Amundsen and Bellingshausen seas prior to the satellite era (post-1979) limits our understanding of the past behaviour and impact of the ASL. The limited proxy evidence for changes in the ASL are primarily restricted to the Antarctic where ice core evidence suggests a deepening of the atmospheric pressure system during the late Holocene. However, no data have previously been reported from the northern side of the ASL. Here we report a high-resolution, multi-proxy study of a 5000-year-long peat record from the Falkland Islands, a location sensitive to contemporary ASL dynamics which modulates northerly and westerly airflow across the southwestern South Atlantic sector of the Southern Ocean. In combination with climate reanalysis, we find a marked period of wetter, colder conditions most likely the result of enhanced southerly airflow between 5000 and 2500 years ago, suggesting limited ASL influence over the region. After 2500 years ago, drier and warmer conditions were established, implying more westerly airflow and the increased projection of the ASL onto the South Atlantic. The possible role of the equatorial Pacific via atmospheric teleconnections in driving this change is discussed. Our results are in agreement with Antarctic ice core records and fjord sediments from the southern South American coast, and suggest that the Falkland Islands provide a valuable location for reconstructing high southern latitude atmospheric circulation changes on multi-decadal to millennial timescales.

Figure 1. Location of the Falkland Islands (FI) and South Georgia (SG) in the South Atlantic (black boxes). Other key records from the region, including Siple Dome (SD) and Palm2 (P2) (red dots). The dashed line denotes the contemporary limits of the ASL domain defined across the 1979–2001 average (Fogt et al., 2012). The mean locations of the southern limb of the Antarctic Circumpolar Current (purple), the polar front (red) and the subantarctic front (green) are shown, following Orsi et al. (1995), based on analyses of hydro- graphic station data available up to 1990. The grey arrows denote the 925 hPa wind (vectors) trends since 1979 from ERA-Interim (Dee et al., 2011), depicting the location and increase in westerly winds over the satellite era (Turney et al., 2017a). Map made using Generic Mapping Tools (GMT) (Wessel et al., 2013).

The Antarctic Circumpolar Wave in the Brazilian Earth System Model (BESM) during recent past (1850-2005)

Luciana Prado¹, Ilana Wainer², Ronald Buss de Souza³

¹Universidade de Brasilia, Brasilia, Brazil, ²Universidade de Sao Paulo, Sao Paulo, Brazil, ³Instituto Nacional de Pesquisas Espaciais, Santa Maria, Brazil

Abstract

Southern Ocean (SO) is a key region for both carbon sink and ozone depletion. Understanding how these processes varied along recent epochs is essential for the evaluation of human impact on climate. Carbon sink and ozone depletion in the SO sector are modulated by air-sea interaction mechanisms. The Antarctic Circumpolar Wave (ACW) is an ocean-atmosphere interaction phenomenon occurred in the SO on interdecadal to subdecadal time scales, and was first observed in sea level pressure (SLP) and meridional wind stress fields. The ACW is influenced by the El Niño Southern Oscillation (ENSO) phase and intensity, presenting a zonal wavenumber 2 configuration forced by the Pacific-South American pattern. When the ENSO intensity decreases, a zonal wavenumber 3 pattern (ZW3) prevails and characterizes the coupled air-sea interactions. Exploring the ACW representation by climate models during recent past periods may be helpful to interpret paleoclimate records of Antarctic climate variability. This study will investigate long-term ACW variability during the recent past (1850-2005) by comparison of the SLP-derived ZW3 index (Cerrone et al. 2017) with the first EOF mode time series of 850 hPa geopotential anomalies south of 20 °S. The indices will be calculated from historical and preindustrial outputs derived from the Brazilian Earth System Model version 2.5 (BESM-OA2.5) and from the Community Earth System Model version 1.1 (CESM1.1). The numerical experiments followed the Coupled Model Intercomparison Project version 5 (CMIP5) protocols. The historical experiments were run from 1850 to 2005 and include all forcings (i.e. variations in atmospheric composition, solar forcing, variations in emission or concentration of natural and anthropogenic aerosols, and land use), whereas the preindustrial experiments were performed with 1850 prescribed conditions. Historical and preindustrial runs will be compared to isolate the unforced variability of the models, and to verify the ability of BESM-OA2.5 in simulating the SO long-term climate variability.

The climatic significance of Holocene length changes at Dart Glacier, New Zealand

Shaun Eaves¹, Lisa Dowling¹, Andrew Mackintosh¹, Kevin Norton¹, Brian Anderson¹, Alan Hidy², Susan Zimmerman², Andrew Lorrey³, Matthew Ryan¹, Lauren Vargo¹, Stephen Tims⁴

¹Victoria University of Wellington, Wellington, New Zealand, ²Lawrence Livermore National Laboratory, Livermore, USA, ³National Institute of Water and Atmospheric Research (NIWA), Auckland, New Zealand, ⁴Australian National University, Canberra, Australia

Abstract

Understanding pre-industrial or natural climate variability provides an important context for assessing the impact of anthropogenic climate change. However, detection and attribution of human impact on the climate system is limited by short instrumental climate records, especially in the Southern Hemisphere. Mountain glaciers are sensitive climate indicators, thus geological records of their past variability offer the potential to augment instrumental records. Dart Glacier is situated in the Southern Alps of New Zealand and has a ~100 yr record of length observations, one of the longest in the Southern Hemisphere. Using cosmogenic ¹⁰Be surface exposure dating of pre-historic moraines we extend the historic length record to show that Dart Glacier last advanced during the late 17th century. Using systematic glacier modelling experiments we constrain the climatic significance of this glacier advance, which coincides with the so-called Little Ice Age. Our findings contribute towards a better understanding of spatial-temporal patterns of Holocene glacier fluctuations in New Zealand, and provide baselines from which to assess the impact of human forcing on the regional glacier-climate system.

Climate variability in Antarctica and the Southern Hemisphere over the past 2000 years (CLIVASH2K)

Elizabeth Thomas

British Antarctic Survey, Cambridge, United Kingdom

Abstract

The CLIVASH2k working group is part of the PAGES 2k network. We aim to improve our understanding of large-scale modes of climate variability and the mechanisms and drivers of climate change in Antarctica, the sub-Antarctic and the wider Southern Hemisphere during the past 2000 years. We build upon previous PAGES syntheses documenting changes in Antarctica over the past 1000-2000 years to focus on the mechanisms driving climate variability. The working group is open to anyone working on climate variability in the southern hemisphere and currently consists of paleoclimateologists working on a range of archives (ice cores, marine sediments, lake sediments, and peat and moss banks), climatologists and climate modellers. Come along to the poster for more information and ways to get involved.

Abstract

Ice cores are a valuable archive of past climate, often studied for their water isotopes that can be linked to temperature. However, the relationship between temperature and $\delta^{18}\text{O}$ in ice is not universal, as precipitation patterns, atmospheric pathways for moisture and preservation of the deposited snow largely vary from site to site. In order to understand the isotopic record of the ice core drilled at Aurora Basin North, East Antarctica (ABN, 71°S, 111°E), we investigate the seasonality and driving mechanisms of snow deposition using the regional atmospheric model MAR and ERA-interim climate reanalysis data during the 2005 to 2014 period, and compare it with snow-pit measurements of δD , $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$ covering the same period at a resolution of about 8 points/year. We find that precipitation events are more intense and more frequent in winter, and that they are associated with warm temperature anomalies, consistent with oceanic air mass advection. Consequently, this will affect the isotope/temperature calibration at this site. We finally discuss the influence of post deposition processes such as wind abrasion and snow evaporation on the snow isotopic composition. We conclude by discussing the limitation of the isotope/temperature calibration and its influence on the climate interpretation of isotope signal at ABN.

A suite of sea-ice markers: Organic compounds in a sub-Antarctic ice core

Amy King^{1,2}, Elizabeth Thomas¹

¹British Antarctic Survey, Cambridge, United Kingdom, ²Department of Chemistry, University of Cambridge, Cambridge, United Kingdom

Abstract

Investigation of organic compounds in ice cores is unlocking a wealth of new information in these climate archives. We present results from the first ever shallow ice core drilled on sub-Antarctic island Bouvet, a climatologically important but understudied region. We analyse a suite of novel and more familiar organic compounds in the ice core, alongside commonly measured ions, presenting new records spanning the last two decades. Methanesulfonic acid shows a significant, positive correlation to winter sea ice extent, as does the novel fatty acid compound oleic acid. Both are sourced from spring phytoplankton blooms, which are larger with greater sea ice extent in the preceding winter. Oxalate, formate and acetate are positively correlated to sea ice concentration in summer; these are compounds for which photo-oxidation and cloud-interaction processes are important but sources require further investigation. This study demonstrates the application of organic compounds from the marine biosphere in generating multi-proxy sea ice records.

Holocene temperature, humidity and seasonality in northern New Zealand linked to Southern Hemisphere summer insolation

Valerie van den Bos¹, Andrew Rees¹, Rewi Newnham¹, Marcus Vandergoes², Janet Wilmshurst^{3,4}, Paul Augustinus⁴
¹Victoria University of Wellington, Wellington, New Zealand, ²GNS Science, Lower Hutt, New Zealand, ³Landcare Research, Lincoln, New Zealand, ⁴The University of Auckland, Auckland, New Zealand

Abstract

In light of contemporary climate change it is more important than ever to understand past shifts in climate, especially past warm phases, and their effects on ecosystems and societies. From compilations of global climate reconstructions, several periods have been identified that might have been warmer than today, the most recent of which is the Holocene Thermal Maximum (~11–5 kyr BP). However, Holocene climate reconstructions display considerable spatio-temporal complexity, which is typically smoothed out in global compilations. We don't have a good understanding of the regional differences around the Holocene Thermal Maximum, especially in the southern mid-latitudes. Additionally, inconsistencies between reconstructions from different proxies are often attributed to seasonal bias or confounding effects.

We use the differences between proxy reconstructions as a source of information about seasonality and precipitation in a multi-proxy investigation of the sediments of Lake Pupuke, northern New Zealand (~37°S). Lake Pupuke is one of the maars in the Auckland Volcanic Field, which comprises 53 basaltic centres located within a 600 km² area. Its laminated sediments contain more than 15 tephra layers from both local and distal sources, which form the basis of a robust age-depth model. A 7-m long sediment core, spanning the last 16 kyr, was analysed for pollen, from which mean annual air temperatures (MAT) and effective precipitation were estimated, and chironomids, from which summer air temperature was estimated.

We found no evidence for a thermal optimum in the MAT reconstruction, questioning the validity of treating the early-to-mid Holocene as an analogue for future climate change in New Zealand. Summer temperature increases between 10 and 3 cal kyr BP, correlating strongly with integrated local summer insolation. Early-Holocene low seasonality (from 12 to 9.3 cal kyr BP) was likely driven by low local summer insolation intensity. An early-to-mid-Holocene wet period (9.6 to 7.5 cal kyr BP) corresponds to relatively high southern westerly wind strength. Mid-to-late-Holocene summers following the wet period were hot and dry, especially 4.0 to 2.4 cal kyr BP, consistent with increased evapotranspiration due to higher summer temperatures. Reduced precipitation due to southward displaced westerly winds or increased El Niño frequency may also have contributed.

Extremes of lunar-induced centennial-scale fluctuations in insolation and gravity at high latitudes

Alison Kelsey

The University of Queensland, St. Lucia, Australia

Abstract

Milutin Milankovitch investigated astronomical forcing of the Ice Ages at orbital scales, during which he identified the latitudinal region bordered by the Arctic Circle as being most sensitive to changes in radiation during the boreal summer. Although the astronomical theory of the ice ages fell into disfavour with the ascendancy of the Greenhouse Gas Theory, the bipolar-seesaw relationship between the Arctic and Antarctic regions and the global nature of many climate signals suggest astronomical forcing of climate, producing different responses based on region and latitude. Current understanding favours orbital forcing of the waxing and waning of the ice-sheets, with outgassing of CO₂ from the Southern Ocean catalysing the bipolar seesaw.

Using physical models of insolation, total solar irradiance, and gravitation, I show the influence of a 133-yr cycle found in astronomical data on insolation at key latitudes. This 133-yr cycle was found in Earth-Moon and Earth-Sun distances and solar declinations, based on the 19-yr cyclical occurrence of the New Moon at perihelion, the closest point in Earth's orbit to the Sun. Maximum swings in TOA insolation were $\sim 2 \text{ W/m}^2$ at the Arctic and Antarctic circles. This cycle has the capacity to induce regional variations in the climate signal at different latitudes and facilitate rapid changes in as little as a decade, but more often in the 57-yr to 76-yr range. Coupled with evidence of quasi-periodic millennial-scale forcing in this astronomical data, it can be inferred that the interaction of Sun-Moon-Earth produces a number of different harmonics and has the capacity to influence ENSO intensity and variability, and the Pacific Decadal and Antarctic Oscillations. With distance being the common factor influencing gravitation, solar irradiance and insolation, astronomical forcing by these factors therefore plays an important role in influencing the coupled ocean-atmosphere response of Earth's climate.

Diatoms in Ice Cores. Exploring a new proxy for reconstructing past wind strength in Ellsworth Land, Antarctica

Dieter Tetzner^{1,2}, Liz Thomas¹, Claire Allen¹

¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Cambridge, Cambridge, United Kingdom

Abstract

In the last decade, several efforts have been carried out to assess the causes of the current rapid recent warming measured on West Antarctica and Antarctic Peninsula. The increase in wind strength and shifts in atmospheric circulation patterns have shown to play a key role in driving the advection of warm air from mid-latitudes to high-latitudes. Winds are also responsible for driving surface melting in the ice shelves, enhancing the removal of surface snow, and for promoting basal melting through the upwelling of deep warm water. All these combined have shown to produce substantial effects on environmental parameters, such as: sea surface temperatures, sea ice extension, air surface temperatures and precipitation.

Even though winds are fundamental components of the climatic system, there is a lack of reliable long-term observational wind records in the region. This has hindered the ability to place the recent observed changes in the context of a longer time frame.

In this work, we present a record of marine diatoms preserved in an intermediate depth ice core retrieved from the Ellsworth Land coast in the Amundsen Sea region. In particular, this work focus in the second half of the twentieth century where we explore the diatom abundance and species assemblages to assess the capacity of this record to represent the local/regional variability in wind strength and circulation patterns that influence the onshore northerly winds.

The Southern Westerly Winds throughout the Holocene in climate model simulations

Maisa Rojas¹, Steve Phipps², Fabrice Lambert³

¹University of Chile, Santiago, Chile, ²University of Tasmania, , Hobart, TAS 7001, Australia, ³PUC, Santiago, Chile

Abstract

Atmospheric circulation at hemispheric scale integrates large-scale features from tropical, subtropical, midlatitudes and polar regions, including the Hadley and Ferrell Cell, as well as the subtropical anticyclones and in the Southern Hemisphere (SH), the Southern Westerly Winds (SWW). The SWW in particular have been a central element in understanding past, present and future climate in the SH and at global scale, due to their importance in the global carbon cycle via its coupling with the Southern Ocean.

We analyse three transient model simulations of the Holocene to investigate the evolution of the SH westerly wind system. The Holocene, the last 11,700 years of Earth history, is usually depicted as a relatively stable climate period in which human civilization has developed; its climate evolution has been driven mainly by slowly varying insolation forcing and is therefore a prime setting for disentangling external and internal modes of variability in our climate system. A better understanding of natural climatic variations in the SH will help quantify the contribution of both anthropogenic and natural variations to current and future climatic changes in this region.

In the present climate, we know that at the seasonal scale mayor latitudinal changes are found in the Pacific Ocean, and to a smaller degree in the Atlantic Ocean, whereas in the Indian Ocean and the Australian / NZ sector the seasonal shift is minimal. In terms of strength, strongest winds are found in the Indian Ocean sector. On the other hand, at upper levels over the Pacific, the subtropical jet features a split jet. These characteristics are reproduced by the models for present climate and throughout the Holocene. In addition, the models show millennial trends in wind strength that follow the insolation forcing, but also multi-centennial variability. Important seasonal variations are found.

A new find of macrofossils of *Picea crassifolia* Kom. in early-middle Holocene sediments of the Qinghai Lake basin

Ruijie Lu

Beijing Normal University, Beijing, China

Abstract

Here we report a new find of abundant woody debris and cones in stratum of two sections located to the east of the Qinghai Lake basin in China. Analysis of the anatomical structure of the wood and cones confirmed that they are *Picea crassifolia* Kom. The results of accelerator mass spectrometry ^{14}C dating indicate that the buried Qinghai spruce grew during 9.7-4.2 ka, and the ages of the large trunks or branches are mainly concentrated within the interval 7.5-6.5 ka. This finding gives direct evidence at species level about the presence of coniferous forest in the early-mid Holocene in Qinghai lake basin. In addition, the buried cones suggest that early-middle Holocene environment was suitable for the propagation of *Picea crassifolia* Kom. The variations in the occurrence of Qinghai spruce forest in the Holocene probably reflect changes in humidity/moisture. The humid early-mid Holocene was suitable for the growth and reproduction of Qinghai spruce forest, while a shift towards an increasingly arid climate during the late Holocene resulted in the disappearance of *Picea crassifolia* Kom. from the Qinghai lake basin, although human activities may also have contributed to the environmental change.

A systematic assessment of late Quaternary hydrological change from valley fill complexes in Namibia

Ella Walsh, David Thomas, Sallie Burrough
University of Oxford, Oxford, United Kingdom

Abstract

Significant hydrological change occurred over southern Africa during the late Quaternary, with drier, western areas impacted by the interplay of temperate and tropical Atlantic and Indian Ocean rainfall sources. On Quaternary timescales, current debates centre on the sourcing of moisture during wet phases, the degree of northerly penetration of winter rainfall systems, and the regional responses to orbital forcing during the Holocene. Given the paucity of geochemical records in Namibia, reconstructing the palaeoenvironmental context of Namibian valley fill sediments presents a potentially important archive for understanding regional hydrological dynamics. Valley fill sediments extend from the presently hyper-arid Skeleton Coast in the North through to tributaries of the Orange River in the South. There exists a discontinuity, however, in how existing studies use data on aggradation of these fills to elucidate the timing of fluvial activity: interpreted variably as either slack-water deposits indicative of increased hydrological activity or as river-end deposits indicative of decreased hydrological activity. This makes it hard to resolve spatial variations within an emerging picture of late Quaternary hydrological change. To address this, this study investigates both the nature and timing of sediment deposition along a northern Namibian ephemeral river valley: the Huab. Valley fill sediments along the Huab have been identified as a particularly significant source of atmospheric dust, yet the palaeoenvironmental context of sediment accumulation in this system has not been studied in detail. Here, the modern ephemeral channel has incised into the valley fill sediments, exposing profiles showing distinct layers in the fill indicating distinct periods of deposition. By explicitly linking a reconstruction of environmental conditions with the timing of sediment deposition, this study aims to systematically reconstruct the late Quaternary fluvial history of the Huab.

Initial optically stimulated luminescence results date periods of deposition in the Skeleton Coast valley fill region to the Holocene. Grain size distributions indicate variations in depositional environments throughout the profiles, presenting evidence of shifts between high and low energy fluvial regimes. Combined with thin section micromorphology, optical microscopy and scanning electron microscopy, we hope to understand the nature of sediment deposition within this system. Ground penetrating radar data collected along transects perpendicular to the river flow show that the laminations in the fill vary in depth over space. Results here indicate lateral variability in the deposition of the fill and present the beginnings of an understanding of how to interpret the fill. Alongside existing fluvial records from other valleys, and geochemical records from the escarpment, this reconstruction of Huab hydrological dynamics will be interpreted in relation to late Quaternary hydrological change in the region. This also presents an important evidence base for understanding the sustainability and sedimentary characteristics of a significant atmospheric dust source.

Reconstructing palaeoenvironmental conditions for human dispersal in the United Arab Emirates

Kira Daehling¹, Gareth Preston¹, Maïlys Richard², Ash Parton¹, Daniela Mueller³, Frank Preusser³, Adrian Parker¹
¹Human Origins and Palaeo-Environments (HOPE) Research Group, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, United Kingdom, ²Institut de Recherches sur les Archéomatériaux - Centre de Recherche en Physique Appliquée à l'Archéologie (IRAMAT-CRP2A) - université Bordeaux Montaigne, Bordeaux, France, ³Institute of Earth and Environmental Sciences, University of Freiburg, Freiburg, Germany

Abstract

Southeast Arabia is now recognised as a key region in the ongoing debate on the influence of climate change on early human dispersal. Long-term, high-resolution records of climate change are limited to ocean cores or speleothem records. The latter have provided a valuable insight into changing hydrological conditions over the past 400 ka. Nevertheless, these records cannot be directly translated into evidence of wetter landscape conditions in the desert interior. As a consequence, our understanding of climate change during some periods is limited to a handful of reliably dated records. This study aims to provide better knowledge on palaeoenvironmental and hydrological change based on new chronological, sedimentological and geochemical results of several fluvial outcrops along two major ephemeral streams (Wadi Iddayah & Wadi Dhaid) in the northern UAE. Both streams lay in the direct vicinity of two well-stratified archaeological sites (Jebel Faya and UAQ 2) and connect the Oman Mountains with the coast representing potentially important migration routes. First results from field-work, laboratory analysis and dating (optical stimulated luminescence (OSL) and radiocarbon) distinguished several alternating phases of fluvial activity, soil formation and arid conditions in the Pleistocene and Holocene, which are compared to phases of human occupation at the archaeological sites.

P-3477

Pleistocene environmental change from more humid to hyper arid conditions in the Gaxun-Nur Basin, NW China

Georg Schwamborn^{1,2}, Kai Hartmann², Bernhard Diekmann¹, Bernd Wünnemann³

¹Alfred-Wegener-Institute, Helmholtz-Centre for Polar and Marine Research, Potsdam, Germany, ²Free University, Berlin, Germany, ³East China Normal University, Shanghai, China

Abstract

Central Asia is a large-scale source of dust transport, but also held a prominent hydrological system during the Quaternary. The endorheic Hei River drainage basin in NW China is placed between the northern Tibetan Qilian Shan and the southern Mongolian Gobi Altay and was chosen as a site to study a sediment archive reflecting this hydroclimatic change. We used a 223 m long core (GN200) that has been extracted from the Gaxun-Nur-Basin at the lower reaches of the river. This is an area, where the river has created a huge alluvial fan as can be seen on satellite imagery. The fan has replaced a formerly extended lake area that existed at least during parts of the Late Quaternary (MIS 3 to 2). Three main and texturally distinct sedimentary facies are identified. Facies C (223-218 m) is dominated by coarse-grained layers (fine- to medium-grained sand) interbedded with fine grained sediments (clayey silt). Facies B (218-110 m) has a succession of banked clayey silt with an increasing frequency of intercalated sand layers (dominated by very fine sand to fine sand) towards the top. Some layers containing coarse sand to very fine gravel form a top subfacies in the unit (between 120-110 m). Facies A (110-0 m) is a succession of fine- to medium- to coarse-grained sand layers interbedded with silt banks that decrease in frequency towards the top. The gradational increase in fine silt content in these silt banks is paralleled by a loss of the clay fraction. The Neogene Red-Clay formation is interpreted to occur at the base of core GN200 represented by facies C. It contains a distinctly pronounced portion of mixed layered clay minerals. Lake sediments, partly fine laminated, occur in the lower part of facies B. These sediments show the highest relative smectite proportion. Fluvial sediments make much of facies A with a pronounced increase of river-related chlorite towards the top of the core. We propose a sedimentation model that stretches over the whole Quaternary and with a transition from a more humid to a more arid sediment environment at around 1.2 Myr BP. The age model is backed up by magnetostratigraphy and constrained by ¹⁰Be/²⁶Al dating. The studied sediment properties include granulometric and geochemical/mineralogical changes (XRF-scans, XRD-mineral analyzes). The mineral indicators are complemented by the vegetation record based on pollen counting.

Late Quaternary Paleohydrologic Changes in the East Gobi Desert

Hongwei Li¹, Xiaoping Yang¹, Fangen Hu², Peng Liang³, Qida Jiang³

¹Zhejiang University, Hangzhou, China, ²Yichun University, Yichun, China, ³Institute of Geology and Geophysics, CAS, Beijing, China

Abstract

Deciphering past landscape in desert under the climate variations is important for projecting future desertification in response to the global warming. The remains of once integrated drainage systems in the desert area are valuable, and in some cases, the only available archive of the past environmental changes. In this study, paleohydrological network in the East Gobi Desert was identified by remote sensing images and digital elevation model. Luminescence, radiocarbon and U series dating methods were used to constrain the chronology. The results show that megalakes with an area at least 14,000 km² occurred during MIS 5, representing ~200% of the present day precipitation and 1100 km northward shift of the northern boundary of humid area in east China. Occurrence of *Corbicula Fluminea* indicates substantially warmer winter than present (>8 °C) has prevailed during MIS 5. Carbonate precipitation and lack of paleohydrological remains during MIS 4-2 does not support a humid MIS 3 in the East Gobi Desert. Driven by the intensified East Asian Summer Monsoon, high lake level appeared again at 6.5 ka BP, while the lake extent was only half of that of MIS 5. Late quaternary precipitation changes in the East Gobi Desert show a different pattern with the stalagmite record in south China, implying the cave $\delta^{18}\text{O}$ value cannot represent the monsoon intensity in northern China. Wet Gobi Desert during MIS 5 is possibly responsible for the “dustier MIS 4” in East Asia and Pacific.

Westerlies Asia and monsoonal Asia: spatiotemporal differences in climate change and possible mechanisms on decadal to sub-orbital timescales

Fahu Chen^{1,2}, Jianhui Chen¹, Wei Huang¹, Shengqian Chen¹, Jianbao Liu², Aifeng Zhou¹

¹Lanzhou University, Lanzhou, China, ²Institution of Tibetan Plateau Research, CAS, Beijing, China

Abstract

The 'westerlies-dominated climatic regime' (WDCR) in the present interglacial period was proposed because precipitation/moisture variations between arid central Asia and mid-latitude monsoonal Asia are out-of-phase or anti-phased on different timescales during the Holocene. In this study, we first review the development of the theoretical framework of the WDCR, and then outline the boundary of its core area: from the Caspian Sea in the west to the western Hexi Corridor in the east, with the northern and southern limits coinciding with the domain of arid central Asia. Next, we present a synthesis of multiple lines of evidence for the occurrence of the WDCR on multi-millennial ('sub-orbital' herein) to decadal timescales during the Holocene. Finally, we examine the possible physical mechanisms responsible for the WDCR. We find that external factors (insolation changes induced by orbital factors) generated the WDCR on a sub-orbital timescale, whereas a circum-global teleconnection/Silk Road pattern was the most significant factor responsible for the WDCR on centennial and decadal timescales. The study provides a comprehensive summary of the development of our knowledge of the WDCR over the past several decades, together with a tentative theoretical framework for understanding climatic and environmental changes within its region of influence. In addition, it forms a scientific basis for environmental management and ecological restoration in this arid region in the context of global warming.

A 4 kyr high-resolution multi-proxy paleoclimate record from Lake Telmen, Central Mongolia

Julian Struck¹, Paul Strobel¹, Marcel Bliedtner^{1,2}, Jens Schumacher³, Lucas Bittner⁴, Enkhtuya Bazarradnaa⁵, Bruno Glaser⁴, Michael Zech⁴, Roland Zech¹

¹Institute of Geography, Friedrich-Schiller-University Jena, Jena, Germany, ²Institute of Geography and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ³Institute of Mathematics, Friedrich-Schiller-University Jena, Jena, Germany, ⁴Institute of Agronomy and Nutritional Sciences, Soil Biogeochemistry, Halle-Wittenberg, Germany, ⁵Institute of Plant and Agricultural Sciences, Mongolian University of Life sciences, Darkham-Uul, Mongolia

Abstract

Semi-arid/ arid Mongolia is a key location for paleoclimatic reconstructions in Central Asia, because it is affected by two large-scale atmospheric circulation systems, the Westerlies and the Asian Summer Monsoon. The climatic evolution of Mongolia during the Holocene is highly debated. Today, Lake Telmen has an area of 209 km², but reconstructed lake level fluctuations during the Holocene indicate past variations of moisture availability. A 160 cm long gravity core was retrieved from this site and analyzed using a multi-proxy approach. This includes granulometric and elemental analyses, as well as leaf wax *n*-alkanes and their compound-specific isotopic signature ($\delta^2\text{H}$, $\delta^{13}\text{C}$). The chronology is based on six bulk radiocarbon ages and reveals a basal age of $3,960^{+370}/_{-540}$ calBP. Low terrestrial input (e.g., low Al, Fe, K, Sr) suggest decreased runoff in the catchment of Lake Telmen and point to overall dry conditions in the area between $3,960^{+370}/_{-540}$ and $2,970^{+270}/_{-450}$ calBP. From $2,970^{+270}/_{-450}$ to $2,550^{+330}/_{-380}$ calBP high terrestrial input and low Mg/Ca ratios indicate more humid conditions and high lake levels. Drier conditions occurred from $2,550^{+330}/_{-380}$ to $1,780^{+340}/_{-380}$ calBP and low lake levels are indicated by high Mg/Ca ratios. This phase was followed by a more humid period between $1,780^{+340}/_{-380}$ and $1,310^{+300}/_{-360}$ calBP (high terrestrial input and low Mg/Ca ratios). From $1,310^{+300}/_{-360}$ calBP onwards, drier conditions occurred with a tendency to more humid conditions again. The findings of this high-resolution multi-proxy study confirm previous investigations from (supra-) regional archives and contribute to a more detailed understanding of paleoclimatic conditions in Central Asia. Future leaf wax $\delta^2\text{H}$ and $\delta^{13}\text{C}$ analyses will give insights to past moisture conditions and changes of moisture sources.

DATED-2: An updated chronology and time-slice reconstruction of the last Eurasian ice sheets.

Anna L.C. Hughes^{1,2,3}, Evan Gowan⁴, Richard Gyllencreutz⁵, Jan Mangerud^{2,3}, John Inge Svendsen^{2,3}

¹University of Manchester, Manchester, United Kingdom, ²University of Bergen, Bergen, Norway, ³Bjerknes Centre for Climate Research, Bergen, Norway, ⁴Alfred Wegener Institute, Bremerhaven, Germany, ⁵Stockholm University, Stockholm, Sweden

Abstract

DATED-1 comprised a fully-documented empirical reconstruction of the changing extent of the last Eurasian ice sheets 40-10 ka (at 1000-year resolution after 25 ka) based on a geological-glaciological assessment of all relevant chronological data (Hughes et al. 2016). All uncertainties within the underlying data, quantitative and qualitative (e.g. precision and accuracy of numerical dates, correlations of moraines, stratigraphic interpretations) are expressed in terms of distance; deviation between maximum and minimum limits, and their relative proximity to the position considered most-credible, indicates the degree of uncertainty along the ice margin for each time-slice, according to current interpretations of the available evidence. Explicitly reporting all uncertainties in this way provides a straightforward means to compare geological data with results from numerical modelling of past ice extent. A by-product was creation of an archive of all published dates (and associated data necessary for their interpretation, quality, and recalculation) relating to the build-up and retreat of the British-Irish, Scandinavian and Svalbard-Barents Kara seas ice sheets. A task that took nearly 10 years, but which is a valuable legacy for a diverse range of the Quaternary community. Both the time-slice reconstruction and underlying chronological data are available via the online data repository PANGAEA in GIS and Google Earth compatible formats, and the reconstruction in NetCDF format on request.

Such syntheses run the risk of being frozen-in-time and losing their relevance if not maintained and updated to reflect the latest observations; new geological data is generated almost continually. Here, we present the second-generation Eurasian ice sheets' synthesis, DATED-2, which brings the chronological dataset and reconstructions up-to-date by including all information published before 1 January 2019 (1 January 2018 for the British-Irish Ice Sheet). Six years on from the DATED-1 census the volume of dates, and also associated information such as from geomorphological mapping, has grown significantly; c. 40% increase in the number of dates, including a near doubling of dates derived from terrestrial cosmogenic nuclide dating, and over 2000 new sites added. Nevertheless, the overall spatial and temporal distribution of chronological information is largely unchanged. The time-slice reconstructions continue to rest on relatively few key dates and the largest uncertainties remain, e.g. the timing of coalescence and separation of the component ice sheets, and the nature of deglaciation of the eastern Barents Sea. We highlight the main changes in DATED-2, present a new calculation of the evolution of ice sheet volume in terms of sea level contributions, and discuss implications for understanding the build-up and deglaciation of the last Eurasian ice sheets.

Hughes, A.L.C., Gyllencreutz, R., Lohne, Ø.S., Mangerud, J., Svendsen, J.I. 2016: The last Eurasian ice sheets – a chronological database and time-slice reconstruction, DATED-1. *Boreas*, 45, 1–45. 10.1111/bor.12142

Evolution of Greenland ice sheet since the Last Glacial Maximum: a model assessment based on PISM

Hu Yang¹, Uta Krebs-Kanzow¹, Lu Niu¹, Paul Gierz¹, Christian Rodehacke¹, Sebastian Hinck¹, Thomas Kleiner¹, Xiaoxu Shi¹, Xingxing Liu^{1,2}, Gerrit Lohmann¹

¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China

Abstract

The evolution of the Greenland ice sheet (GrIS) since the Last Glacial Maximum (21ka BP) is accessed by the Parallel Ice Sheet Model (PISM). In order to get the climate forcing for the GrIS, several time-slice simulations have been conducted by the AWI Climate Model (AWI-CM) following the PMIP4 protocol. It shows that the GrIS has reached its maximum volume (relative to present) of around 3 m ice-equivalent sea level at 17 ka BP. Moreover, a minimum ice volume of -0.2 m ice-equivalent sea level is observed during the mid-Holocene (5ka-4ka BP). Since then, the GrIS has experienced an overall increasing trend in ice volume until the 1960s. The model shows that the anthropogenic global warming has reversed the background increasing trend of GrIS since the 1960s. Our study suggests that the GrIS ice volume greatly lags the climate forcing, implying that the consequence of global warming on sea level rise may continue and last for thousands of years.

P-3483

Testing the drivers of retreat of the last British-Irish Ice Sheet: a numerical modelling study

Edward Gasson¹, Chris Clark², Jeremy Ely², Sarah Bradley²

¹University of Bristol, Bristol, United Kingdom, ²University of Sheffield, Sheffield, United Kingdom

Abstract

Following efforts of the BRITICE-CHRONO consortium the highly resolved retreat history of the last British-Irish Ice Sheet (BIIS) presents a valuable test for numerical ice sheet models. In turn, physics-based models can be used to test different hypotheses for drivers of retreat of the ice sheet. In this study we use a hybrid ice sheet-shelf model driven with a climate model. Our intention is not to try and reproduce the reconstructed extent of the BIIS as accurately as possible, but to find areas where our modeling framework struggles, with the ultimate goal of improving the model. We highlight two areas where there is a significant disagreement between the model and the reconstruction and describe efforts to remedy this disagreement. Firstly, the model fails to simulate ice inception over northwestern Scotland and western Ireland. We suggest that this is due to an underestimate of orthographic precipitation due to our low resolution climate model forcing. A new parameterization for orthographic precipitation has been developed that improves ice sheet inception. Secondly, although the pattern of deglaciation is similar to reconstructions, it is consistently ~ 4 kyr later than suggested from the BRITICE-CHRONO compilation. Again, we highlight an area in our modeling framework that could explain this discrepancy and the steps we have taken to improve the model. To conclude, we discuss what our numerical simulations may tell us about drivers of retreat of the last BIIS.

¹School of Natural Sciences and Psychology, Liverpool John Moores University, Liverpool, United Kingdom, ²Bjerknes Centre for Climate Research, Bergen, Norway, ³NORCE, Bergen, Norway, ⁴COWI, Bergen, Norway, ⁵School of Science and the Environment, Manchester Metropolitan University, Manchester, United Kingdom, ⁶NERC Cosmogenic Isotope Analysis Facility, Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom, ⁷Centre for Arctic Gas Hydrate, Environment and Climate, The Arctic University of Norway, Tromsø, Norway, ⁸Department of Earth and Planetary Sciences, McGill University, Montreal, Canada, ⁹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom

Abstract

The last deglaciation of the Fennoscandian Ice Sheet (FIS) is well documented through extensive mapping and dating of marginal positions. Empirical and modelling studies typically show a 2-3 km thick ice sheet as the Last Glacial Maximum, deglaciating to cold-based ice domes in northern and southern Norway. There is unfortunately very little direct evidence that permits robust reconstructions of the changing geometry of the ice sheet interior during deglaciation. Instead approximations have been deduced from indirect evidence, including extrapolation from remote margin positions and isostatic loading estimates inferred from relative sea level reconstructions with the uncertainties they carry. Here we present new geomorphological mapping and surface exposure ages (¹⁰Be) from the Snøhetta region of southern central Norway providing direct evidence of interior ice sheet anatomy during an interval with strong external climate forcing. This region is at the centre of the hypothesised southern FIS ice dome, therefore staying ice covered until final deglaciation after circa 10 ka. Surface exposure ages from the sides of Mt. Snøhetta (2286 m a.s.l.) suggest the region became ice free before 16 ka. Ages of two well-developed moraines from valleys flanking Snøhetta at 1550-1450 m altitude suggest formation at 11.6 ± 0.2 ka and 11.8 ± 0.2 ka, corresponding to the termination of the Younger Dryas (YD, 12.8-11.7 ka). Two additional moraines deposited by the waning ice sheet at the same altitude support this regional deglaciation pattern. Our results imply that high-elevation areas in Central and Southern Norway emerged prior to the YD which could allow for the co-existence of cirque glaciers at the time in question. These observations also suggest that the downwastage of the FIS was far more rapid and dynamic than previously thought and in part synchronized with the deglacial pattern of the margins of the FIS as well as corresponding shifts in ice sheet volume.

Abstract

Numerical ice sheet models are central for our ability to test ice sheet response to climatic change. To validate the models, empirical data for comparison with model outputs are required. MAGIC-DML is an international collaboration focused on filling critical data gaps in our knowledge of the timing and pattern of ice surface changes on the western Dronning Maud Land (DML) margin of the East Antarctic Ice Sheet (EAIS). A combination of remotely sensed and field-based geomorphological mapping is being used in combination with cosmogenic nuclide analyses to reconstruct changes in the vertical extent (thickness) of the ice sheet surface since the Pliocene. We use the nunatak 'dipstick' approach to measure the timing and rate of ice sheet surface lowering. Accurately determining the above-ice elevation is critical for interpreting cosmogenic nuclide measurements on such vertical profiles as it is the elevation of a sample site relative to the present-day ice surface which defines the amount (and when combined with simple exposure ages of the sites, the rate) of ice sheet thinning.

A significant challenge to this method is encountered where nunataks are surrounded by a highly discordant present-day ice surface. In western DML, a significant topographic escarpment up to several hundred meters high forms the edge of the East Antarctic Plateau, with ranges of nunataks separating the plateau ice from that below. Due to this separation, ice flow on the plateau is not necessarily directly related to that below, complicating the determination of above-ice elevation of sample sites. Here we present some preliminary results from attempts to explore possible solutions to the above-ice elevation problem in this situation.

Abstract

A climate in northern Africa is highly dependent on interaction of a tropical monsoonal circulation in the south and moist Atlantic/Mediterranean air masses in the north. A contact between them is defined as the Intertropical Convergence Zone (ITCZ) and it shifted several times north-south in the Holocene. The Faiyum Oasis was all the time outside the northern limit of the summer monsoon but the modern Qarun Lake is a relic of an ancient prehistoric, mostly freshwater water body. In 2014 a research drilling at the southern shore of the lake was done, funded by the National Science Centre in Poland (decision no. DEC-2012/05/B/ST10/00558). Complex geochemical, diatom, pollen and magnetic susceptibility examination of a fragment of the core of lake deposits dated at 8.5 – 6.8 cal kyr B.P. prove that fine-laminated sediments represent high-level stands of the lake in the early mid-Holocene, implied by a summer hydrological linkage with the Nile and a winter rainfall brought by the westerlies from the Mediterranean. Based on geographical derivation of tree and herb pollen, environmental affiliation of diatom taxa and varying geochemistry of the examined lake sediments, three main groups of the early mid-Holocene wind trajectories are reconstructed. Northwestern winds were presumably stronger than the northern winds and their weakening enabled expansion of southern winds. Two main atmospheric circulation phases are established with three turns of northwestern and southern winds before 7.83 cal ka B.P., followed by two sequences of northern, northwestern and southern winds after 7.83 cal ka B.P. Northwestern and northern winds brought winter rainfall and caused water turbulence in the lake, and the southern winds were accompanied by regional aridification, lower lake level and brackish episodes. The presented model of wind trajectories extends significantly our understanding of a crucial role of the Mediterranean atmospheric circulation on climate variability in northeastern Africa in the early mid-Holocene.

The preliminary results of the Holocene stalagmite palaeoenvironmental record from Postojna Cave, Slovenia

Matej Lipar¹, Russell Drysdale^{2,3}, Jian-xin Zhao⁴

¹Anton Melik Geographical Institute, ZRC SAZU, Ljubljana, Slovenia, ²School of Geography, University of Melbourne, Melbourne, Australia, ³EDYTEM, UMR CNRS 5204, Université de Savoie-Mont Blanc, Le Bourget Du Lac-Cedex, France, ⁴School of Earth and Environmental Sciences, The University of Queensland, Brisbane, Australia

Abstract

Southwestern part of Slovenia represents a transitional climatic zone between the continental and Mediterranean conditions controlled by the air masses from above the Mediterranean, and majority of the precipitation originating from the Atlantic Ocean. Following the worldwide trend of climate warming, the average air temperature in Slovenia is also rising and the precipitation regime, including the intensity of precipitation, is changing. It is postulated that a highly diverse and for the most part of a transitional nature climatic conditions on Slovenian territory (merged in the contact of Alpine, continental and Mediterranean climatic conditions) can result in hazardous weather phenomena leading to natural disasters such as droughts and floods. Understanding the variability of the Holocene climate is therefore essential for accurate predictions of future climate change and the environmental response.

Slovenian territory, as a region merged in the contact of Alpine, continental and Mediterranean climatic conditions, still lacks comprehensive palaeoclimatic data from diverse proxies. We therefore began to focus on speleothems, which are valuable palaeoclimatic archives, with the oxygen and carbon isotope composition as the most commonly used proxies. They are abundant in the Postojna Cave System, one of the most visited show caves in the world.

The preliminary results of a Holocene speleothem reveal its growth rate between 6.6 and 3.3 ka BP to be around 4.7 cm ka⁻¹. There is a notable variation in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotopes throughout the growth period. Applying the difference in rainfall $\delta^{18}\text{O}$ during a temperature change in Slovenia (0.3 ‰/°C), and the calcite/water fractionation at the mean annual temperature of the cave (8.7°C; \sim -0.25/°C) the net difference is too small for stalagmite $\delta^{18}\text{O}$ to indicate only temperature changes, so it is likely that the oxygen isotope variations of the stalagmite (-8.11 ‰ to -4.52 ‰) are also caused by the variation in the amount of moisture. On the other hand, changes in $\delta^{13}\text{C}$ (-11.58 ‰ to -10.17 ‰) are usually interpreted based on the proportion of C₃ and C₄ plants growing above the cave, but only across major climate transitions. Limited to Holocene and considering ecosystem disturbances during the Holocene, it most likely reflects changes in biogenic soil CO₂ production caused by anthropogenic activities above the cave. Both $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ show greatest environmental instability around 4 ka (BP), which could relate to the “4.2 Event” in the central Mediterranean, but further research is needed to confirm this.

Abstract

There is increasing evidence that during Late Antiquity a significant climatic deterioration in the Northern Hemisphere occurred with important decrease in temperature during VI and VII century CE (e.g. Büntgen et al., 2016). In the Italian peninsula there are several pieces of historical and archeological evidence of climatic deterioration during this period, such as increased flooding (Cremaschi & Gasperi, 1991). However, these are controversial (Sqatri, 2010; Cremonini et al., 2013) and very few paleoclimate archives possess the resolution for defining in detail the paleoclimate of the Late Antiquity (Sadori et al., 2016) within the Italian region. Here we present a stable isotope record from a stalagmite collected in the Renella cave, supported by 9 U/Th ages covering a period from the I to IX century AD, with decadal resolution. Between ca. 500 and 650 CE stable isotopes indicate a particularly prominent, double spiked, period of wetter conditions. This corresponds, within age error, to the double spiked reduction in temperature in central Europe (Büntgen et al., 2016) and a prominent period of negative NAO condition as reconstructed by Olsen et al. (2012). This reconciles archeological evidence and historical accounts, indicating that the reported increases of flooding are not just related to the decline of the Roman Empire, but corresponded to wetter climatic conditions.

Moisture sources of Lake Lisan (Dead Sea Basin, Near East) during its maximum highstand period in MIS 2

Steffen Mischke¹, Nicolas Waldmann², Birgit Plessen³

¹Faculty of Earth Sciences, University of Iceland, Reykjavík, Iceland, ²Department of Marine Geosciences, University of Haifa, Haifa, Israel, ³Helmholtz-Zentrum Potsdam Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany

Abstract

Ancient shorelines and exposed laminated lake sediments at high positions above the modern Dead Sea level show that its late Pleistocene precursor, Lake Lisan, filled a significantly larger basin. Previous studies showed that the level of Lake Lisan was ca. 200 m higher than those of the Holocene Dead Sea between 30-20 ka, and that Lake Lisan and the Sea of Galilee in the north of the Dead Sea Basin formed a merged water body during times of highest lake levels. However, a significant increase in regional moisture availability during the first half of Marine Isotope Stage 2 was not indicated by speleothem and other climate records in the region.

Therefore, we investigated sediments of the Lisan Formation in the northern, western and southern vicinity of the Dead Sea to tackle the question of the water source regions of Lake Lisan during its highstand periods in the late Pleistocene. Upper Cretaceous to Eocene marine foraminifera originating as detrital particles from catchment rocks are used here for the first time to trace the significance of locally generated runoff to Lake Lisan. Allochthonous foraminifera are abundant in sediments of a section near the Yarmouk River inflow into the Jordan River Valley. In addition, valves of autochthonous brackish water ostracods and of probably allochthonous freshwater (*sensu lato*) ostracods were recorded, indicating strong discharge to Lake Lisan from northern sources.

Abundant ancient foraminifera in sediments from exposed sections at Massada and in the Arava Valley provide evidence for significant runoff generated in the presently hyper-arid region in the southwest and south of the Dead Sea. These results indicate that precipitation was apparently not only significantly higher in the northern upland regions of Lake Lisan (Mount Hermon, the Golan Heights and the Upper Galilee) but also in the low-lying region of the Negev Desert.

Holocene Paleoenvironments in the Western Mediterranean Sea : palynological evidences on the Algerian coast

Vincent Coussin¹, Aurelie Penaud¹, Nathalie Combourieu-Nebout², Odile Peyron³, Nadine Tisnérat-Laborde⁴, Nathalie Babonneau¹, Antonio Cattaneo⁵, Jacques Deverchere¹

¹Univ. Brest, IUEM, UMR 6538 LGO Laboratoire Géosciences Océan, CNRS, Plouzane, France, ²HNHP UMR 7194 CNRS – Département Préhistoire MNHN, Paris, France, ³ISEM, UMR 5554 CNRS, Université de Montpellier, Montpellier, France, ⁴Laboratoire des Sciences du Climat et de l'Environnement, LSCE/IPSL, UMR 8212 UVSQ-CNRS-CEA, Gif-Sur-Yvette, France, ⁵IFREMER, Géosciences Marines, Technopôle Brest-Iroise, Plouzane, France

Abstract

Along the Algerian coast, present and past oceanographic and climatic conditions are complex. Atlantic Ocean surface waters penetrate today into the Mediterranean Sea by the Gibraltar strait; then, the Algerian current follows the North African coast according to a whirlwinds succession, itself responsible for recurrent deep water upwelling plumes in the Alboran Sea.

This study aims to reconstruct the paleoenvironment changes over Holocene along the Algerian coast associated to the hydrological dynamic on planktonic ecosystems at high temporal resolution (decadal to pluri-decadal). Based on palynological analysis, our goal is to show past sea surface hydrological changes and their sensibility to the regional and global climatic variability. We use the MD04-2801 core (Algerian coast, 2067 m water depth, Prisma cruise) which cover the last glacial and the Holocene with a secular resolution. More than one hundred pollen/dinocysts samples have been counted for the last 14 000 years BP. Among main features, we highlight (i) periods dominated by recurrent upwelling cells during the Younger Dryas (12.7 to 11.7 ka BP) and the Early Holocene (11.7 to 8.2 ka BP) as well as from 6 ka BP onwards, and (ii) periods characterized by increased fluvial outflows between 8.2 and 6 ka BP during the African Humid Period. The comparison between our results and available marine palynological records underlines the Algerian margin singularity in terms of dinocyst assemblages, especially regarding the over-representation of heterotrophic taxa on the Algerian margin, that allows discussing upwelling dynamics through time.

These preliminary results (Master 2 thesis defended in Spring 2018) are part of the PhD project « From western to eastern Mediterranean Basin: Marine palynological evidences for understanding Holocene gradients in climatic and paleohydrological processes » (October 2018–October 2021, Univ. Brest, Brittany Council, France). This project is defined by 3 principal research axes: i) the methodological development of monospecific pollen grain radiocarbon datings on marine cores, ii) the establishment of temporal oceanic reservoir age series by the comparison of the pollen and carbonates radiocarbon ages from the same sedimentary levels, iii) the Holocene palaeoclimatic high temporal resolution (pluri-decadal) study with a robust chronology allowing for a better understanding of the rapid climatic variability. First datings on monospecific pollen grains (*Pinus*) have already delivered some results on 3 levels of MD04-2801 core (ECHOmicADAS spectrometer for AMS 14C dates, LSCE, Paris). Despite their great uncertainty, these first results highlight the potential to succeed and are encouraging for the pursuit of the project. Also, marine palynological data (dinocysts) will be compared with continental palynological data (pollen, spores and other non-pollen palynomorphs) so as to cross land-sea, climate-hydrologic, information across the Holocene. This project is funded by the CNRS (INSU EC2CO(DRIL)-LEFE(IMAGO), Mistrals-PaleoMex), the LabexMer, Univ. Brest and the Brittany Council.

Paleofaunas and Climate in Mediterranean region: a South-east French view

Antigone Uzunidis¹, Jean-Philip Brugal¹, Philippe Fernandez², Pierre Magniez¹

¹AMU, CNRS, Min. Culture, UMR 7269, Aix-en-Provence, France, ²AMU, CNRS, Min. Culture, UMR 7269, Aix-en-Provence, French Southern Territories

Abstract

The Mediterranean realm in Southeast France is located between three mountainous regions (Alps, Pyrenees and Massif-Central) and divided by a main north-south river and valley named The Rhône. The hydrological basin of this river is very important and presently the influence of the Mediterranean climate is sensitive higher in this Rhône' corridor. These geomorphological features condition some partitioning, with two sub-regions (Provence at east of Rhone, and Occitanie at west), as well as a wide coastal plains and more elevated zones at the border of reliefs. In this contribution we will propose a synthetic view and multi-approaches studies (paleontology, paleoecology, biogeography, ecometry...) about the large mammalian associations considered within a diachronic perspective, namely from Late Middle Pleistocene to Late Pleistocene (from MIS 12 to MIS2). This time period is contemporaneous of major climatic phases (especially glacial vs interglacial stages), the succession of Neanderthal and Modern Human cultures, as well as a marked turnover in the faunal biomes known as an important limit between two sub-series: the Middle and the Late Pleistocene. More of 35 archeo-paleontological sites (and many more levels) record as many herbivore and carnivore associations through this space-time which can be analyzed in their dynamic sequence, quantifying several eco-biological factors (body-size, diet category..), including peculiar forms (ex. Cervid: *Haploidoceros*) and evolutive lineage or taxa replacement (ex. *Canis*, *Bison*, *Equus*...). We must note the importance of geographical factors in the taxa distribution together with the sea-level fluctuation especially marked in the west part of the region (Occitanie). Moreover, the area of Rhone delta and the corridor of this river condition strong wind flow which develop some thick deposits of eolian sands (loess), indicators of locally quite cold condition. Among evolutive traits, the particular case of caballine horses is interesting because showing special adaptive features related to the mild Mediterranean climate (peripheral zones) regardless of global climate conditions. Lastly, ecometrical analysis (meso- and micro-dental wear) developed on some sites and taxa are a valuable tool to precise local environmental features within the global climatic variations. It generally suggests a high resilience and adaptive capacities from the large and medium size herbivores (Equids, Bovids, Cervids). Paleofaunas constitute a well-documented terrestrial archives for paleoclimate reconstruction, raising issues about interactions with climate and local geographic factors; our study allow us to envision the real biological changes, responses or resilience of the mammalian guilds/biomes within this peculiar Western Mediterranean space.

The use of coastal geological features and geomorphological evolution as sea-level pressure pattern indicators: two study cases from Apulia (Italy)

Massimo CALDARA, Vincenzo De Santis
Università degli Studi di Bari "Aldo Moro", BARI, Italy

Abstract

We present two study cases which show how coastal geological features and/or geomorphological evolution can be an useful tool for reconstructing the sea-level pressure patterns.

The first case is the comparative study of the sedimentation patterns at two locations on the Apulia coast, Riviera sud di Manfredonia and Marina di Ugento. Up to c. 5500 cal. yr BP, a phase of accumulation of flint pebbles from the Gargano headland occurred at Riviera sud di Manfredonia (Adriatic coast); their transport from the Gargano headland (north of the study site) is incompatible with the current northward littoral drift and can be explained by a prevalence and dominance of N, NE and E winds and consequent southward littoral drift. After c. 4500 cal. yr BP, there was a rapid accumulation of sediments at Marina di Ugento (Ionian coast), which is best explained by a prevalence and dominance of S, SW and SE winds. The two different wind regimes identified can be explained by a change in the mean pressure configuration in the central Mediterranean. The first phase (until c. 5500 cal. yr BP) consisted of more frequent cyclogenesis to the east-southeast/south of the Italian Peninsula, followed by a second phase (from c. 4500 cal. yr BP) of more frequent cyclogenesis to the west-northwest. The period 5500-4500 cal. yr BP represents a transitional phase.

The evolution of the Ofanto river delta between the 18th century and the present, compared with the contemporary evolution of the Volturno river delta can also provide indications of pressure patterns that occurred in the last centuries. We started by the principle that, all other factor being equal, a phase of advancing in the delta is promoted by a phase of frequent floods. Thus we analysed the data on recent floods (1970-2015), and we found that the most favourable situations for floods at both rivers are: omega-blocking, deep low-pressure trough, strong meridional circulation (mode Ω) which create Mediterranean low pressure systems. Instead, a zonal circulation (mode W), can only cause floods on Volturno river. Since the evolution of a delta is driven by the frequency of floods, and because we found that the frequency of floods is guided by synoptic patterns, then a relationship can be established between delta evolution and synoptic patterns in the past. Consequently, past phases of the contemporary progradation of the Ofanto and Volturno deltas suggest the increasing frequency of mode Ω , while phases of simultaneous progradation of the Volturno delta and stability and/or retreat of the Ofanto delta are indicative of the increasing frequency of mode W. This conclusion is reinforced by the fact that we demonstrated that anthropogenic factors which interacted with the delta evolution did not control the first-order evolution.

Holocene paleoenvironmental and climate change in the western Mediterranean deduced from a multi-proxy analysis from the Padul wetland record (Spain)

María J. Ramos-Román¹, Gonzalo Jiménez-Moreno¹, Jon Camuera¹, Antonio García-Alix¹, R. Scott Anderson², Francisco J. Jiménez-Espejo³, Dirk Sachse⁴, Jaime L. Toney⁵, José S. Carrión⁶, Cole Webster², Yurena Yanes⁷

¹University of Granada, Granada, Spain, ²Northern Arizona University, Flagstaff, AZ, USA, ³Instituto Andaluz de Ciencias de la Tierra-University of Granada, Granada, Spain, ⁴German Research Centre for Geosciences GFZ, Potsdam, Germany, ⁵University of Glasgow, Glasgow, United Kingdom, ⁶University of Murcia, Murcia, Spain, ⁷University of Cincinnati, Cincinnati, USA

Abstract

The Mediterranean area is an interesting location to carry out paleoclimate studies due to its geographic situation between subtropical and temperate latitudes. The Holocene is a significant period to study past climate change, with the objective of analyzing climate patterns, estimating future climate scenarios. In this framework, a high-resolution multi-proxy approach (from millennial to centennial-scale) in the sedimentary sequence of the Padul wetland has been accomplished. To do this, pollen, inorganic and organic geochemical and sedimentological analyses have been performed in the uppermost 3.67 m of the record. This study has been based on seven radiocarbon dates (AMS) used to constrain an age-depth model where the 3.67 m of the sequence corresponding with 11.6 cal kyr BP. The study of the entire Holocene allows us to determine the significant climate shift that occurred during the middle-to-late Holocene transition. From around 9.5 to 7.6 cal kyr BP a significant expansion of deciduous *Quercus* occurred reflecting maxima in humidity in the regional environment. Locally, insolation maxima induced high evaporation, counterbalancing the effect of relatively high precipitation, and triggered very low water table in Padul and the deposition of peat sediments. A transitional period occurred between 7.6 and 4.7 cal kyr BP with a regional change toward more regional aridity and then regional aridification and locally higher water levels due to the decrease in summer insolation (probably related with lower summer evaporation). Superimposed on the general climatic and environmental long-term trends during the Holocene is millennial-scale variability, recorded through several abrupt decreases in forest pointing to arid events ~ 9.6, 8.5, 7.5, 6.5 and 5.4 cal kyr BP with cyclical periodicities (~1100 and 2100 yr) during the early and middle Holocene. A change in the periodicity of these events towards a ~1430 cal kyr BP during the late Holocene around 4.7–4, 2.7 and 1.3 cal kyr BP. The comparison of our results with other paleoclimate records suggests that during the early and middle Holocene forest declines are at least partially controlled by external forcing (i.e. solar activity) and the late Holocene variability is related with internal mechanisms (oceanic-atmospheric).

Abstract

The Mediterranean Sea is a semi-enclosed sea where regional climates exert control on the formation of deep water masses at its two basins (eastern and western). At present, there are four major intermediate and deep water convection cells: Levantine Basin (intermediate), Aegean Sea (deep) and Adriatic Sea (deep) on the eastern basin, and Gulf of Lions (deep) on the western basin. These cells are interconnected and act as a driving engine of the Mediterranean thermohaline circulation (MedTHC).

Major changes on the MedTHC occurred during the Early-Middle Holocene (9.5 – 6.5Kyr), when the Mediterranean Sea was characterized by an asynchronous oceanographic pattern between its two sub-basins. On the western, there was a major strengthening in the deep overturning cell, meanwhile, on the eastern started one of its major phases of stagnation, resulting in the Sapropel 1 event (S1). Sapropels are caused by complex interactions between climatic and biogeochemical processes and are considered diagnostic of periods with anoxic deep-waters.

We present new results obtained from the South Adriatic Sea, at a location where deep waters are connected to the waters of the Ionian Sea through the Otranto Strait. This site is well suited to investigate Holocene climatic changes due to its unusually high sedimentation rate and the proximity to the Adriatic deep water convection cell. We have focused on high resolution analysis of the S1 interval of the core ND14M-bis (655m water depth).

Changes in surface water properties were reconstructed based on the ecological interpretation of planktonic foraminiferal assemblages. This information is also complemented with stable isotopes ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$) data of *Globigerina bulloides*. Additionally, variations in deep water properties were reconstructed in base of the geochemical analyses of the U/Mn ratio measured in planktonic foraminiferal coatings, as well as the paleoecological interpretation of benthic foraminiferal assemblages. All this information is combined with XRF elemental data from the bulk sediment.

The results allowed us to clearly define the S1 and its interruption phase. Our new data suggest the onset of surface waters stratification prior to the beginning of sapropel S1. The increase of the abundance of *Globigerinoides ruber* white, and decrease of *Neogloboquadrina pachyderma*, *Globorotalia scitula* and *Globorotalia truncatulinoides* support surface ocean stratification. The deposition of the sapropel is shown by the increase in deep water nutrient content, represented in our data as an increment of XRF Ba and *Globigerinoides ruber* pink. The U/Mn data and the benthic foraminiferal assemblages further support the occurrence of highly dysoxic waters during both phases of S1, and a rapid re-oxygenation event during the interruption, also marked by *Globigerinoides ruber* pink and *Globorotalia inflata*. We finally propose a sequence of events for the occurrence of S1 in the South Adriatic Sea.

Abstract

The Mediterranean Sea is a semi-enclosed sea formed by two different basins connected through the Strait of Sicily. Changes in the climatic conditions in the region exert control on the formation of dense water masses that fuel the Mediterranean Thermohaline Circulation (Med-THC) through 4 main convection cells. All these cells are interconnected through the Med-THC system, but their individual response during past climate changes is not fully understood.

During the Holocene, a major change occurred in both deep and intermediate convection cells in the E-Mediterranean Sea at the same time of the last sapropel (S1) formation between 10 and 6 kyr cal. BP. But little is known about the impact of these changes in the water properties exported into the W-Mediterranean Sea through the Strait of Sicily. The present study focusses on the analysis of the sediment core NDT-6 from the South Tyrrhenian basin, the easternmost basin in the Western Mediterranean Sea and close to the exit of the Strait of Sicily.

Core NDT-6 was extracted at 1066 m water depth, which is the present-day depth of the interphase layer between the eastern and western Mediterranean water masses in the region. Thus, this core is suitable to evaluate changes in the properties of the water masses transferred from the E-Mediterranean into the W-Mediterranean. A precise chronological framework for core NDT-6 has been established by ¹⁴C accelerator mass spectrometry (AMS) dates on planktonic foraminifera. Here we focussed on the interval between 5936-10501 kyr BP where S1 formation occurred in the E-Mediterranean Sea. Sedimentation rates for this period are between 15.92 and 37.31 cm/kyr allowing the resolution of the interval in study to be between 27 and 62 years per cm.

Changes in surface water properties are reconstructed using stable isotopes ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$) measurements in *Globigerina bulloides*, as well as based on planktonic foraminiferal ecology. Fluctuations in deep water properties are reconstructed using geochemical analyses in benthic foraminifera (stable isotopes and Mg/Ca ratios), U/Mn ratios measured in planktonic foraminiferal coatings and combined with benthic foraminiferal assemblage analysis. Finally, variations in the intensity of deep water currents is explored by means of grain-size analyses measured on the terrigenous fraction.

Major changes in all the proxies are observed particularly during the time of deposition of the first phase of the S1 (S1a) and during the S1 interruption. Our data reveal the occurrence of rapid changes (decadal scale) in surface water properties and also in the temperature and oxygen content of intermediate waters. We hypothesize that changes in the E-Mediterranean circulation might have had a major impact on the Tyrrhenian intermediate waters particularly during the S1b.

This research has been financially supported by ERC-TIMED project 525 (683237) and NEXTDATA project (www.nextdataproject.it).

P-3496

Sea surface temperatures & planktonic foraminifera palaeoecology during short-term climate oscillations of the Late Pleistocene in the Gulf of Lion.

Margaret A. Browne, Angela Cloke-Hayes
Mary Immaculate College, University of Limerick, Limerick, Ireland

Abstract

The modern Mediterranean can be characterised as a warm oligotrophic sea, with steep thermal and salinity gradients from west to east. In contrast to these generalised patterns, the North-Western Mediterranean is unique in that it is one of the coldest regions of the Mediterranean Sea; it is an area of deep water formation with high sediment influx from the Rhone Delta plume; and it is strongly influenced by global climate patterns, such as the North Atlantic Oscillation. It is well-known that Mediterranean deep-sea sediments are an excellent archive of the intensity and evolution of both regional and global climatic fluctuations during the Late Pleistocene. However, historically the Western Mediterranean has been less systematically investigated, in comparison to the eastern basin. Therefore, this research utilises the planktonic foraminiferal assemblage of a high-resolution sediment core (M40/4 82-2SL) from the Gulf of Lion, to determine the extent of climatic oscillations during the Late Pleistocene in this region, along with the variations in localised hydrology and ecology, and how microfaunal communities responded to these changes.

The chronology of the core was constrained by 9 radiocarbon dates, and the core extends back to the end of Heinrich Stadial 1 (HS1) (~15.5kyr), providing a detailed record of the Bølling-Allerød (BA), Younger Dryas (YD) and Holocene in this region. Using Artificial Neural Networks, the average annual sea surface temperatures (SST) during the BA (~15.08°C) were approximately 3°C lower than modern SST in the W. Mediterranean. During the YD, SST decreased to an average of 8.2°C, approximately 10°C lower than today and 3.5°C lower than the LGM average in the Western Mediterranean [Hayes et al., *Quaternary Science Reviews*, 24, 999-1016 (2005)]. A principal component analysis (PCA) indicates that stratification is the main ecological variable governing species distribution (PC1: 57.03%), along with productivity (PC2: 18.65%) and temperature (PC3: 16.74%). In addition, this high resolution of the core allows for detailed examination of shorter centennial-scale events, such as the 8.2 event and Inter-Allerød Cold Period.

Abstract

The sedimentary sequence developed in Formentera Island records the successive and abrupt climatic changes occurred since the last Interglacial in this part of the Western Mediterranean. Geomorphological, sedimentological and palaeopedological analyses, supported by luminescence dating, phytolith content and magnetic susceptibility allowed reconstructing the environmental and climatic evolution along an entire glacial cycle.

Above the last coastal remains of possibly MIS 5a age, with a sea level close to the present one, a complete terrestrial sedimentary sequence records the change from the humid and warm end of MIS5a, through the arid MIS4 towards a progressively wetter MIS3. During warmer and humid periods, redder colluvial and alluvial deposits with soil development took place; on its turn, arid periods are characterized by dune development, where slight moisture changes are evidenced by differences in root bioturbation (Bardají et al., 2017).

MIS3 is represented in the sedimentary sequence by an intensely bioturbated mass-flow dominated alluvial/colluvial unit with at least three different pedogenic phases, topped by a calcareous crust. On top of this crust a markedly different red clayey unit stand out in the sequence.

This unit shows a marked increase in total number of phytoliths with more dune/intradune grasses than halophytic meadows and presence of fresh water shrubs, that point to a higher water table; magnetic susceptibility also records a marked peak within this unit, witnessing an increase in humidity and temperature. TL/OSL analyses have given ages (17 - 20 ky) that point to late MIS2, correlatable in age to GS-2.1b, stadial that seem to have been slightly warmer than GS-2.1a and GS-2.1c as shown by Greenland data (NGRIP data, Rasmussen et al., 2014).

A compositional metanalysis of pollen data reveals climate influence on vegetation in the Central Mediterranean region during the late Holocene

Fabrizio Michelangeli¹, Federico Di Rita¹, Giulia Furlanetto², Roberta Pini³, Cesare Ravazzi³, Marcello Vitale¹, Donatella Magri¹

¹Sapienza University of Rome, Rome, Italy, ²University of Milano-Bicocca, Milan, Italy, ³CNR - Institute for the Dynamics of Environmental Processes, Laboratory of Palynology and Palaeoecology, Milan, Italy

Abstract

The Mediterranean area represents a transitional climatic zone between the temperate conditions of continental Europe and the subtropical regime of the African continent. This ecotonal feature determines a high climatic heterogeneity within the Basin: different atmospheric mechanisms and their interplays influence the amount, distribution and seasonality of precipitations, and eventually determine changes in the distribution of plant communities on millennial/centennial time scales. In this study, we present a meta-analysis of Italian Palynological Data from 32 well-dated and detailed lacustrine and marine records, including more than 90,000 observations for the last 3200 years. All the data were interpolated and homogenized at a secular resolution, to allow comparison of the different time-series. The compositional nature of pollen data was considered statistically in a unique holistic system using the R package “compositions”. Pollen taxa were grouped in Plant Functional Types, to ecologically characterize the vegetational variations found along the Italian Peninsula through time. Concordant/discordant vegetation patterns and synchronic/diachronic fluctuations at different latitudes and in different phytogeographic and ecoregional contexts were found. The role of human impact in determining environmental changes and in blurring the natural climatic oscillations during the last thousands of years was considered. A clear 2.8 ka cal BP event is statistically recognized, involving the Italian vegetation with contrasting latitudinal trends: it appears as an arid event affecting southern Italy and leading to a forest decline south of ca. 43°N, while no drought effect on forest cover nor changes in overall composition are statistically recorded north of this latitude below the timberline ecotone. By contrast, a considerable increase in forest cover was found during the Roman Classical Period (RCP) all over the central Mediterranean. Despite increasing human impact in the last part of the Holocene, the forest development during the Roman Period is in line with the so called “Roman Humid Period”. In this case, the compositional-PCA suggests the dominance of natural climatic variability over the anthropogenic influence in determining vegetational landscape changes. Considering our data in a wider geographical context, it was possible to find evidence for a longitudinal variability characterized by opposite vegetational trends in response to precipitation distribution patterns. Thus, studying the Central Mediterranean region provides an important contribution for understanding the so called “see-saw pattern” between the western and eastern regions of the Mediterranean Basin.

Organic Rich Layer deposition in the Alboran Sea (Western Mediterranean Sea) over the last 800 kyr

Aleix Cortina, Joan O. Grimalt, Belen Martrat, Marta Casado
Institute of Environmental Assessment and Water Research (IDAEA), Barcelona, Spain

Abstract

Over the past million years sapropels were deposited in the Eastern Mediterranean basin. In the western basin, similar sapropel layers were not formed; instead non-laminated Organic-Rich Layers (ORL's) were found. These ORL contain total organic carbon (TOC) concentrations of at least 0.8 %, and are assumed to be weak equivalents of the sapropel layers (TOC>2%). In this study, we investigate the Western Mediterranean climatic conditions during the last 800 kyr by using the ORL record from the Alboran Sea as indicator of hydrological conditions. The study of organic matter preservation in this area is of special interest since saline Mediterranean Outflow Waters (MOW) spreads on the deepest Alboran Sea, and changes in the rate of formation of these deep Mediterranean waters could affect North Atlantic circulation and thus global climate. Furthermore, a comprehensive study of ORL's occurrence and genesis over the last eight climatic cycles is still missing.

Herein, we present a continuous and high-resolution record of the concentration of C₃₇alkenones ([C_{37:2}+ C_{37:3}]), n-nonacosane and n-hexacosanol. The concentration of C₃₇alkenones ([C₃₇]) has been demonstrated as an excellent proxy of TOC in this area, implying that it can be used as an indicator of ORL formation. The effect of bottom ventilation is evaluated with the Alcohol Index, which is based on preferential degradation of n-hexacosanol vs n-nonacosane. Moreover, $d^{18}O_{\text{seawater}}$ is used with the aim of reconstructing past hydrographic changes. Our results show that ORL's were deposited during all major deglaciations. The persistent parallelism during the last 800 kyr between ORL deposition and low bottom ventilation indicates that the main driver of sedimentary C₃₇ concentration in the Alboran Sea is the variability of Western Mediterranean Deep Water formed in the Gulf of Lions, primary productivity playing a secondary role. Two different ORL profiles were identified. Deposition type I, with well-defined C₃₇ concentrations peaks prior to interglacial was associated to rapid and short deglaciations. In these cases, the orbital configuration was characterized by a maximum lag of 4 kyr between precession and obliquity, with higher values in the 65°N caloric summer half-year insolation curve. Deposition type II, with C₃₇ concentrations increasing slowly associated to slow and long deglaciations. In these cases, the orbital configuration was characterized by a longer lag between precession and obliquity, that resulted in values of the 65°N caloric summer half-year insolation curve leading to interstadial and latter to interglacial conditions.

Last glacial and deglacial environments of sub-alpine Northern Tasmania

Patrick Moss¹, Amirah Farrell¹, Judith Vink¹, Peter McIntosh², Adrian Slee²

¹The University of Queensland, Brisbane, Australia, ²Forest Practices Authority, Tasmania, Hobart, Australia

Abstract

Most information on environments for the last glacial period [including the Last Glacial Maximum (LGM)] for Tasmania have been obtained from palaeoecological records from western Tasmania (e.g. Lake Selina) and glacial evidence from the Central Plateau, with a lack of records from eastern Tasmania and sub-alpine regions (~600 to 800 m elevation) in general. This study will report the findings for two new sites that cover the last glacial and deglacial periods, Nicholas Swamp, located in a depression within the dolerite Nicholas Ranges at 859 m elevation, north east Tasmania, and Yellow Marsh, a *Sphagnum*/Buttongrass/Heath mire situated at Surrey Hills, north central Tasmania at 685 m elevation. Both records extend beyond the traditional Last Glacial Maximum period (i.e. between 22,000 to 18,000 years ago), with Nicholas Swamp providing a 48,000 year palaeoecological record and Yellow Marsh a 30,000 year geochemical and palaeoecological record. Key findings suggest a positive moisture balance for northern Tasmanian sub-alpine environments for at least the last 30,000 years, potential support for an extended LGM (i.e. 30,000 to 18,000 years ago) in eastern Australia (see Petherick et al., 2017) and evidence of increased burning and *Sporormiella* decline between 48,000 to 40,000 years that may indicate megafaunal extinction associated with anthropogenic activity at Nicholas Swamp. Further, both records provide insight into the Last Glacial Interglacial Transition (LGIT) or deglacial period. The Yellow Marsh record shows a transition from alpine herb-fields to rainforest around 12,000 years ago followed by the emergence of the modern vegetation (mixed rainforest/eucalypt forest/buttongrass moorland) between 10,000 to 9,000 years ago. The Nicholas Swamp record shows alpine herb-fields dominating the late glacial period (30,000 to 18,000 years ago) followed by vegetation indicating a climatically more variable LGIT and Holocene period.

SHeMax: A regional perspective on the timing of the Last Glacial Maximum in Australia

Haidee Cadd¹, Lynda Petherick², Jonathan Tyler¹, Annika Herbert³, Timothy Cohen⁴, Timothy Barrows⁴, Justine Kemp⁵, Reka-H Fulop^{4,6}, Kale Sniderman⁷, James Shulmeister⁸, Jasper Knight⁹

Abstract

It has been hypothesised that the last glacial maximum (LGM) in Australia occurred over multiple stages and at different times geographically, however this hypothesis has yet to be tested objectively. Such an objective comparison is complicated by several factors, including the variety of proxy archives, palaeoenvironmental proxies and dating techniques employed. In addition, recent refinement of the Southern Hemisphere radiocarbon calibration curve, plus advances in Bayesian age modelling and in analysing age-uncertainty in time series, require an approach that treats all data consistently. In order to gain a greater understanding of the spatial and temporal patterns of climate change during the MIS2, we have compiled proxy records of climate variability from across Australia for the period 35 – 15 ka. Continuous records covering at least 10,000 years, as well as discontinuous records of fluvial and glacial activity, were included in the synthesis. For each record, a revised age-depth model was developed using Bayesian age modelling techniques. Complex records (e.g. pollen records) were reduced to one-dimensional Principal Curves, in order to provide a non-linear summary of patterns of change in the full data-sets. Monte-Carlo change point analysis was then used to identify the timing of major changes within each record, along with the uncertainty around that date. We assess the spatial heterogeneity of the timing of the major climatic changes during the 35 – 15 ka period and determine the probability of common timing of change across Australia. Explicitly incorporating the age uncertainties associated with each record allows for a more robust interpretation of synchronous periods of change. Further expansion of our analyses will allow interrogation of both spatial and temporal synchronicity and coherency of the most recent and extreme climate and hydrological changes in Australia.

Developing a chronostratigraphic framework for the Quaternary of southern Africa

Jasper Knight, Jennifer Fitchett

University of the Witwatersrand, Johannesburg, South Africa

Abstract

The Quaternary System (last 2.58 Ma), characterized by both significant climate change and the development and spread of human and other species, has been examined in much detail in order to define the timings of different climatic phases within this System, and the regional to global synchronicity of these phases. This effort is underpinned by the principles of chronostratigraphic correlation put forward by the International Commission of Stratigraphy, a commission of the International Union of Geological Sciences (IUGS). The Subcommittee on Quaternary Stratigraphy has chronostratigraphic charts for many regions of the world but southern Africa is notably missing. This is a critical omission, given the importance of the region in hominin evolution during the Quaternary. Here, we propose procedures for, and a preliminary chronostratigraphic subdivision of, the later part of the Quaternary System of southern Africa (south of ~15oS). A key difference between southern Africa and many other parts of the world is that the Quaternary has no regional glacial expression (either morphologically or chronostratigraphically), meaning that the glacial-interglacial terminology for Quaternary environmental changes are not meaningful. As such, we use Antarctic Isotope Maxima from the Vostok record as a starting point, providing a high resolution regional temperature curve for regional comparison. The methodology we have adopted integrates multiple published climatic/environmental proxies from many existing sites and records in southern Africa. We look for evidence of a significant system change in the record, corresponding to some kind of threshold-like effect that is of regional scale, synchronous, and does not correspond to merely local variability. The system change should be manifested in several different proxies and should be constrained by some geochronometric control. We also use archaeological evidence (technological and/or cultural) as a valid proxy. Results of this analysis are broadly consistent with the Quaternary chronostratigraphic framework for other parts of the world, but some differences, similarities, and problems remain due to the poor spatial and temporal resolution of southern African records for this period.

Regional climate event stratigraphies for Australia for the period 35-15 kyr BP

Lynda Petherick¹, Haidee Cadd², James Shulmeister³, Jasper Knight⁴

¹Victoria University of Wellington, Wellington, New Zealand, ²University of Adelaide, Adelaide, Australia, ³University of Queensland, Brisbane, Australia, ⁴University of the Witwatersrand, Johannesburg, South Africa

Abstract

Here we synthesize climatic variability in Australia for the period 35-15 cal. kyr BP, sub-dividing the period into “climate events” by region. This timeframe encompasses the termination of MIS3, the traditionally-accepted timing of the last glacial maximum (LGM: ca. 24-18 kyr) and the onset of the deglaciation. A review of palaeoclimate records from Australia shows evidence for the onset of the LGM prior to 24 kyr, providing the impetus for this work. Emerging records also show that climate during the period 35-15 kyr was significantly more complex than the traditionally-accepted state of increased aridity. In this study we aim to (a) determine whether periods of major climate change occurred synchronously across Australia, (b) identify regional climate events, (c) describe regional climate conditions during these events, and (d) postulate drivers of regional climatic variability for the period 35-15 kyr. To achieve this, Australia can be first divided in six palaeoclimatological regions: summer dominant rainfall, summer rainfall, seasonally uniform rainfall, winter rainfall, winter dominant rainfall, and arid. We integrate continuous and discontinuous records from multiple proxies and environmental archives, identifying spatial and temporal patterns within each region. This allows for regional trends and changes to be identified, and regional signals to be disentangled from broader-scale climate events. In this study, climate event stratigraphies were constructed for each region, based on multiproxy evidence and where these proxies represent a diagnostic climatological signature. Following this procedure, time-coherent climate changes are described, which largely represent spatially-consistent changes in effective moisture availability (rather than temperature), likely including changes in seasonality. From such analysis, drivers of climate variability can be postulated, likely including changes in moisture source areas, trajectories of low-latitude cyclones, and monsoonal and El Niño/Southern Oscillation strength.

P-3504

Examining the use of a fossil pollen ratio on the Australian Last Glacial Maximum (LGM) record to determine rainfall seasonality.

Annika Herbert, Jennifer Fitchett
University of Witwatersrand, Johannesburg, South Africa

Abstract

Rainfall seasonality is variable in Australia, with three major rainfall seasonality zones across the continent. The northern part is dominated by summer rainfall, most of the central area has no dominant seasonality, or is too arid to have one determined, and most of the southern part of the continent is dominated by winter rainfall, except in the east, where there is no dominant season of rainfall. It has previously been difficult to find adequate proxies to estimate past rainfall seasonality, with the Last Glacial Maximum (LGM) being a particularly important period to study, given the known global changes in precipitation patterns. We propose using the ratio of fossil pollen Asteraceae to Poaceae as such a proxy, where high ratio scores indicate winter rainfall and low ratio scores indicate summer rainfall. This ratio has been used with some success in multiple studies in South Africa, a country affected by two major rainfall seasonality zones, summer and winter. In this study, we examine the validity of using this ratio as a proxy for rainfall seasonality on the Australian LGM record. We use the wider chronozone of 15-35 ka BP to signify the LGM but will also look at narrower time slices. We focus here on the east coast, which has the highest concentration of records. Our results demonstrate the usefulness of this ratio, with a slope-like pattern visible along a north-south transect. In Tasmania the winter rainfall zone is apparent, and in tropical Queensland the results indicate a precipitation pattern dominated by summer rainfall. In between are mainly intermediary sites with no dominant rainfall seasonality during the LGM. Interestingly, some of these intermediary sites are located quite some distance north of the modern boundary between the summer-dominated and non-seasonal rainfall zones. This suggests that the non-seasonal rainfall zone may have been wider during the LGM, possibly extending into the current subtropics. Apart from this, the eastern Australian rainfall seasonality zones during the LGM appear to have been quite similar to those of today.

P-3505

Geomorphological and chronological evidences for the Last Glacial Maximum in the Cachapoal Valley (Southern Central Andes of Chile, 34-35°S)

Lasafam Iturrizaga¹, Reynaldo Charrier², Sébastien Carretier³, Vincent Regard³

¹University of Potsdam, Potsdam, Germany, ²Universidad de Chile, Santiago, Chile, ³Université de Toulouse, Toulouse, France

Abstract

The study presents results of a geomorphological reconstruction of the Quaternary glacier extent in the Cachapoal Valley in the Southern Central Andes of Chile. The Cachapoal Valley shows striking evidences of a formerly more extensive glacier expansion. Classical U-shaped valleys, moraines and roches moutonnées are amongst others geomorphological witnesses of the former glaciations. Topographically and climatically, the Cachapoal Valley provides favorable conditions for glaciation. The E-W trending valley, a tributary of the Rapel River, drains one of the most southern located mountain massifs of the Andes exceeding altitudes of above 5000 m (Picos del Barroso 5180 m). The upper catchment areas are home to some of the largest glaciers of the Central Andes, among them the 12 km long Cachapoal Glacier. In climatic terms, the valley is located in the transition zone from the Dry Central Andes to the Wet Andes with increasing annual precipitation southwards. Thus, the research area marks a key location for the discussion on the dominant factor in the temperature-precipitation regime in regard to the timing of the LGM. In the present research project, geomorphological field work was carried out to identify and map the glacial landform assemblages in the Cachapoal Drainage Basin. Additionally, surface exposure datings were obtained from boulders situated on the crest of lateral moraines in the assumed LGM-glacial margin and along the modern Cachapoal Glacier using cosmogenic ¹⁰Be. The interpretation of the field evidences suggests a dendritic paleo-ice stream during the Last Glacial Maximum with the main affluents of Cachapoal (60 km), Cortaderal (40 km) and Cipreses (37 km) flowing down at least to an elevation of about 950 m a.s.l. In principal, this is in accordance with previous works in the study region. However, the results will be discussed in the light of the discourse of the genetic interconnection of moraines and landslides as amongst others the reconstructed LGM ice margin is located in a large-scale landslide area. The contribution aims to provide additional facts for the establishment of a more detailed relative and absolute glacial chronology of the Central Andes during the Last Glacial Maximum and to shed light on the determination of the nature and timing of glacier changes during the last glacial cycle.

P-3601

The character of Caspian Sea level fluctuations in Late Pleistocene-Holocene.

Ekaterina Badyukova

Moscow State university, Moscow, Russian Federation

Abstract

Stratigraphy of the Caspian Sea history as a whole was created in the early 20th century. Most of the data were obtained from the outcrops along the Lower Volga. In them khvalynian deposits lie in the form of thin layers. These are chocolate clays (CC) and sometimes sand layers which are deposited on the sediments of different genesis – subaerial atelian loams, alluvial sand or marine khazarian sediments. It was believed that CC are the deposits of the deep Early Khvalynian basin when the level of the Caspian Sea reached 50 m.

A detailed study of CC – distribution in the Northern Caspian Plain, the character of their position in the outcrops, lithology, etc., allowed us to assert that CC are the lagoons deposits (Badyukova, 2010). As soon as we came to this conclusion, it was necessary not only to interpret all previously studied outcrops differently but also to review the history of the Caspian Sea level fluctuations in the at the end of Quaternary period.

In this connection, the main attention was paid to the laws of the coastal zone reaction to the sea level fluctuations, which were not taken into account earlier. To explain the existing contradictions, the idea of forming lagoon-transgressive terraces against the background of sea level fluctuations, where CC were formed, was put forward. Directly from the surface, CC could form only if there were such terraces.

As a result proposed another scheme of the Caspian Sea level fluctuations, different from the conventional one. According to it, there was the Great Khazarian transgression, the level of which, judging by many outcrops, was slightly lower than the Early Khvalynian transgression. This is indicated by many sections on the Volga where at that time extended the estuary up to Saratov. The entire subsequent history of the Caspian Sea is a gradual sea level fall interrupted by its rising. Early and Late Khvalynian transgressions occurred on the background of general sea level fall, their amplitude did not exceed 20-25 m. This indicates the dimensions of different age alluvial deposits, observed in the outcrops sequentially located along the Lower Volga and other rivers (e.g., rivers Large and Small Uzen) at lower hypsometric levels.

Thus, there was no deep Atelian regression. Moreover, Early Khvalynian transgression did not begin from minus - 100-120 m but was from approximately 0 m. Formation of lagoon-transgressive terraces and CC occurred in various stages. Therefore, the age of the Early Khvalynian transgression varies – from the older on the high terraces to the younger on the lower hypsometric levels.

P-3602

The Caspian - Black Sea - Mediterranean corridor: water exchange and migrations of fauna during the last glacial epoch

Tamara Yanina, Valentin Sorokin
Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

The last glacial epoch (MIS 2) includes some climatic events: the LGM (26.5-20 ka), the early deglaciation (20-14.7 ka) and the late glacial (14.7-11.7 ka). The late glacial displayed relatively short-term climatic fluctuations known as the Bølling and Allerød (14.7-14.0 and 13.6-12.9 ka) separated by the cooling of the Middle Dryas, and conspicuous cooling of the Younger Dryas 12.9-11.7 ka. During this entire interval, temperatures were changing at a considerable rate. These climatic changes found reflection in development of basins of the Caspian - Black Sea - Mediterranean corridor. They represented the basins of different types. The transgressive and regressive condition of the Caspian Sea (the lake basin) depended on its water balance. The mode of the Mediterranean Sea was defined by fluctuations in the level of the Ocean. The condition of level of the Black Sea depended on the levels of the Mediterranean and the Caspian Seas. In the Mediterranean Sea, the Tyrrhenian transgression was replaced by a long, uneven decrease in sea level. In the MIS 2 horizon of deep-water deposits of the Sea, cold-water foraminifera prevail. Proof of a deep decline in sea level from 100 to 130 m gave a set at this time. In the Pontian, the regressive Neoeuxinian basin (from -110 to -130 m) with mostly fresh water mollusks developed during the LGM. A connection with the Mediterranean Sea was absent. The Sea of Azov was a coastal plain crossed by the Don River whose mouth was located 50 km south of the Kerch Strait. The climatic conditions resulted in a negative water balance for the Caspian (Khvalynian) Sea, causing a sea-level drop. The Khvalynian transgression resumed during deglaciation after the LGM. The Early Khvalynian transgression, having reached the level of the Manych threshold, created an erosive valley and discharged into the Neoeuxinian basin. Transgression of the Caspian type began in the Neoeuxinian basin during deglaciation too. The transgressive interval was dominated by Pontocaspian mollusk species. The occurrences of Khvalynian species in the Neoeuxinian deposits confirm the overflow of Caspian waters. This interval corresponds to a rise in water level to -20 m. At the same time, the presence of Neoeuxinian faunas in the Marmara basin and northern Aegean suggests Black Sea overflow. The Neoeuxinian basin was overflowing. Glacio-eustatic increase in the level of the Ocean in the Mediterranean Sea carries the name of the Flandrian transgression with modern Mediterranean mollusks. Penetration of waters into the Black Sea basin caused the Chernomorian (Black Sea) transgression with euryhaline and moderately stenohaline Mediterranean mollusks. In the Caspian Sea at the beginning of the Holocene there was a deep Mangyshlak regression. The investigations are supported by the RFBR (Projects 18-05-00296, 18-05-00684).

P-3603

Inner structure and age of development of the Baer knolls in western Volga delta

Daria Lobacheva, Radik Makshaev
Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

The history of the study of Baer knolls (BK) counts more than a century. There are several theories of the origin of BK. In this paper, we provide information about the inner structure of Baer knolls in the western (Mirny, Dolgiy, Troitsky) and central (Yaksatovo, Nartovo) parts of the Volga delta.

The aim of the study is to identify the inner features of the structure of BK and the mechanism of their forming. To achieve this aim, several methods were used (granulometric, geochemical, malacofaunistical and radiocarbon).

BK in the Volga delta, in general, have a similar inner structure. In the basement there are chocolate clays (CC) with lenses of sand. Above there is a lower thickness (LT). The LT consists of cross-bedded dark brown clay and silt with thin layers of detritus. The thickness of LT is about 4–5 m. Above there is an upper thickness (UT) which consists of lighter pale-brown sand and silty clay. The lamination is mainly oblique with monoclinical and wedge-shaped structure. The thickness of UT is 2-3 m.

The grain-size analysis confirms the presence of UT and LT, which are separated by erosion boundaries. Based on grain-size and geochemical data the LT and CC composition are mainly similar. The LT usually contains finer fraction, it has two modes in coarse clay and coarse silt (0.01-0.05 mm). The UT is distinguished by a sand composition with two peaks in clay (0.001-0.005 mm) and fine-grained sand (0.05-0.25 mm).

The radiocarbon dating of the LT in the Yaksatovo BK is 15280 ± 180 cal yr BP.

A malacofaunistical analysis was carried out for two knolls (Mirny and Yaksatovo). On the contact of the LT and CC in the Yaksatovo, shells were found *in situ* *Didacna protracta*, *D. parallella*, *D. parallella borealis*, *D. praetrigonoides*. In Mirny, on the contact between the LT and UT, *D. praetrigonoides*, *D. protracta* were found. These species were distributed at the end of the Lower Khvalynian and the beginning of the Upper Khvalynian stages.

The geomorphology of the central part of the delta reveals that the ridges in the lowermost part are absent, and the thickness of alluvial sediments is more than 20 m, which means that there was an active river runoff in this area that destroyed the ridges (Rachkovskaya, 1951). Consequently, BK could have been formed since the end of the Early Khvalynian transgression, and especially during the Late Khvalynian and the Early Holocene. Probably, the LT was formed in the subaquatic conditions, while the subaerial (aeolian) processes, played an important role in the formation of UT.

This work is supported by the RSCF (Project 16-17-10103).

P-3604

Stable oxygen isotope analysis of the Northern Caspian Basin during the Late Pleistocene

Alina Berdnikova¹, Elena Garova^{1,2}, Tamara Yanina¹, Frank Wesselingh³, Sabrina van de Velde³

¹Lomonosov Moscow State University, Moscow, Russian Federation, ²University of Iceland, Reykjavík, Iceland,

³Naturalis Biodiversity Center, Leiden, Netherlands

Abstract

Over the past years our group of researchers from MSU and OAO «MorInzhGeologia» studied Late Pleistocene sedimentary evolution of the North Caspian basin (Bezrodnikh et al., 2015, 2016, 2017; Bolikhovskaya et al., 2017; Sorokin et al., 2018; Yanina et al., 2018). Here we report on stable oxygen isotope analyses of cores KOP-4 and IGS-1, from the Caspian North-Western area. The studies are based on drilling material from the shelf. Isotope analysis was carried out on ostracod shells.

Global climate changes were fundamental for both the transgressive-regressive state of the Caspian basins, as well as for glacier formation and retreat on the Russian Plain. Isotopic composition changes reveal the influx of fresh water in the Northern Caspian Basin as well as it reflects global climatic changes. Thereby we show the correlation between transgressive-regressive events among Ponto-Caspian basins and glacial-interglacial epochs at the East European Plain during the Late Pleistocene.

Previously the obtained cores were studied with lithological, faunistic, palynological and geochronological (radiocarbon) methods (Svitoch et al., 2008). We used this data for more accurate paleoreconstruction.

Our first isotopic results show climate factors driving Caspian Sea level fluctuation during the Late Pleistocene. Insignificant peaks of lighter $\delta^{18}\text{O}$ ratios meaning the increase of meteorological component in water balance, characterize small-scale warm transgressions – like Late Khazarian (-7,04‰) and Novocaspian (-6,24‰), which took place during the interglacials. The Hyrcanian interval is characterized by high amplitude changes of $\delta^{18}\text{O}$ ratios: records vary from -3,37‰ in lower part to -10,62 ‰ in the middle part (maximum transgression) and again up to -3,65‰ in the upper part of the layer, showing regression that marks the onset of the Atelian regressive stage. The very low $\delta^{18}\text{O}$ ratios (-10,55‰) found in the base of the interval overlying the base of the Atelian interval. Such values indicate near fresh water conditions at the time. The $\delta^{18}\text{O}$ ratios in the Khvalynian interval ranges from -13,46 ‰ to 1,16 ‰. The isotopic curve reflects a number of states of the Khvalynian basin level. Thereby the maximum influence of fresh water inflow into the North Caspian basin was during the Khvalynian. The $\delta^{18}\text{O}$ value -1,62 ‰ was recorded for the Mangyshlakian layer. The last recorded $\delta^{18}\text{O}$ value -5,86‰ in the Novocaspian layer corresponds with the isotopic composition of the North Caspian water today.

The investigations are supported by RFBR Grant 18-05-00684 (lithological analyses) and RSF Grant 16-17-10103. Further study of Caspian Sea sediments by isotope methods will allow to get interesting results and settle some arguable issues of the Caspian region paleogeography.

Shoreline evolution of the northwestern Turkey (Marmara Sea-North Aegean Sea) evidenced by sea-level markers and relative sea-level changes: preliminary assessment

Ufuk TARI¹, Cenk Yaltırak¹, Gürsel Sunal¹, Nazlı Olgun²

¹Department of Geological Engineering, Istanbul Technical University, 34469, Maslak, Istanbul, Turkey, ²Eurasia Institute of Earth Sciences, Istanbul Technical University (ITU), 34469 Maslak, Istanbul, Turkey

Abstract

Here, we present new data on the morphological, biological and sedimentary records of paleo-sea levels in the northwestern Turkey (Marmara Sea-North Aegean Sea), and discuss their potential use to reconstruct relative sea level changes. These markers represent a significant paleo-environmental proxy because they can record both the vertical and the horizontal evolution of the shoreline. There is a paucity of presently available data in this sector of the Marmara Sea, which is a tectonically active area strongly controlled by the North Anatolian Fault Zone. In addition, late Quaternary relative sea-level changes (RSL) at this region were not homogenous and variations in the tectonic setting played a crucial role in the coastal evolution. In this study, our investigation provides new insights into to delineate regional sea-level variations in the different sections of the Marmara Sea using a wide range of coastal sediments in terms of layering characteristics, stable isotope compositions, consecutive cementation structures, radiocarbon and luminescence dating. Coastal deposits are characterized by locally abundant shells, uplifted near-shore deposits, submerged beachrocks and coastal lagoon sediments the borders of the western Marmara Sea at different elevations. Notches and shore platforms are also identified as erosional morphologies, particularly in microtidal environments in this area situated in various altitudes above modern sea level and we correlate them with RSL changes. Fossil and living populations as biological indicators allow the vertical shift between present and former sea level to be established. In fact, the interaction between coastal processes and uplifting fault blocks contributes to the preservation of geomorphologic and/or biological records of vertical movements through time. Therefore, a detailed mapping of paleo-sea-level markers will be carried out as a tool to quantify coastal uplift/subsidence and RSL changes in this study. Firstly, we also apply online radiocarbon analysis for the ability of reaching a high spatial resolution from marine shells and coastal sediments in different sites along coastline. This study intends to determine a more accurate rate of uplift/subsidence history for the northwestern Turkey and to delineate the relationships between the geological features and regional sea-level variations, using radiocarbon and luminescence dating and field data relationships.

Abstract

Within the framework of the Russian-Armenian project “Paleolimnological aspect of study of ecosystem evolution of alpine Russian and Armenian lakes»” in July-August 2018, we investigated four high-mountain lakes of Armenia. The research was carried out in the lakes Kari, Umroy, Akna and Sev. All investigated lakes are located at the altitude about 3000 m above sea level. The lakes were first investigated using a multi-proxy method that includes paleolimnological, geomorphological, hydrological, geochemical and biogeographic studies. From all the lakes, sediment sequences were collected for pollen, diatom, geochemical and radiocarbon analyses. For all the lakes bathymetric maps and three-dimensional models of the lake kettles were constructed, as well as the geomorphological maps of the catchment basins. According to preliminary results, the maximum age of the lake formation is about 7 ka. The studies were carried out as a part of the RFBR project No. 18-55-05008 and Science Committee of the Ministry of Education and Science of the Republic of Armenia No. 18RF-045.

The middle Pleistocene sediments of Caspian Sea: the first absolute dates

Nikolai Tkach¹, Nikita Sychev², Radik Makshaev¹, Tamara Yanina¹

¹Lomonosov Moscow State University, Moscow, Russian Federation, ²Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation

Abstract

During the Quaternary Caspian Sea level changed several times. Researchers have been exploring the Caspian Sea for two centuries. However, there is still no consensus on the number of transgressive-regressive events, their scale, chronology, and causes. The most controversial question is about the chronology of paleogeographic events, since absolute dates were obtained only for the last two transgressions: the New-Caspian (the Holocene) and the Khvalynian (the late Pleistocene). The most interesting transgression is Khvalynian, which had a catastrophic character in the opinion of some researchers.

Estimated age of the last huge transgression (Khvalynian; max. highstand +50 m a.s.l.) by different researchers varied from 70,000 years to 11,000 years, i.e. from the first half of the Wurm to the beginning of the Holocene. Estimated age are based on thermoluminescence dating (Shakhovets, 1987, Rychagov, 1997), electron paramagnetic resonance spectroscopy (ESR) (Molodkov, 1992), uranium-ionium (Kuznetsov, 2008; Arslanov et al., 2015), radiocarbon dating (Arslanov et al, 2013; Arslanov et al., 2015; Tudryn et al., 2013).

However, there hasn't been dating of sediments that correspond to the maximum level of the Khvalynian basin.

Along the valley of the Volga River and the inflowing valleys of small rivers, the Caspian Sea created a network of ingression bays during the largest transgressions. In the 20th century, the Middle Volga region was studied and described in details. But for all this time only two absolute dates have been obtained by the radiocarbon method, which are probably irrelevant. Determining the stratigraphic position of the sediments is difficult due to the almost complete absence of the malacofauna.

We sampled sediments for OSL-dating in one of the most studied sites - Maliy Karaman (Moskvitin, 1962), which reveals coastal sediments (described as deposits of the last major transgression - Khvalynian) and underlying loess with soil horizon.

We conducted the dating in the OSL-laboratory in All-Russian Geological Institute (VSEGEI), Saint-Petersburg. We expected dates as the first decades thousands years and therefore used quartz grains. Purity test and recovery test were conducted. However, it was found that the equivalent dose is significantly higher than we thought, and the quartz is saturated. Therefore, the sediment was analyzed by feldspar according to the post-IR IRSL protocol (Thiel et al., 2011).

For coastal sediments dates were obtained that correspond to the end of MIS 8 — the beginning of MIS 10, and for loess with soil horizon — MIS 13.

Thus, coastal sediments can be correlated with a much more ancient Caspian transgression (early-Khazarian; max. highstand +35 m). Thus, these are the first dates for the middle Pleistocene deposits of the Caspian Sea and the first absolute dates in the Middle Volga region.

¹Moscow State University, Moscow, Russian Federation, ²Caspian Sea National Research and Study center, Sari, Iran, Islamic Republic of

Abstract

Iranian coasts of Caspian sea is a unique region for understanding the history of the Caspian Sea in the Pleistocene, its correlation with the global and regional climate changes. The reason is representativeness of Quaternary sections, presence of both marine and subaerial sediments, paleontological richness of the materials and available for study.

At present, large-scale studies of the subaerial deposits of the region - first of all - the so-called Iranian loess plateau are being carried out. Works on the paleoclimatic reconstructions of the region in Holocene were performed by S.A.G. Leroy (2016). However, the Iranian coast remains one of the few sections of the Caspian where sea level reconstructions based on geomorphological evidence have not been performed. In our work, we tried to reconstruct the history of the development of the last and largest transgression of the Caspian Sea – Early Khvalynian, and to reveal the stages of its development in the territory of Northeast Iran. The object of research was the valley of the Gorgan River, in the sides of which a series of sections with marine, alluvial and aeolian deposits is revealed. We have described more than 30 sections throughout the valley, within the bounds of the possible influence of the Khvalynian transgression (up to a height of +70 m abs).

For the first time, deposits of mixed alluvial-marine genesis, reflecting the early Khvalynian transgression of the Caspian Sea, were found in the sections. Completed OSL-dating of sediments allowed to reconstruct the stages of development of the natural environment of the region after the LGM. Thus, 14-15 thousand years ago the middle part of the valley of the Gorgan River was covered by the waters of the Caspian Sea. In sections of the middle part of the Valley (altitude of +30 m), this stage is represented by rhythmic clays and loams of mixed marine and alluvial genesis. The transition to purely alluvial floodplain deposits. The upper part of the section is represented by subaerial loess deposits, with thickness of 7-8 m. The subaerial phase of sedimentation began about 11 thousand years ago with a high rate of formation of loesslike deposits.

Obtained new data allow us to reconstruct the history of the development of the region's geomorphology in the final stages of the Early Khvalynian transgression of the Caspian Sea (14-12 thousand years ago) and the subsequent continental stage, during which a deep cutting of the Gorgan River channel is noted with a synchronous accumulation of a thick layer of loess.

First optically-stimulated luminescence ages of the early khvalynian "chocolate clays" of the Lower Volga

Mikhail Svistunov¹, Redzhep Kurbanov^{1,2}, Warren Thompson³, Andrew Murray³, Tamara Yanina²

¹Institute of Geography RAS, Moscow, Russian Federation, ²Geography Faculty, Moscow State University, Moscow, Russian Federation, ³Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Roskilde, Denmark

Abstract

During the Late Quaternary dramatic changes in relative sea-level are known to have occurred in the Caspian Sea. However, all previous attempts at resolving the uncertainty associated with the timing of these transgressive/regressive events using standard dating methods have produced inconclusive or controversial results. For the first time a reliable Late Pleistocene chronology has been derived using optically stimulated luminescence (OSL), and post-IR IRSL290 analysis of quartz and K-feldspar grains extracted from 20 sediment samples collected along the Lower Volga River. Analyses were conducted on multi-grain aliquots of the sand-sized fractions of loessic sediments, marine clays and the overlying modern soils from three exposed sections ~50km downstream of Volgograd. The signals from all quartz samples were dominated by the fast component; there was no significant IR sensitivity, and no significant dependence of D_e on preheat temperature. The post-IR IRSL290 signals from the 5 samples examined also met all laboratory-based criteria for a reliable estimate of equivalent dose. Resetting of the luminescence signals was investigated based on the differential bleaching rates of quartz OSL and K-feldspar signals; we conclude that all signals were sufficiently reset prior to deposition.

Our results show unambiguously that the Early Khvalynian marine Chocolate Clays present at all three sections were deposited post-LGM, between ~13.5ka and ~17 ka ago. These ages are further constrained by those from the overlying Kastanozem soils (0.7 to 9.1 ka) and underlying loess-soil series (19-30 ka). Relative (Caspian) sea-level during the Early Khvalynian must have been well above the sampling altitude of 9.33 m (Srednyaya Akhtuba), 8.51 m (Raigorod) and 6.98 m (Leninsk) to explain the absence of significant alluvial sand and to allow the deposition of the clay-sized particles of the Chocolate Clays marker horizon.

Abstract

At the present time the stages of the Caspian sea-level evolution during the largest Late Quaternary Khvalynian transgression remains open. There have been attempts to establish an absolute chronology based almost entirely on radiocarbon dating, often of individual shells. This approach is of course limited to <50 ka but in any case has given very conflicting results; as a result, no consensus view of the transgression/regression history has evolved. In an attempt to resolve these problems, a major project (IGCP-481) was established to re-date the more recent transgressions using radiocarbon¹⁶. Unfortunately, most ages were again unexpectedly young and stratigraphically inconsistent.

Existing radiocarbon chronology does not allow to resolve two transgressions (Early and Late Khvalynian). Based on clear palaeontological and geomorphological evidence, these must be very different in age, but shells associated with both transgressions gave very scattered ages of between 8 and 50 ka (Arslanov et al, 2015). Another controversial issue is the stage between Early and Late Khvalynian – Enotaevka regression.

During 2014-2018 fieldworks we made an effort to find the section with clear continental sedimentation profile within two Khvalynian transgressive series. And such deposits were identified at Kosika location, on the right valley side of the Volga river, 4 km to the North of the Kosika village. The total thickness of the outcrop is 10 m. The outcrop is confined to the western base of the Baery knoll. The part of the outcrop with the most clear position of the Enotaevka regression deposits is confined to the northern limit of the Baery knoll. The profile of the paleosol represented by a series of genetic horizons and reveals clear evidence of erosion. Apparently, the original profile was abraded during the Later Khvalynian transgression resulting in preserved illuvial horizon. This strata passes into the marine clays with poor collection of shells (mostly *Dreissena* Sp).

The applied luminescence dating allowed us to reconstruct the timing of the main stages of the environmental evolution during the second half of Khvalynian transgression. 15 OSL-dates describes main stages: re-worked Upper Khvalynian sands of the upper Baery knoll strata is dated $8,3 \pm 0,5$ ka; paleosol formed in the Enotaevka regressive horizon dated 12 – 13 ka; Lower Khvalynian sediments is characterized with three dates 19-22 ka; the basis of the section (Hyrcaian horizon) is dated 113-133 ka.

This research for the first time reveals the structure of Enotaevka regressive series of the Lower Volga and describes the numerical age of the main stages of the Late Quaternary environmental evolution of the region.

Loess formation and Caspian Sea level changes in the Southern Caspian Lowlands, Iran, during the Late Quaternary

Martin Kehl¹, Manfred Frechen², Farhad Khormali³

¹University of Cologne, Institute of Geography, Cologne, Germany, ²Leibniz Institute for Applied Geophysics (LIAG), Geochronology and Isotope Hydrology, Hannover, Germany, ³Gorgan University of Agricultural Sciences and Natural Resources, Department of Soil Sciences, Gorgan, Iran, Islamic Republic of

Abstract

The formation of loess involves several climate-related processes including the production of silt-size particles, aeolian transport, deposition of dust and its post-depositional alteration. Topography and geomorphological factors play significant roles in loess formation, too. For instance, diachronic changes in the location and extent of dust deflation areas may significantly affect dust lithology and accumulation rates. It is widely anticipated that the water level of the Caspian Sea strongly fluctuated during the Late Quaternary. Accordingly, the spatial extent of the southern Caspian Lowlands, a major proximal source area of mineral dust accumulated in loess deposits of Northern Iran, may have fluctuated significantly affecting both the extent of dust deflation areas and regional climatic conditions. The loess of Northern Iran is structured by a large number of interglacial and interstadial palaeosols, formed under forest or steppe vegetation. We established high resolution records of sediment grain size, colour, carbonate content and magnetic susceptibility backed by micromorphology and luminescence dating at several loess exposures. These records are synthesized to propose a detailed pedostratigraphy for Northern Iranian loess including strongly developed palaeosols formed during the Eemian interglacial, equivalent to Marine Isotope Stage (MIS) 5e, and during interstadials of the Early Last Glacial (MIS 5c, and 5a). Moreover, weakly developed interstadial palaeosols formed during the Last Pleniglacial (MIS 4 to MIS 2). The records clearly reflect pronounced changes between dry and moist climatic conditions. It appears that during MIS 5 precession cycles controlled the pattern of dust accumulation and soil formation in Northern Iran, whereas during the Pleniglacial geomorphological factors induced by Caspian Sea level changes may have been responsible for fluctuations in dust accumulation rates and soil formation intensity. This and further hypotheses on possible connections between loess formation and its preservation on the one hand and Caspian Sea level fluctuations on the other hand will be discussed.

Estimation of the Eastern Caucasus (NE Azerbaijan) uplift based on the Neogene-Quaternary marine deposits study

Yaroslav Trikhunkov¹, Talat Kangarli², Evgenia Shalaeva¹, Pavel Frolov¹, Fuad Aliev²

¹Geological Institute, Russian Academy of Sciences (RAS), Moscow, Russian Federation, ²Institute of Geology and Geophysics, Azerbaijan National Academy of Sciences, Baku, Azerbaijan

Abstract

The Lateral Range of the Eastern Caucasus is one of the highest ridges of the mountain system of the Greater Caucasus. Its neotectonic deformation influences the adjacent homoclinal Gusar plateau, which smoothly rises towards the ridge from the Caspian coastal zone. The plateau is composed of marine and continental sediments of Pont-Apscheronian age, which lie in transgressive unconformity with the pre-Pliocene folded basement. The studied Akchagylian formation is represented by gray clays, silts and sands with traces of wave-formed ripples, sandstones and shell limestones. These deposits are covered by clays, silts and pebbles of the Gusar Unit of Apscheronian age, where limestone interbeds with *Apscheronia propinqua* are described (Geological Map, 1960). The described signs indicate the marine or coastal genesis of the sediments that form the plateau.

From the north the Lateral Range of the Eastern Caucasus is adjacent to the Gusar Plateau. We have investigated the synclinal plateau-like Chereke massif (2383 m), made of similar sediments, and drawn in this way into the folded deformations. The lower part of the Chereke section is represented by silts and siltstones, sands, sandstones with traces of wave-formed ripples. The upper part is formed by pebble-boulder conglomerates, calcareous sandstones with traces of wave-formed ripples, shell detritus with whole shells of gastropods and bivalve molluscs of the family Mactridae. The listed signs indicate the marine genesis of these deposits. According to V.E. Khain the lower section of Chereke has Maikopian age and the tops belong to the Sarmatian, but according to the data of T.N. Kangarli sediments have Cimmerian (Productive formation) and Akchagylian age respectively.

The uplift of the Gusar plateau was caused by total uplift of the mountain building. The top of Akchagylian marine deposits is situated at the height of 1600 – 1700 m a.s.l., and they are covered by Apscheronian deposits with 1906 m maximum height (Mt. Big. Suval). Thus, taking into account the rise of the sea level in Apscheronian time, the amplitude of deformations of the Gusar plateau can be estimated at 1500 m for the period after the end of Apscheronian sedimentation (about 1 Ma). The rate of uplifting of the plateau, based on these data, is 1.5 mm per year and correlate with the rates of uplift of the Shirak depression of the Armenian Highland (1.3 – 1.8 mm per year; Trifonov et al., 2017).

In the future comparative analysis of the Gusar Plateau deposits (Mt. Big. Suval) with the Lateral Range (Chereke massif) deposits will allow to confirm or deny their similar genesis and age and calculate the rates of the uplift of the latter.

The work is supported by grants of RSF (18-00-00977), and RFBR-18-00-00977 (geoarcheology).

Calibrating the timing of the Thera eruption: A new annual radiocarbon record

Ronny Friedrich¹, Bernd Kromer¹, Sabine Remmele², Susanne Lindauer¹, Alexander Land², Lukas Wacker³, Jesper Olsen⁴, Charlotte Pearson⁵

¹CEZA, Mannheim, Germany, ²Uni Hohenheim, Stuttgart, Germany, ³ETH Zürich, Zürich, Switzerland, ⁴Aarhus University, Aarhus, Denmark, ⁵University of Arizona, Tucson, USA

Abstract

One of the largest volcanic eruptions in the past 10000 years - the Minoan eruption of Thera (also called 'Santorini' eruption) is an important event in many fields of research.

A variety of environmental and paleoclimate archives utilize the physical markers left by the eruption for synchronizing timescales of ice cores, sediment records and speleothems. The eruption of Thera also leaves a chronological marker in archaeological archives, tying together the Aegean and Near Eastern chronologies.

To date, the precise timing of the event is being debated. Archaeological evidence and physical evidence in the form of radiocarbon dates show large discrepancies. Archaeological data place the eruption in the mid-16th century BC the earliest while radiocarbon dates point toward the late 17th century BC.

The accuracy of the radiocarbon calibration data has recently been explored by other researchers as a possible reason for the discrepancies. High-resolution tree-ring data indicate a possible offset to the calibration data included in IntCal13.

We present an additional dataset of annual radiocarbon results from a German oak tree covering the period 1625 to 1510 BC. A subsection of the dataset was analyzed in multiple laboratories to examine laboratory offsets and for quality assurance purposes. We will explore offsets to the calibration data and compare the new dataset to other recently published tree-ring data as well as its impact to radiocarbon calibration around the eruption of Thera.

P-3614

Chronological synchronization using annual ^{14}C data - possibilities from the mid-second millennium BC

Charlotte Pearson¹, Lukas Wacker², Matthew Salzer¹, David Brown³, Alex Bayliss⁴

¹University of Arizona, Tucson, USA, ²ETH Zurich, Zurich, Switzerland, ³Queens University Belfast, Belfast, United Kingdom, ⁴Historic England, London, United Kingdom

Abstract

Long sequences of annual ^{14}C data created from measurements of securely dated annual tree-rings offer a number of prospects to improve and synchronize multiple lines of dating evidence. This can be especially important during periods where chronological discrepancies exist and where there is debate over the possible impact of natural events on human societies. Here we present 420 years of continuous annual ^{14}C data from the early to mid-second millennium BC. We explore the reproducibility of certain features within this annually based sequence using a number of different tree-ring species including oak from Ireland (Timahoe, Co. Kildare, latitude 53.3450) and bristlecone pine from the USA (White Mountains, California, latitude 37.5327). Data produced by two radiocarbon laboratories are presented to explore inter-laboratory differences on analyses of the same tree. We discuss prospects for improved calibration and chronological synchronization on the basis of these new results.

Temporal evolution of Norwegian Sea radiocarbon content during the last deglaciation, towards a regional ^{14}C calibration curve

Jo Brendryen^{1,2,3}, Haflidi Haflidason^{1,2}, Yusuke Yokoyama⁴, Kristian Agasøster Haaga^{1,2,3}, Bjarte Hannisdal^{1,2,3}

¹Department of Earth Science, University of Bergen, Bergen, Norway, ²Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway, ³K.G. Jebsen Centre for Deep Sea Research, University of Bergen, Bergen, Norway, ⁴Atmosphere and Ocean Research Institute, University of Tokyo, Tokyo, Japan

Abstract

The marine radiocarbon reservoir age effect in the Norwegian Sea is known to have been highly variable during the last glacial period, and at times considerable larger than the modern value of approximately 400 years. Nevertheless, marine ^{14}C chronologies have typically assumed a marine radiocarbon reservoir age similar to the modern value, typically around 400 to 440 yr. Although the uncertainty of this assumption is commonly acknowledged, a lack of constraints on the temporal evolution of the reservoir age in the Norwegian Sea during the deglaciation has prevented a more accurate calibration of marine conventional ^{14}C ages.

We present a new reconstruction of the deglacial (12.5-19 ka) (near) surface ^{14}C reservoir ages in Norwegian Sea. We have compiled ~100 new and previously published ^{14}C dates from four sediment cores and placed them in a new chronological framework based on correlation to proxy records sensitive to North Atlantic climate from Greenland ice cores and a radiometrically dated speleothem record from Hulu Cave, China. The alignment was corroborated by a tephra marker bed found both in the Norwegian Sea sediments and Greenland ice cores. The new chronology enables us to directly compare our Norwegian Sea ^{14}C time-series to the atmospheric ^{14}C content represented by the Intcal13 calibration curve and to reconstruct the reservoir ages. Our results show that the deglacial reservoir ages deviated substantially from modern values, and had considerable variability, which needs to be taken into account when working with marine ^{14}C chronologies. We discuss implications of the new reservoir age reconstruction on chronologies of marine ice sheet and paleoclimate reconstructions.

P-3616

The Glacier Peak ash in Scotland

Sean Pyne-O'Donnell¹, Britta Jensen²

¹Queen's University Belfast, Belfast, United Kingdom, ²University of Alberta, Edmonton, Canada

Abstract

The Lateglacial period (~14.7 – 11.7 cal. ka BP) eruptive stage of Glacier Peak in the northern Cascade Range deposited a number of ash layers (tephras) in quick succession, forming visible event-stratigraphic marker layers (isochrons) across much of western North America. Geochemically distinctive microscopic glass shards from the most explosive eruptions of this stage remain detectable in a 'cryptotephra' layer (not visible in stratigraphy to the naked eye) of rhyolitic composition in lake sediments on the NE Atlantic Seaboard, where it is dated to 13.74 – 13.45 cal. ka BP (2σ).

Here, we report the first trans-Atlantic detection of Glacier Peak cryptotephra (set G) in a Lateglacial lake site in western Scotland, ~7000 km from source. At this location (Loch Ashik, Isle of Skye), Glacier Peak shares a crowded tephrostratigraphy with two well-documented cryptotephra layers of likely Icelandic origin: the Borrobol Tephra (14.19–14.00 cal. ka BP; 2σ) and the geochemically equivalent Penifiler Tephra (14.06–13.81 cal. ka BP; 2σ) which occur singly or together in a number of terrestrial Lateglacial sequences in Scotland and Scandinavia.

Previous tephra work at this site, as well as other localities, has not identified shards of Glacier Peak composition. This may be due to masking of such ultra-distal layers by the relatively greater concentrations of the closely preceding, and thus stratigraphically overshadowing, Penifiler and Borrobol tephtras which often exhibit reworked post-peak shard distributions. However, the use of higher resolution 0.5 cm contiguous stratigraphic sampling and off-peak geochemical analysis in this study resolves previously unseen shard concentration variations within these distribution tails which are consistent with additional tephra layers and which are shown to contain a relatively greater proportion of Glacier Peak composition.

It is likely that other sedimentary sequences with faster accumulation rates will allow better stratigraphic distinction of the Glacier Peak layer from the Penifiler tephra. Additionally, Glacier Peak may be present elsewhere in the European tephrostratigraphy in sequences where the Borrobol and Penifiler tephtras were not deposited, and consequently where it will be less obscured.

The introduction of the well-dated Glacier Peak isochron into the regional tephrostratigraphy of Scotland should aid in constraining local age models. It will also permit direct trans-Atlantic correlation of sedimentary sequences for the mid-Lateglacial period, which was characterised by abrupt and short-lived climate oscillations. Accurate assessment of the relative timings of such palaeoclimate events is key to determining causal forcing mechanisms throughout the North Atlantic region.

P-3617

Millennial-scale tephra reworking: distinguishing "pseudo" tephra isochron from genuine one

Kyoko Kataoka¹, Atsushi Urabe¹, Yoshitaka Nagahashi²

¹Niigata University, Niigata, Japan, ²Fukushima University, Fukushima, Japan

Abstract

Primary tephra deposits have been believed as isochronous marker beds in a stratigraphic sequence. Such tephra deposits and even invisible crypto-tephra have been widely applied for geology, geomorphology, archaeology and palaeo-environmental studies. The concept of tephra isochron is based on a hypothesis that all tephra are derived from primary (often of airborne nature) depositional origin. However, wind, water, and gravity processes can rework tephra in both time and space. Resedimentation of tephra can form a new discrete layer later in the depositional sequence, or it can be distributed as crypto-tephra over a range of different stratigraphic horizons. Without considering detailed transport and depositional processes involved in individual tephra layers/grains, any state-of-the-art petrological and geochemical analyses cannot evaluate a true tephra isochron.

The present study aims at understanding the duration and persistence of reworking and resedimentation of tephra based on sedimentological, petrographical, and geochemical analyses of tephra from the Holocene fluvial and deltaic sequences in northeast Japan. The examples presented here are 1) visible discrete tephra beds occurring in different stratigraphic horizons; however, the material itself is sourced by a single eruption, and 2) crypto-tephra composed of glass shards from multiple volcanic and sedimentary sources with different ages.

In the Niigata Plain, four sediment cores (KN-1, SN-1, MZ-1 and TA-1 cores) located progressively seawards of the coastline yield discrete and visible (or some cryptic) pumice concentrated layers derived from the 5.4 cal ka Numazawako tephra from Numazawa volcano at almost the similar depth (15-20 m below the ground level) of the delta front facies. The ¹⁴C ages of the pumice concentrated layers show that each pumice layer formed at KN1520 = 5.7-3.0 cal ka; SN1636 = 4.8-1.7 ka; MZ1832 = post 3.0 ka; and TA1930 = 1.2-0.3 ka. This indicates that the Numazawako tephra continued to be reworked for > 4000 years after the eruption with delta progradation. In addition, geochemical data indicates that tephra materials originating from an earlier eruption of Numazawa volcano and from other calderas were incorporated into the deposits.

In the Tsugaru Plain, the post-2.5 ka subsurface deposits have 10 to 80 % glass shards content (in 1/8 mm-1/16 mm size) throughout the sequence. Geochemistry of glass shards points to different sources such as those from 1) the most recent AD 915 eruption of Towada volcano, 2) earlier caldera forming eruptions (30 ka, 15 ka), and 3) erosion of the Pliocene pyroclastic bedrock. These results clearly signify the fact that tephra reworking processes can continue long after an eruption has ended, and can persist even during the background sedimentation period. Furthermore, regarding the glass shards chemistry, if the numbers analyzed grains are too small, it can result in a misleading interpretation of tephra from a single eruption.

Developing a tephrochronological framework and assessing tephra delivery within the Atlantic sector of the Southern Ocean between 10-40 kyr BP

Peter Abbott^{1,2}, Samuel Jaccard², Steve Barker¹, Julia Gottschalk³, Luke Skinner⁴, Claire Waelbroeck⁵

¹Cardiff University, Cardiff, United Kingdom, ²University of Bern, Bern, Switzerland, ³Columbia University, Palisades, USA, ⁴University of Cambridge, Cambridge, United Kingdom, ⁵Université de Paris-Saclay, Gif-sur-Yvette, France

Abstract

Tephrochronology is a powerful technique for the correlation of disparate palaeoclimatic sequences from a range of depositional environments and is underpinned by frameworks of isochronous ash deposits. A regional tephra framework for the Atlantic sector of the Southern Ocean and Antarctica, both downwind from several volcanic systems, could facilitate the correlation of important marine and ice-core palaeoclimatic archives. Such correlations could be used to explore the phasing of climatic changes between the ocean and atmosphere, improve existing chronological models and assess the magnitude of the marine reservoir effect. In addition, the Southern Ocean is thought to be a key area for the outgassing of CO₂ via deep-water ventilation during the last deglaciation. Establishing tighter constraints on the phasing between sedimentary evidence for deep-water ventilation, and ice-core evidence for past atmospheric CO₂ variations could help in testing models of past relationships between climate and CO₂. While there is an emerging tephra framework for the Antarctic ice-cores, limited investigations have been conducted on Southern Ocean marine records, particularly studies focused on the identification of cryptotephra, ash horizons not visible upon core inspection.

Here we report on high-resolution tephrochronological investigations of two marine cores from the Atlantic sector of the Southern Ocean (MD07-3076 and TN057-21). These cores have been investigated using recently developed methods for the identification of marine cryptotephra, which have focussed on finer grained material than prior investigations. Within the MD07-3076CQ record a peak in colourless glass shards only present in the 25-63 µm grain-size fraction and with a profile indicative of isochronous deposition has been identified. This deposit has an age of ~25.3 ka BP and ongoing geochemical analysis will determine the source of the eruption and permit a comparison with tephra horizons in the Antarctic tephra framework. Within both records several zones of elevated green/brown (dacitic/basaltic) glass shard concentrations, most clearly resolved in the 25-63 µm fraction, and with profiles indicative of non-isochronous or secondary deposition can be observed. The shard concentration, peak form and duration of these zones differs between the cores, however, there is a general similarity in their timing with events centred around ~17.5, ~24, ~31 and ~36 ka BP. These periods of tephra deposition are consistent with past studies of the coarse fraction of cores from the region, which attributed their occurrence to either Antarctic ice sheet instability or fluctuations in sea-ice transportation of ash. Ongoing geochemical work to identify the source of the deposits and comparisons to palaeoceanographic proxies will contribute to the debate regarding the mode of tephra delivery to these sites.

Quantitative geochemical fingerprinting: machine learning to trace tephra to source

Matthew Bolton¹, Britta Jensen¹, Kristi Wallace², Nore Praet³, David Fortin⁴, Darrell Kaufman⁵, Marc De Batist³

¹University of Alberta, Edmonton, Canada, ²Alaska Volcano Observatory, Anchorage, USA, ³Ghent University, Ghent, Belgium, ⁴University of Saskatchewan, Saskatoon, Canada, ⁵Northern Arizona University, Flagstaff, USA

Abstract

Cross-correlating unknown tephras to reference samples of known origin requires exhaustive data archives of glass geochemical data, and, typically, extensive manual searching and digital plotting of glass data. Expert interpretation, combined with prior knowledge and numerous plotting permutations is a well-established method to discriminate and identify tephras. However, quantitative methods of discrimination have the potential to expedite the parsing of likely reference sources and to remove a level of subjectivity from geochemical analysis.

Here we explore how machine learning algorithms can be employed to source unknown tephra layers to volcanoes from Alaska's Aleutian Arc-Alaska Peninsula and Wrangell volcanic field. A series of supervised classification algorithms including neural networks, support vector machines, decision trees, and random forests among others, have been trialed to predict the origin of tephras from 10 sources. The models were trained on nearly 2,000 electron microprobe analysis (EMPA) glass measurements from the University of Alberta Earth and Atmospheric Science's Tephra Collection and Geochemical Database and the Alaska Volcano Observatory. Performance was evaluated internally (via cross-validation on training data) and externally (using held-out data from the source dataset and literature).

All classifiers tested performed well. Random forests and artificial neural networks and their combination as an average ensemble were consistently among the best performing algorithms, with accuracy >96% and kappa scores >0.96 on unseen data on a point-by-point basis. They were 100% accurate when individual analyses were averaged per sample. As a test case, geochemical data representing 15 tephras from sediment cores of Eklutna Lake, south-central Alaska, USA, were tested using the best performing algorithms. The source predictions of the models were directly comparable to those gleaned from traditional plot-based correlations, but were produced in a fraction of the time, and returned quantitative pseudo-probabilities of source volcano correlations to each tephra.

Combined with stratigraphic and chronologic data, as in the case of Eklutna Lake, machine learning methods are a boon to tephrochronologists. We are now able to rapidly parse vast geochemical datasets in a systematic and quantifiable fashion, even when mixed populations are present. Unknown tephras that would historically be time-consuming to correlate can now be quickly focused to source, permitting further identification, ideally to eruption. However, just as is the case with traditional plotting methods, to make these new tools most useful, complete high-quality databases of reference glass geochemistry are required. Any model is only as good as the data upon which it is trained. Fortunately, glass geochemical data archives and their critical metadata are growing worldwide. As new data is produced and made available, analytical tools that leverage this information must be co-developed. This work is but one such adaptation to the "big data" of modern tephrochronology.

Cryptotephra investigation in the Carpathian Mountains

Rebecca Kearney¹, Paul Albert¹, Richard Staff², Ilona Pal³, Daniel Veres⁴, Enikő Magyari^{5,6}

¹Research Laboratory for Archaeology and the History of Art, University of Oxford, Oxford, United Kingdom, ²Scottish Universities Environmental Research Centre, University of Glasgow, Glasgow, United Kingdom, ³Isotope Climatology and Environmental Research Centre (ICER), Institute for Nuclear Research, Hungarian Academy of Science, Budapest, Hungary, ⁴Institute of Speleology, Romanian Academy, Cluj-Napoca, Romania, ⁵Eötvös Lóránd University, MTA-MTM-ELTE Research Group for Paleontology, Department of Environmental and Landscape Geography, Budapest, Hungary, ⁶Isotope Climatology and Environmental Research Centre (ICER), Institute for Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary

Abstract

Understanding of the timing and mechanisms of past abrupt climate change can be increased with the integration of palaeoclimatic records. However, chronological uncertainty associated with dating errors on individual past records prevents the full investigation of synchronies and asynchronies within the climate system. The application of cryptotephra (non-visible volcanic ash) allows palaeoenvironmental records to be precisely correlated across potentially thousands of kilometres in addition to building and improving local chronological models.

Here, we present the first, distal cryptotephra record from two sites in the Southern Carpathian Mountains (Romania). Our crypto-tephrostratigraphic investigations concentrate on the Late-glacial portions of the Lake Lia and Lake Brazi sedimentary sequences. We have identified several discrete tephra layers within these two records. Major and minor element volcanic glass chemistry (Electron microprobe analysis and LA-ICP-MS) reveals that the cryptotephra layers derive from various volcanic sources (e.g. Aeolian Islands, wider Mediterranean, Central Anatolia, Icelandic).

One significant finding of this investigation is the ultra-distal occurrence of the Askja-S tephra in both records, dramatically extending the known south-eastern dispersal of this ash from the Plinian eruption date refining the age of the eruption to 10,824±97 cal yrs BP (Kearney et al., 2018). Crucially, the Askja-S now offers a precise chronological tie-point facilitating the alignment of climate archives from NW Europe through into Eastern Europe immediately after the Preboreal climatic oscillation. Additional new cryptotephra include a largely unknown Late-glacial period eruption from Lipari in the Aeolian Islands, an eruption recorded from Ischia in the Tyrrhenian Sea and numerous previously unknown eruptions originating from central Anatolia. These cryptotephra investigations clearly illustrate that the central Carpathian Mountains offer an ideal location to integrate the tephrostratigraphic frameworks of disparate volcanic regions, and in doing so, provide a more robust chronological framework for palaeoclimate records in the region and further afield.

Tephra layer refining Middle Pleistocene chronology of Serbian loess

Yu Fu¹, Qingzhen Hao¹, Chunqing Sun¹, Slobodan Marković², Long Han¹, Xinbo Gao¹, Nemanja Tomić², Zhengtang Guo¹

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ²Physical Geography, Faculty of Sciences, University of Novi Sad, Novi Sad, Serbia

Abstract

An accurate chronology is one of the critical premises of reconstructing past climate variability from Quaternary loess archive. However, beyond the upper limit of OSL (~100 kyr) and radiocarbon dating (~40 kyr), chronology of middle Pleistocene loess mainly relies on orbital tuning, with the most recent independent age control of the Brunhes-Matuyama boundary, which hardly meets the requirements of further paleoclimatic investigations in higher resolution and precision. Fortunately, in Serbian part of Danube loess, which is considered to be the most complete loess-paleosol sequences over the past million years over Europe, several primary tephra layers interbedded may provide valuable age anchors for better constraining loess chronology in middle Pleistocene interval.

We here focused on a tephra layer interbedded in the loess unit V-L4, estimated corresponding to MIS 10. The tephra was 1-2 cm thick in yellowish brown color, mainly consists of coarse-silt-sized grains. Glass shards were orange to brown in color, with thick-walled, cusped and pumiceous shards morphology. The mineral assemblage was made up of clinopyroxene, plagioclase, sanidine, biotite and apatite. To determine its origin and age, we conducted *in situ* major elements electron microprobe analyses (EMPA) of glass shards, clinopyroxene and feldspar grains, and ⁸⁷Sr/⁸⁶Sr, ¹⁴³Nd/¹⁴⁴Nd analyses of glass shards by a thermal ionization mass spectrometry (TIMS), and compared the results with potentially linked eruption materials.

Except for the glass shards showed low oxide totals (76-87%) and depletion of alkalis, which was incapable of any correlation, the composition of clinopyroxene and feldspar, and isotope ratio of glass shards showed consistency with Villa Senni eruption, dated to 351-357ka, from Alban Hills, Italy.

The clinopyroxene composition of this tephra layer also coincides with that of the Bag Tephra, a widespread tephra interbedded in Quaternary loess along the Danubian valley of Hungary and Slovakia, suggesting they might be isochronous deposits. The Bag Tephra was speculated to be product of Villa Senni eruption, which however lacks geochemical evidence. Our study proved this linkage, and might contribute to unifying loess strati-chronology frame over the Danube region.

The age of tephra layer in V-L4 provides a solid anchor for the chronology of Serbian loess. According to the estimated sedimentation rates, the bottom age of Serbian loess V-L4 was restricted to ~355-364ka, which coincides with the long-lasting warm climate of MIS 11 in east Asia, revealed by Chinese loess records. Our study further confirmed the pedostratigraphic and climatostratigraphic coherence between Serbian and Chinese loess, shedding new lights in future land-sea correlation and environment dynamics study.

Correlating cryptotephra layers: data visualisation or a statistical challenge?

Ian Matthews

Royal Holloway, University of London, Egham, Surrey, United Kingdom

Abstract

The successful application of tephrostratigraphic research relies on the robust characterisation and correlation of ash layers. This is most typically conducted by utilising stratigraphic, sedimentological, textural, and chemical data. However, in distal and ultra-distal regions, which are frequently the focus of cryptotephra investigations, these data are restricted and therefore characterisation and correlation of tephra layers relies upon small amounts of glass chemical data. Further complexity in interpreting ash layers in distal regions is derived from: repeating chemical signatures; taphonomic considerations; chemical degradation of tephra; bi-modal and non-normal chemical populations; and the discovery of far travelled tephra layers derived from volcanic centres 1000 kilometres from the study region. These additional factors, alongside the small amount of chemical data available, means that miscorrelation of ash layers is possible and in order to minimise the impact of this, secure correlations should be based on rigorous and objective criteria.

At present the major-element classification of tephra layers is carried out via variations of the Total Alkalis - Silica plot and this provides uniform information about the properties of the ash layer. This visual matching approach to set criteria is a robust way of classifying the layers identified but the approach is frequently extended to support correlations between layers. Visual correlations via bi-plots are embedded in cryptotephra research but are prone to subjective assessments with operator preferred element oxides plotted against raw reference data or more usually manually defined chemical 'fields'.

More robust approaches to correlation using statistical measures of distance are available but due to the small amounts of data and the complexities explained above these have not been uniformly adopted by cryptotephra researchers. This may, in part, reflect the often violated or untested assumption of Gaussian data distribution for each class that these suite of techniques require i.e. the low numbers of analyses available from potentially non-normal data sets mean that distance measures between populations that uses centroids are unlikely to provide robust correlations.

This research suggests alternative approaches to both the visualisation and correlation of tephra glass chemical data from cryptotephra layers identified in NW Europe. This poster explores the uses of techniques that either relax the requirements of Gaussian data distribution or provide non-parametric alternatives, these are: (1) kernel density estimates; (2) flexible discriminant analysis¹; and discriminant analysis using Gaussian mixtures². The effectiveness of each approach is considered alongside more traditional linear discriminant techniques.

Towards a tephrochronological framework for Finland

Maarit Kalliokoski^{1,2}, Esther Ruth Guðmundsdóttir², Stefan Wastegård³

¹Department of Geography and Geology, University of Turku, Turku, Finland, ²Nordic Volcanological Center, Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland, ³Department of Physical Geography, Stockholm University, Stockholm, Sweden

Abstract

Tephrochronological frameworks are an excellent tool for dating and correlating sedimentary archives, archaeological sites and landforms both in proximal as well as distal areas. This is reflected in the rapid increase in routine tephrochronological studies across Northern Europe during past decades. However, very little tephrochronological work has been carried out so far in Finland. The main aim of our research is therefore to assess the possibilities of using tephrochronology as a dating method in Finnish climate and environmental research and to construct a robust tephrochronological framework for Finland.

We searched for cryptotephra in materials forming the palaeoenvironmental archives most commonly used in Finnish environmental studies: both peat sequences as well as homogeneous and varved lacustrine sediments. Our research sites cover southern and central Finland from the Åland Islands in the west to the Russian border in the east. Additionally, two subarctic lakes in northern Finland were included in the study. Tephra shards were extracted using acid digestion and heavy liquid separation, which resulted in detection of cryptotephra in 17 of our 34 sites. Due to low shard concentrations, the shards were enriched by using a micromanipulator when preparing mounts for electron probe microanalysis (EPMA), performed at either the University of Edinburgh or the University of Iceland. Despite applying rigorous laboratory methods to concentrate the shards, and using a narrow 3 – 5 µm beam during analysis, robust geochemical results could not be obtained from all the layers, due to small size and high vesicularity of the shards. Out of the 37 detected tephra deposits 18 have been geochemically fingerprinted this far.

A majority of the identified tephra originate from historical Hekla eruptions (e.g. Hekla 1845 and Hekla 1510). This is different from what has been recorded in Swedish sequences. Tephra from the large mid-Holocene Hekla eruptions forms the backbone of the Swedish tephrochronology and historical products of Hekla are largely absent in Sweden (Wastegård, 2005). The seemingly scarce occurrence of mid-Holocene Hekla tephra in Finland could partly be explained by low shard concentrations impeding geochemical fingerprinting or possible poor preservation of thin and vesicular shards in acid peat bogs. Presence of Hekla 1845 and 1510 tephra in Finland, as well as the fall-out of Hekla 1947 tephra in southern Finland (Salmi, 1948), reveals a similarity between the tephra historical records in Britain, Ireland and Finland, indicating a similar meandering tephra transport pathway during each of these eruptions. As our research is on-going, we expect the tephrochronological framework for Finland to significantly improve in the near future.

Towards a comprehensive tephrostratigraphic framework for Quaternary rhyolitic volcanism in New Zealand: employing cryptotephra methods to find the hidden eruptions.

Jenni L Hopkins¹, Diane Seward¹, Richard Wysoczanski², Steffen Kutterolf³, Siwan Davies⁴, Nina Kukowski⁵

¹Victoria University of Wellington, Wellington, New Zealand, ²National Institute of Water and Atmospheric Science, Wellington, New Zealand, ³GEOMAR, Helmholtz Centre for Ocean Research, Kiel, Germany, ⁴Swansea University, Swansea, United Kingdom, ⁵Friedrich Schiller University, Jena, Germany

Abstract

The Taupo Volcanic Zone (TVZ), located in the central North Island, New Zealand, is currently one of the most active volcanic systems on Earth. Thought to have initiated ca. 1.6 Ma, it has produced numerous supervolcanic eruptions including Earth's youngest, the Kawakawa/Oruanui at 25.4 ka. However, our understanding of the eruptions from this system are skewed towards the last 61,000 years due to the preservation bias of proximal, younger, larger deposits. This means that a high percentage of the TVZ eruptive history is unknown; thus, existing magnitude-frequency models may underestimate the recurrence of the TVZ eruptions. Macro- and crypto-tephra deposits situated downwind of the TVZ (onshore and offshore eastern New Zealand, ~50 – 200 km from source) offer the potential of augmenting the existing record of volcanism. However, the disjointed nature of tephra horizons in the terrestrial record, coupled with large uncertainties in dating methods (e.g. Hopkins and Seward 2019), mean that producing a comprehensive record from onshore deposits is challenging. In addition, existing offshore marine cores are either proximal (≤ 250 km) and short (<6 m, ≤ 30 ka), or long but distal and therefore only preserve the largest events. To resolve these limitations, we present preliminary results from a new, combined onshore- and offshore-study.

Macroscopic tephra deposits from within 6 new proximal (ca. 200 km offshore) and long (ca. 2 Ma) cores were analysed and cross correlated using major and trace elements and mineral assemblages. These macroscopic deposits, coupled with well-defined onshore marker horizons, provide a robust chronological framework within which the cryptotephra deposits will be identified. The time consuming and laborious method of subsampling throughout a core for cryptotephra is not viable in this study where the cores are numerous and long (totalling >300 m). We therefore propose identification methods using novel core scanning techniques (photographic and X-ray density imagery, magnetic susceptibility and density measurements, and elemental profiles by X-ray Fluorescence). We aim to identify the components of the scan data that highlight the macroscopic tephra horizons, then use these and semiquantitative petrography to locate potential cryptotephra horizons. These will then be analysed for major, and where possible trace element compositions, to allow correlations to be made. This will produce a comprehensive overview of the eruptions from the TVZ, and result in a database of geochemically referenceable, stratigraphically constrained tephra marker horizons for Quaternary eruptions in New Zealand.

Abstract

Two tephra horizons are used as marker horizons in the Hungarian loess stratigraphy to support the correlation between different loess-paleosol sequences. The older is described at twelve locations in the Carpathian Basin and termed 'Bag Tephra' after one of its type locality. This volcanic ash layer is supposed to be related to the eruption of the Monte Vulture (Central Italy) about 351 ka ago. After detailed investigations of the Bag tephra at many localities the same origin and/or age of Bag Tephra became questionable due to its different physical properties and unclear stratigraphical position (Sági et al., 2008).

Four loess successions, Basaharc, Hévízgyörk, Isaszeg and Pásztó, were dated and petrographically investigated, to get more information about the age and chemical composition of these tephra horizons. Luminescence dating (post-IR IRSL-290 method) and Amino Acid Racemization technique were applied to make age constrains for the deposition and formation of loess layers. Scanning Electron Microscope investigations were elaborated to gain petrographic information about the tephra horizons.

Luminescence and AAR results are in agreement at Basaharc, but some discrepancy was found at Hévízgyörk. Based on pIRIR-290 minimum ages and luminescence properties of the investigated samples the Bag tephra horizon could be divided into two groups (Basaharc, Isaszeg – Pásztó, Hévízgyörk). The two types of the 'Bag tephra' were confirmed by petrographic properties of the investigated tephtras. The same magmatic province (Central Italy) is assumed for both groups, however the same eruption center is not sure. Petrographical differences imply that either the eruption centers and/or the eruption times were different which produced the two types of tephra horizons.

Thanks to the Leibniz Institute for Applied Geophysics, Hannover and to the Hungarian NRDIO projects K119366 and 100315. This research was also funded by the Bolyai János Research Scholarship and the ÚNKP-18-4 New National Excellence Program of the Ministry of Human Capacities.

Potential of tephrostratigraphy to constrain the sequence of glacial-retreat and sea-level change during the Last Glacial Termination in north-western Scotland

Dorothy Weston¹, Ian Matthews¹, Alison MacLeod², Adrian Palmer¹, John Lowe¹

¹Royal Holloway, University of London, London, United Kingdom, ²University of Reading, Reading, United Kingdom

Abstract

The precise pattern and timing of ice retreat and sea-level change in north-western Scotland since the LGM is not yet fully understood, with some interpretations proving controversial. This is, at least in part, due to the lack of chronological precision available in studies during this period. It is important to resolve these issues, as the behaviour of the ice sheet in Scotland during this period reflects a response to several environmental variables.

This study aims to investigate key sites that have the potential to refine the chronology of deglaciation in north-western Scotland during the period c. 17 - 11 ka BP and to clarify the temporal and spatial complexities of this period. The focus is on the extent to which tephra layers can provide a more robust chronological framework for the established patterns of deglaciation and associated isostatic adjustment e.g. Ballantyne (2010), Ballantyne & Stone (2012), Ballantyne & Small (2018), Bradwell et al. (2008) and Shennan et al. (2000).

The field area extends between 58 - 56° N, from the Summer Isles to Ardnamurchan, an area in which isolation basins offer particular advantage, due to their near-field location with respect to retreat stages of the Dimlington and subsequent re-advance of the Loch Lomond ice sheets. This poster will present stratigraphic and tephrochronological data from a series of new and previously investigated palaeolake basins in the study region.

Abstract

In Central Europe, the Late Glacial period (~14700-11650 cal. BP) was characterized by dynamic environmental changes. 12,900 years ago, the cataclysmic Laacher See volcanic event (VEI = 6; 6.3 km³ of magma) occurred in western Germany 40 km south of Bonn. The eruption devastated the surrounding late Allerød landscape and caused substantial lahar-like flood waves in the Lower Rhine and English Channel area. The interaction of magma with groundwater resulted in a highly explosive phreatomagmatic discharge, exceptionally long-distance transport of volcanic shards, and a climate deterioration. The Laacher See Tephra (LST) is found over much of western Central Europe and forms the most important stratigraphic marker in Late-glacial deposits. We assume that, contrary to many published works, the LST ash cloud traveled also directly east from the volcano. Therefore, we have studied lake sediment cores from three sites located in the Bohemian Forest Mts., Czech Republic-Germany-Austria border area (distance of 450 – 470 km from the volcanic crater). The characteristic LST particles were documented in all the cores using X-Ray Fluorescence scanning, magnetic susceptibility measurements, and direct observation by scanning electron microscopy. Subsequently, we used the TESCAN Integrated Mineral Analyzer (TIMA) for automated volcanic shard counting and precise identification of the cryptotephra depth range. Our geochemical results show the closest match with MLST-B phreatomagmatic phase of the eruption. Moreover, a significant amount of LST related phosphorus, often the limiting nutrient in both terrestrial and freshwater ecosystems, was found in the sediments. In this regard, we also assessed the potential effect of the tephra deposition on the vegetation cover and lake communities using pollen, charcoal, diatom, cladoceran, and chironomid analyses. Our first results suggest no significant impact on composition of terrestrial vegetation contrasting with a distinct change in diatom, cladoceran, and chironomid assemblages. The discovery of the LST in the Bohemian Forest opens the potential of tephrochronologically supported research of Late-glacial sites in eastern Central Europe. The study is supported by the Czech Grant Foundation (17-05935S – LAYERS).

¹Massey University, Palmerston North, New Zealand, ²Aarhus University, Aarhus, Denmark, ³Moesgaard Museum, Aarhus, Denmark, ⁴Ludwig Maximilian University, Munich, Germany

Abstract

The Plinian eruption of Laacher See Volcano deposited a widespread phonolitic tephra bed across much of Europe. Its wide dispersal and distinct geochemical signature make the Laacher See Tephra (LST) an important isochrone for the Allerød interstadial/GI-1, especially for connecting the tephrochronological records of Central Europe with the North Atlantic and the Mediterranean.

While distal LST generally occurs in chronologically consistent stratigraphic contexts, it does exhibit variations in sedimentological characteristics between locations, such as thickness, contacts, scatter, and bedding, and in the compositional range of glass shards. Some sites even record multiple ash layers, at times interpreted as the result of post-depositional processes but at others as indicating potential precursor eruptions, thus re-igniting previous debates of multiple eruptions from this volcano.

Given the importance of the LST as chronostratigraphic marker, resolving these competing interpretations is crucial. Yet, with outcrop profiles displaying distal tephra beds being extremely rare, most tephrochronological studies rely on bore cores, usually few in number from a given site, making comprehensive assessments of post-depositional dynamics difficult. In an effort to assess core sampling representativity, we carried out a comprehensive field study at the Paddenluch outcrop near Berlin, where distal LST is visible in the cross-sectional exposure of an infilled glacial melt-water channel. We used a combination of high-resolution sedimentological, tephrochronological, geochemical and palynological methods to test strategies for effective sampling of distal LST, characterise the main marker horizon, identify potential secondary LST beds, and classify post-depositional processes.

A core taken from the relatively undisturbed edge of the channel was subjected to the same macro- and micro-scale analysis as targeted open-profile sediment columns from the channel centre, including a part of the section where slumping has evidently deformed the sequence resulting in a wavy appearance and repetition of the ash layer. Micro XRF scans clearly displayed the microstructure of the deformed sediments while core scans highlighted the duplicated LST beds. Fine-scale pollen and cryptotephra analysis, complemented by radiocarbon dating, proved further useful tools to reveal the repetitive nature of the slumped sequence within small-scale sediment-column samples. It also helped identify two significant erosion events in the Younger Dryas that are represented as intervals rich in reworked LST. However, no secondary LST beds were found below the marker horizon.

Our study suggests that, when relying on bore core data for tephrochronological studies, it is crucial to collect multiple cores from each location and to apply a combination of micro-analytical methods in order to carefully assess potential variations with respect to primary and post-depositional processes. Our results also imply that suggestions of precursor eruptions from Laacher See Volcano based on distal tephra occurrence should be treated with utmost caution.

Abstract

Evaluation of the magnitude, dispersal and tempo of explosive eruptions relies on building robust event stratigraphies by correlating proximal and distal tephra sequences. In the distal environment, the physical characteristics of these sequences are not distinctive enough to allow for robust correlations. Since the 1980s, major element glass chemistry has been employed to make correlations allowing distal and proximal records to be integrated. However, some volcanic centres produce eruption deposits with similar major element glass chemistries over thousands of years and thus it is difficult to correlate distal occurrences to their proximal equivalents. This has been largely circumvented by acquiring trace element compositions of the glass shards but sometimes the problem of not having a unique glass chemical fingerprint still exists. Some crystal phases (e.g., Fe-Ti oxides and biotite) are useful for correlating tephra deposits when the glass compositions are similar, or if the glasses are too microlite-rich or altered, but these phases are not always present. Apatite is a common accessory phase in evolved eruption deposits. It can incorporate both volatiles and trace elements (e.g., rare earth elements) into its crystal structure, and has been shown to be useful in correlating K-bentonites of altered, Ordovician tephra deposits in North America (e.g., Carey et al., 2009), and some other studies have suggested that apatite compositions can be used to correlate tephra (e.g., Sell & Samson, 2011; Takashima et al., 2017). However, detailed studies that show whether apatite compositions can be used to distinguish successive eruption deposits from the same volcano are lacking. To address this problem, we have extracted apatite microphenocrysts from eruption sequences comprising multiple eruption events (including large caldera-forming and smaller explosive events) from various volcanoes around the world and analysed the major, volatile and trace element compositions of the apatites to determine which elements are the most reliable for correlating the eruption deposits. These data show that the compositions of apatite in successive eruption deposits are often indistinguishable and sometimes similar to those from different volcanoes. These results indicate that apatite compositions cannot be used to correlate tephra deposits.

Paleomagnetic secular variation and relative paleointensity during the Holocene in South China – Huguangyan Maar Lake revisited

Zhenyu Yang

Capital Normal University, Beijing, China

Abstract

The scarcity of reliable paleomagnetic secular variation (PSV) records from East Asia especially from low-latitude regions impedes better understanding of global PSV mechanisms. Here we report on a high-resolution PSV record during the Holocene from a composite 10.6 m long core with high-sedimentation rates from Huguangyan Maar Lake (HML) in subtropical-tropical South China (21°9'N, 110°17'E). Detailed rock magnetic results demonstrate that the natural remanent magnetization resides in single-domain and pseudo single domain magnetite. Alternating field demagnetization of natural remanent magnetization of u-channel samples yields six distinct inclination highs at ~7500 BC, ~5100 BC, ~4600 BC, ~3600-3400 BC, ~1600-1200 BC and 600-800 AD, three inclination lows at ~4800 BC, ~600-300 BC and ~1000-1300 AD and three eastward declination trends at ~3600-3200 BC, ~2600-2400 BC and 400 BC-200 AD. The similarity between the HML PSV record and other independently-dated records from East Asia and geomagnetic field models corroborates the robustness of our age model and Holocene PSV record. Strikingly, centennial- to millennial-scale PSV features of the HML are correlatable, within age uncertainties, with other Holocene records from Europe, North America and Canada, suggesting that such directional patterns are likely to be hemispheric in scale. Although relative paleointensity data of HML are affected by environmental factors (e.g., diagenetic alteration), the record still provides a regionally-important new PSV reference curve whose conspicuous features may serve as stratigraphic markers for East Asian paleo-records.

SR-XRF analyses of varved sediments in Altay and Caucasus as a source of high-resolution paleoclimatic information

Andrey Darin¹, Mikhail Alexandrin², Olga Solomina²

¹V.S. Sobolev Institute of Geology and Mineralogy, SB RAS, Novosibirsk, Russian Federation, ²Institute of Geography RAS, Moscow, Russian Federation

Abstract

Varve sediments are among the most promising proxies for high-resolution paleoclimatic reconstructions. In this study, we present the results of the bottom sediment microanalysis performed with Scanning X-ray fluorescence method in the “Siberian Synchrotron and Terahertz Radiation Centre” (BINP SB RAS, Novosibirsk). The sediment of the two lakes located in the periglacial zone in the Altay (lake Kucherla, 49°52'33"N, E 86°24'52"E, 1790 m asl,) and the Caucasus (lake Donguz-Orun, 43°13'26" N; 42°29'35"E, 2500 m asl) with vaguely discernible annual layers were scanned with the step of 100 µm to obtain the profiles of more than 20 chemical elements. These results were combined with the photographs of the investigated sediment cores in order to identify the elements (or elemental ratios) that would mark the annual boundaries and delimit the layers more confidently. We found out that the best markers recording the annual changes in grain-size are Rb/Sr and Zr/Rb ratios. After establishing the precise sediment chronologies with the annual resolution, we compared them with the meteorological records. The varve thickness chronology in Kucherla and terrigenous elements chronology (annually averaged values of Fe, Ti, Zn and Mn) in Donguz-Orun are positively correlated with annual precipitation at the local meteorological stations (both with the same coefficient of correlation equal to 0.44, $p < 0.01$). We also found out that the content of bromine in Donguz-Orun sediment is positively correlated with annual temperature ($r = 0.41$, $p < 0.01$). Statistically significant negative relationship observed between the concentrations of terrigenous elements in the sediment of Lake Donguz-Orun and tree-ring width of local pine chronology ($r = -0.56$, $p < 0.01$), as well as the age control with ¹³⁷Cs and ²¹⁰Pb independently confirm the accurate dating of the sediment sequence. These findings open opportunities for high-resolution multiproxy climate reconstructions in both Caucasus and Altay – relatively poorly studied regions with low anthropogenic stress. The studies were supported: Kucherla - by the Grant 18-55-53016 ГФЕН_a, Donguz-Orun by the Grant 17-05-01170

Emerging hypotheses about the Holocene palaeoclimate in the Sahara: landscape response, biome continuity, and termination of wet and arid phases

Andrea Zerboni¹, Kathleen Nicoll²

¹Università degli Studi di Milano, Milano, Italy, ²University of Utah, Salt Lake City, USA

Abstract

In the Sahara, the Early and Middle Holocene (ca. 11–5.5 ka) are marked by northward expansion of the Afro-African monsoon across the southern and central Sahara, causing higher precipitation and a more abundant plant cover. This phase is generally defined as African Humid Period (AHP) and it is commonly considered to be a ubiquitous wet phase. A number of studies describe the effects of Holocene climate changes over the region at medium to high resolution, but today, field-based studies are very limited due to geopolitical instability. This limits our full understanding of the true extent and the dynamic of environmental changes over the Sahara and how different regions – and different landscape units within a same region – have reacted to climatic changes and climatic instability. In a patchwork of sometimes old-fashioned studies, new hypotheses are emerging, many of which are based upon land-sea correlations informed by analyses of offshore cores. Some conclusions, anyway, contrast with field-based palaeoclimatic and geoarchaeological evidence. In this contribution, we will pose some questions that remain still unsolved or poorly investigated and we will discuss some hypotheses in context of new and published data. Key questions concern the duration and termination of the AHP: was it an abrupt or gradual process? And, was the AHP continuous or interrupted by rapid climatic events (RCCs)? Finally, when was the beginning of the Anthropocene in the Sahara? A fresh look at field-based geomorphological and geoarchaeological data from different regions of the Sahara suggest that the duration and termination of humid conditions associated with the AHP were not the same everywhere, and were influenced by local physiographic factors in addition to climatic forcing. Continental archives also suggest the occurrence of at least a major break of humid conditions during the AHP at the transition between the Greenlandian and the Northgrippian stages of the Holocene. This break was possibly triggered by the global cooling at ca. 8.2 ka BP, and lasted a few centuries in North Africa. This transition likely had some significant consequences on the populations within the region. Another question of interest for the Sahara involves the timing of the shift from a natural to a human-dominated landscape. Emerging evidence from key sites in the Sahara suggests an early beginning of human activities characteristic of the Anthropocene, driven by the early diffusion of Neolithic herders, and later influences that included attempts at cultivating within the oases in the context of a progressive aridification of the region.

(Institut National des Sciences de l'Archeologie et du Patrimoine), Rabat, Morocco

Abstract

The Sahara is the world's largest dust source with significant impacts on trans-Atlantic terrestrial and large-scale marine ecosystems. Contested views about a gradual or abrupt onset of Saharan aridity at the end of the African Humid Period dominate the current scientific debate about the Holocene Saharan desiccation. In this study, we present a 19.63 m sediment core sequence from Lake Sidi Ali (Middle Atlas, Morocco) at the North African desert margin. We reconstruct the interaction between Saharan dust supply and Western Mediterranean hydro-climatic variability during the last 12,000 yr based on analyses of lithogenic grain-sizes, XRF geochemistry and stable isotopes of ostracod shells. A robust chronological model based on AMS ¹⁴C dated pollen concentrates supports our multi-proxy study. At orbital-scale there is an overall increase in southern dust supply from the Early Holocene to the Late Holocene, but our Northern Saharan dust record indicates that a gradual Saharan desiccation was interrupted by multiple abrupt dust increases before the 'southern dust mode' was finally established at 4.7 cal ka BP. The Sidi Ali record features millennial peaks in Saharan dust increase at about 11.1, 10.2, 9.4, 8.2, 7.3, 6.6, 6.0, and 5.0 cal ka BP. Early Holocene Saharan dust peaks coincide with Western Mediterranean winter rain minima and North Atlantic cooling events. In contrast, Late Holocene dust peaks might correspond with positive phases of the North Atlantic Oscillation. By comparing with other North African records, we suggest that increases in Northern Saharan dust supply do not solely indicate sub-regional to regional aridity in Mediterranean Northwest Africa but might reflect aridity at a trans-Saharan scale. In particular, our findings support major bimillennial phases of trans-Saharan aridity at 10.2, 8.2, 6.0 and 4.2 cal ka BP. These phases coincide with North Atlantic cooling and a weak African monsoon.

Abstract

The climatic changes during the Early-Middle Pleistocene transition are a key to understand the ecosystem dynamics that involved the *Homo erectus-ergaster* distribution. The Aalat pedostratigraphic succession represents a continental archive in the African Rift Valley (Dandiero basin, Danakil depression, Eritrea), where remains of *Homo* around 1 Ma were identified. High-resolution magnetostratigraphy and some tephra layers at the top and the bottom gave good chronological constraints to this succession, dated between the base of the Jaramillo subchron and the lower Brunhes chron. Despite the present-day arid, desert climate, the Aalat section records a persistence of water-driven, fluvio-lacustrine environments over more than 250 ka, which suggests a major tectonic control on sedimentation, although climate changes are clearly overprinted. Macro- and micromorphological features, along with physico-chemical, mineralogical and geochemical data, up to now poorly available for Pleistocene paleosols in East Africa, depict a poor to moderate degree of paleosol development, in line with high rates of sedimentation around 0.8 mm/a. Nonetheless, cyclical pauses of aggradation led to major geomorphic stability, which permitted the development of calcic, petrocalcic and petrogypsic horizons at different stratigraphic heights (likely developed during 10²-10³ years to some ten thousand years), alternated with Fe-oxide-stained, reddish to yellowish paleosol horizons. This alternation suggests cyclical changes from dry to wet environmental conditions, which fit well with aeolian dust fluxes and marine isotope stages of glacials and interglacials at higher latitudes. This pattern is also consistent with that of the $\delta^{13}\text{C}$ obtained from the carbonate concretions and limestones, which depicts a prevalence of C4 plants during more arid stages, alternated with C3/C4 ecosystems during wetter phases. The $\delta^{18}\text{O}$ signature is more complex, showing a noticeable pattern change from the lower to the upper-intermediate part of the Aalat succession. This shift can be linked to an episodic distribution of rainfall events and/or changes in basin hydrology, at least partly controlled by tectonic activity, which in turn promoted changes in water availability of sedimentary processes.

The *Homo erectus* settlement lasted apparently for a short time span, because of the onset of a prolonged, high-discharge fluvial sedimentation lasted about 125 ka, following more than 50 ka characterized by lacustrine and deltaic sedimentation, or an aridity phase which led to the development of thick, complex carbonate hardpans at the base of the fluvial facies. These events could have made the area less suitable for human settling and could have hindered preservation of fossils and artifacts.

Based on climofunctions available in the literature, mean annual precipitation and temperature were estimated for some reference pedogenic horizons, such as a well-developed calcrete hardpan and the most mature red paleosol. These values can be assumed as tentative reference values for Pleistocene glacials and interglacials in this area.

Abstract

Chew Bahir (4°40'N, 36°50'E; 600 m asl) is a playa basin in southern Ethiopia located between the Main Ethiopian and Kenyan rifts. It is classified as an 'amplifier' lake, with a seasonally inundated basin floor covering an area ~ 30 km E-W and 70 km N-S. Palaeo-shorelines indicate profound hydrological changes occurred during the Late Quaternary, hypothesised to be linked to changes in the location of the principal wind systems and air masses (ie. Intertropical Convergence Zone and the Congo Air Boundary). The sedimentary archive from this basin provides an opportunity to develop a continuous record of terrestrial tropical climatic variability through multiple glacial cycles and to explore the links between climate and human evolution and dispersal in eastern Africa.

In December 2014, parallel sedimentary cores were drilled as part of the Hominin Sites and Paleolakes Drilling Project through the International Continental Drilling Program, with a composite splice sequence ~ 290 m in depth developed. A chronological framework based on a combination of optically stimulated luminescence, argon-argon and radiocarbon dating, further supported by tephrochronology, indicates the palaeoenvironmental record extends back more than 600 kyr. The diatom record from Chew Bahir would be expected to highlight changes in salinity and water chemistry in response to hydroclimatic fluctuations and provide an important component of the multi-proxy record. Initial assessment of core material revealed a lack of biological remains and that diatoms were not preserved through most of the sequence, except for three short (~1 - 3 m) sections of core, centred around ~2 m, ~70 m and ~85 m composite depth. The Chew Bahir palaeoenvironmental record is therefore reliant on geochemical and physical proxies throughout much of the sequence. The three short sections of well-preserved diatoms do however provide valuable supporting evidence for palaeoenvironmental interpretations of more continuous proxy data such as the oxygen isotope record from carbonates. Furthermore, analysis of diatom assemblages from contiguous 2 cm samples through well-preserved sections provides high-resolution snapshots of climatic variability during the three intervals.

In the uppermost, Holocene section, there is a clear shift from a freshwater, planktonic assemblage dominated by *Stephanodiscus* and *Aulacoseira* species to more saline lake conditions represented by *Nitzschia fonticola* and

subsequently *Thalassiosira cf. faurii*. This increase in salinity charts the end of the African Humid Period and progressive lake level lowering. The earlier phases of good diatom preservation in the Late Pleistocene reveal fluctuating lake levels with more diverse assemblages including some freshwater benthic species as well as some intervals rich in planktonic taxa of moderate salinity such as *Cylotella meneghiniana*. The diatom data from Chew Bahir, where present, indicate that the basin responded rapidly to changing moisture availability with distinct changes in salinity of lake waters.

Abstract

The UNESCO-listed Ounianga basin in northeastern Chad hosts two clusters of unique desert oasis lakes, which range from hypersaline to fresh. Continuous inflow of fossil groundwater from the Nubian Sandstone Aquifer (NSA) sustains these lakes against the strong climatic moisture deficit. Palaeoenvironmental proxies in the continuous sediment archive of Lake Yoa - the deepest (26m) lake located in Ounianga Kebir - have constrained the transition from the early-Holocene African Humid Period towards the current hyperarid climate regime (Kröpelin et al. 2008, Francus et al. 2013), but showed limited hydrological response to Late-Holocene climate variability (Eggermont et al. 2008).

We present multi-proxy work on Late-Holocene sediment records from three shallow (<6m) lakes in the lake cluster at Ounianga Serir. Our proxies include magnetic susceptibility, x-ray fluorescence, loss-on-ignition sediment composition, charcoal and invertebrate remains. Our combined evidence indicates that these three lakes experienced site-specific but broadly synchronous palaeohydrological shifts. Some of these events broadly match known episodes of widespread hydroclimatic change documented from other records in the central Sahara and elsewhere. We conclude that variation in evaporation linked to changes in temperature and/or wind strength must have resulted in basin-wide lake-level shifts, notwithstanding most likely fairly constant groundwater input from the NSA. This work shows that the iconic freshwater lakes of Ounianga Serir, generally thought to be hydrologically stable 'relict' lakes, are more dynamic and climate-responsive than previously evaluated.

⁸Nelson Mandela University, Port Elizabeth, South Africa

Abstract

Understanding the past variability in African hydroclimates is important in studies into the earth's climate system, paleoanthropology and future climate change. Speleothems provide one of the highest-resolution, precisely-dated archives of past hydroclimate change. The Past Global Changes (PAGES) working group Speleothem Isotopes Synthesis and Analysis (SISAL) brings speleothem records together in a single easily accessible database. The database can be used to analyse multiple datasets together rather than in isolation. This big data approach allows for better spatial analysis of past hydroclimate variability and better integration with climate models. Here we detail the progress of the Africa working group, highlighting the spatial and temporal coverage provided by the SISAL database, and providing initial analysis into past speleothem isotope variability across the continent.

Speleothem deposition at the southern and northern extremities of the present day ITCZ migration appears to be more common during late Pleistocene interglacials than during glacial phases suggesting an overall increased latitudinal range of ITCZ migration or a widening of the tropical rainfall belt during interglacials. During glacial phases speleothem deposition is recorded mainly in the hemisphere that has higher summer insolation. In northwestern and southern Africa precession and eccentricity influence speleothem growth, largely through changing synoptic storm activity. Comparison of recent speleothem stable isotopes with modern isoscapes suggest speleothem $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ approximate modern precipitation $\delta^{18}\text{O}$ and vegetation $\delta^{13}\text{C}$. We assess the spatial variability of speleothem $\delta^{18}\text{O}$ over the last 12,000 years as an example of database use. Due to restrictive bedrock geology and dry climate African speleothem records are spatially and temporally flashy, but hotspots of cave records still provide great insight into regional climatology. Continued research should combine the high-resolution snapshots they provide with other longer term, low resolution hydroclimate records already available, such as sediment cores from lakes and near shore marine environments.

Dust accumulation variability in the Chinese Loess Plateau since the LGM with implications to dust sources and emission dynamics

Zhiwei Xu¹, Thomas Stevens², Shuangwen Yi¹, Joseph A. Mason³, Huayu Lu¹

¹Nanjing University, Nanjing, China, ²Uppsala University, Uppsala, Sweden, ³University of Wisconsin–Madison, Madison, USA

Abstract

Loess deposits in the Chinese Loess Plateau (CLP) are valuable terrestrial archives widely used to reconstruct past dust and East Asian monsoon dynamics. High sampling resolution chronological studies have revealed significant site-specific variations in loess sedimentation. In this study, we investigated on the spatial and temporal variability of loess sedimentation in the CLP during the past twenty thousand years (ka), by synthesizing new records from the desert margin and loess sites from the central CLP. We found that strong dust accumulation at the desert margin after about 15 ka is synchronous broadly with reduced dust accumulation or less preservation in the main plateau. This spatial inhomogeneity of loess sedimentation is controlled by various dust transportation, trapping, and postdepositional processes in different geographic settings, and is related to past monsoon climate change. Our study further implies that the boundary between the dust depositional region and the source region shifted during glacial-interglacial cycles, because dust was trapped at the desert margin when it became vegetated during the humid and warm interglacial period. During the glacial period, however, this region was strongly eroded and dominated by the extension of sand dunes. We propose that the desert margin serves as a transition zone that accumulates dust during interglacials and emits dust during glacials. This provides an important dust transport and recycling pathway that carries dust from the source region to the depositional region over glacial-interglacial cycles.

To further investigate the dynamics of dust emission from the source area, we recently applied the PI-SWERL (Portable In-Situ Wind Erosion Laboratory) to measure in the field the potential of sand dunes and other desert landforms to emit dust in the deserts in northern China. The preliminary results revealed different dust emission processes and mechanisms between different geomorphic units. Both geological reconstruction and field observations indicate that loess covering by sand dunes could emit dust efficiently.

Different approaches for dust source determination – two case studies from Iran

Christian Opp¹, Hamidreza Abbasi², Mansour Ahmadi Foroushani², Michael Groll¹

¹Philipps-Universität, Marburg, Germany, ²Philipps-Universität, Marburg, Iran, Islamic Republic of

Abstract

Iran, like most of its neighboring countries, is part of the northern hemisphere subtropical dryland belt and thus a relatively high percentage of the country's area is covered by semi-deserts and deserts. These areas – inside and outside of Iran – are very effective dust sources. The aeolian processes are further promoted by high wind speeds supported by the nearby Persian and Oman Seas. Dust and sand storms are a widespread problem throughout Iran, but identifying the exact dust sources is, due to the outlined complex geographical structure, challenging. The study presented here uses two different approaches to determine the dust sources of samples collected in Eastern and South-Western Iran.

The Eastern Iranian case study, which was carried out in the Iranian Sistan region and the adjacent Registan region in Afghanistan, utilizes the fact that emission, transport and deposition of dust are predominately controlled by wind. This approach calculated the Drift Potential (DP), the Resultant Drift Direction (RDD), the Resultant Drift Potential (RDP), and the RDP/DP ratio using the Fryberger (1979) method based on data from 16 meteorological stations for the period 1999-2015. Together with wind regime determination, satellite based mapping and field campaigns in the Iranian part of the study area, the temporal variation of the wind systems and the spatial distribution of the dune systems were determined.

The second case study used the chemical characteristics of dust collected in the South-Western provinces of Iran to determine the dust sources, which were expected to lie outside of Iran. The concentrations ($\mu\text{g/g}$) of Be, Na, Mg, Al, Si, K, Ca, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Sr, Cd, Ba, and Pb, retrieved from ten passive dust deposition samplers were analyzed using ICP-MS (Inductively Coupled Plasma Mass Spectrometry). Acid digestion (HCl: HNO₃) using *Aqua Regia* (ISO/DIS 17294-2:2014 conc.1:50) were employed for the total elemental analysis. Correlations between daily dust event data and the elemental composition of the dust samples over a four year sampling period allowed the determination of the dust sources with the help of key indicating elements (according to Geiger and Cooper 2015).

As main sources of dust, desiccated ephemeral lakes (Hamoun and Hoor) have been identified in the East-Iranian study area. Besides dry lakes and salt marshes, especially in Khuzestan, also other dust sources, both natural (c.f. weathering crusts, marine aerosols) and anthropogenic (cf. vegetative burning) were determined in the South-Western study area.

The Ponte Crispiero Late Pleistocene Loess/Palosols succession (central Apennine, Italy): insight on dust origin and transport

Monica Bini¹, Mauro Coltorti², Giovanni Zanchetta¹, Marco Lezzerini¹, Ilenia Arienzo³

¹Pisa University, Pisa, Italy, ²Siena University, Siena, Italy, ³Osservatorio Vesuviano INGV, Napoli, Italy

Abstract

There is an increasing detailed documentation on the loess succession in central Italy, in particular at the margins of the Po plain (e.g. Cremaschi et al. 2015). However, the origin of the loess deposits inside the central Apennine is still debated (e.g. Giraudi et al., 2013; Boretto et al., 2017). In this poster, we present mineralogical and geochemical (major, minor, trace element and ⁸⁷Sr/⁸⁶Sr ratio) data of the Loess/Paleosols succession outcropping at Ponte Crispiero (Chiesa et al., 1990, central Apennine). The Ponte Crispiero loess chemistry is clearly distinguishable from other European loess, and shows both affinity with sediments of some central Italian rivers and in particular some (even if not complete) similarity with the Po alluvial plain deposits. This suggests that during low stand sea level there was a dust transport from the Adriatic margin toward the central Apennine valley.

Abstract

Scanning electron microscopy was commonly used on microstructure study of loess and paleosol for changes of the Quaternary paleoclimatic environment. However, there are at least three deficiencies on the previous research. First, the SEM sample surface is usually not smooth enough to accurately reflect internal structures. Second, the scanning area is too small to make a statistics. Third, mineral components cannot be identified in a large scale at one time and the spatial distribution of minerals, except for quartz, in loess and paleosol was seldom studied.

In this paper, a method by BSE/EDX associated with a new sampling tool and image processing technology is presented to overcome three shortcomings above mentioned. With the method, minerals in loess and paleosol sample can be identified through comparing the chromatic value difference between unknown mineral and [standard](#) mineral in a patented color database. Six samples were taken from paleosol S₀, S₁ and loess L₁ separately on Luochuan, China. 320 SEM/EDX images with magnification 500 times the original size for each sample were obtained, including 40 base map images and 280 dots mapping images representing the distribution of 7 elements as Si, Al, Ca, K, Fe, Mg and Na separately. We replace the white dots on dots mapping images with 7 different colors according to 7 different elements and change the image background to transparent. After overlaying and stitching 320 images together, the micromorphological characteristics in more than one square [millimeter](#)s of sample surface were analyzed and grain size distribution of three kinds of mineral, quartz, silicate minerals, especially carbonate minerals, with different deposition thickness, were also provided separately.

The results show that: (1) Obvious peak fluctuation on particle size distribution of silicate and carbonate minerals existed between the grain size fraction of 1-3 μ m of paleosol S₀, S₁ and loess L₁ sample. (2) Many evenly distributed elongated and flaky particles with size fraction of 60~100 μ m in paleosol S₀, S₁ and loess L₁ sample were observed, including not only quartz, but also kaolinite and mica. (3) It is also observed that both silicate mineral particles coated with carbonate mineral cutans and carbonate mineral particles coated with silicate mineral cutans exist a lot at the same time on paleosol S₀, S₁ and loess L₁ sample.

The observations infer that the origin particle size of paleosol S₀, S₁ and loess L₁ could be more uniform or coarser than previously thought and carbonate in them could be delivered in clastic form by aeolian processes.

Stepwise shifts in Asian dust provenance and East Asian winter monsoon intensification since ~7.2 Ma revealed by detrital zircon age

Hanzhi Zhang¹, Huayu Lu¹, Stevens Thomas², Han Feng¹, Yu Fu³, Junyan Geng³, Hanlin Wang¹

¹Nanjing University, Nanjing, China, ²Uppsala University, Uppsala, Sweden, ³Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The evolution and forcing mechanisms of the East Asian winter monsoon during the late Cenozoic are unclear, largely because appropriate proxy indicators for reconstructing variations in this long-established wind system are lacking. In this study, we used a compilation of detailed zircon U-Pb age spectra of a continuous eolian sedimentary sequence in the northern and southern Chinese Loess Plateau to reveal changes in dust provenance, which are closely associated with the evolution of the East Asian winter Monsoon (EAWM). The detrital zircon dating results for the 47 analyzed levels with detailed age constraints indicate that the EAWM strengthened stepwise at ~7.2 Ma, ~2.6 Ma, 1.2-0.9 Ma and at the Last Glacial Maximum. These changes are synchronous with global cooling and ice cover expansion in the Northern Hemisphere. Our reconstruction of the dust provenance and wind strength suggests that the strengthening of the East Asian winter monsoon was probably driven by global cooling, which caused an increasing temperature gradient between the North Pole and the tropics, resulting in outflowing anticyclonic winds. The growth of Himalayan-Tibetan Plateau has less impact on the stepwise EAWM evolution since the late Miocene.

Geochemical evidence for the provenance of loess deposits in the eastern Qinling Mountains, central China

Qingzhen Hao¹, Nan Li², Xujiao Zhang³

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ²School of Earth and Space Sciences, Peking University, Beijing, China, ³School of Earth Sciences and Resources, China University of Geoscience, Beijing, China

Abstract

Determination of provenance of the loess deposits in the eastern Qinling Mountains, central China, is important for improving our understanding of the dust emission, transportation and deposition in the Asia region. It has long been a controversial issue whether the widespread *Xiashu* loess in southern China was derived from the northern Asian interior deserts or aridified local fluvial/flood plains in southern China during the glacial. The eastern Qinling Mountains lie between the Chinese Loess Plateau (CLP) and subtropical China, and consequently on the transportation pathway of the East Asian Winter Monsoon carrying dust from the northwest to southeast. In this study, four sections from the two major basins in the eastern Qinling Mountains were investigated. Among these sections, Liuwan (34.143°N, 110.137°E) and Shipo (34.183°N, 110.250°E) sections are located in Luonan Basin, and Shangluo (33.885°N, 109.914°E) and Dabozi (33.719°N, 110.237°E) sections, in Shangdan Basin. The grain-size distribution of 39 bulk samples, and the major and trace element compositions of the <20 μm fraction of 23 samples mainly from the first loess layer of the four sections were analyzed and compared with the Xifeng loess which is of typical in the CLP. The geochemical composition of Xifeng loess samples is used to characterize the average geochemical composition of the northern deserts. The results show that the grain-size distribution of the bulk samples from the eastern Qinling Mountains is similar to that of the Xifeng loess, indicating the four studied loess sections are of typical eolian origin. The immobile element ratios of the <20 μm fraction (e.g. TiO_2/Al_2O_3 , La_N/Sm_N , Gd_N/Yb_N , La_N/Yb_N , Eu/Eu^* , Zr/Nb , Hf/Nb , Y/Nb , La/Nb , Th/Nb , Ta/Zr , Zr/Hf) in the loess deposits from the eastern Qinling Mountains are different from those of loess from the CLP. According to the aerodynamic property of aeolian dust, only dust particles finer than 20 μm can transport a few tens to a few hundred kilometers under typical windstorm conditions. The clear distinction in immobile element ratios of <20 μm fraction between samples from the two regions indicates that the loess deposits in the two regions have different provenances, and the loess on the eastern Qinling Mountains did not primarily come from northern deserts. We suggest that the adjacent alluvial deposits and clastic sediments from the weathered bedrocks are the dominant dust sources of the loess deposits from the Eastern Qinling Mountains. This study therefore provides new evidence supporting our previous conclusion that *Xiashu* loess in southern China is not mainly derived from the northern deserts and the role of the East Asian winter monsoon in transporting the dust the northern deserts to southern China have been overestimated.

The origin of large depressions of eastern Azov region plain (southern Russia)

Andrey Zakharov, Evgeny Konstantinov
Institute of geography RAS, Moscow, Russian Federation

Abstract

On the watersheds of the eastern Azov region, there are dozens of large depressions. Their sizes can reach tens of square kilometers. The outlines of these depressions are like a drop or an egg. The vast majority of large depressions are oriented approximately north. To date, the problem of the origin of large depressions in the eastern Azov region does not have an unambiguous solution. The following hypotheses were put forward: paleothermoclast, erosion-suffusion, subsidence-loess, estuary-lake. Yet, none of them is not finally confirmed and not refuted. This is due to the lack of correct data on their geological and geomorphological structure. Also, the problem of these large depressions evolution in the future remains unclear. Is their extensive growth possible or will they remain stable? The goal is to find at and identify the mechanisms for the formation of large depressions.

As a result of the morphometric analysis of large depressions, a unity of their origin was revealed. For geological and geomorphological research, we chose a key object. It is a typical large depression - "Chervonaya pad". The material for the study was obtained by hand drilling and outcrop investigation on the coast of the Taganrog Bay. As a result of the research, we obtained a new data on the geological structure and morphology of large depressions. Two types of sediments were distinguished in the structure of large depressions and interfluvies. At the top lays the loess cover with paleosols developed in it. Sub-aqueous deposits lie beneath the loess cover. The thickness of the loess inside the depressions is less than on watersheds and the number of paleosols is also less. The roof of the underlying sub-aqueous deposits lies sub-horizontally. Traces of lake sediments, cryogenesis, and tectonic faults were not found in the structure of large depressions. The new data allow us to make some important conclusions on the origin and mechanisms of formation of large depressions in the eastern Azov region:

- 1) Large depressions of eastern Azov region were formed by a directional flow.
- 2) These depressions were formed with not water-related processes.
- 3) They were formed by denudation in the loess.
- 4) The position of the buried soil complexes allowed us to estimate the age of the studied depressions. According to the obtained data, depressions were already formed by the beginning of the Eemian inter-glacial.
- 5) As a result of the study, we proposed an eolian denudation mechanism for the formation of large depressions.

Aggravation of summer monsoon rainfall over south-western India by the dust entrainment in Middle East

Manjunatha Busnur, Manjunatha H.V.

Department of Marine Geology, Mangalore University, Mangalagangothri-574 199, Mangalore, India

Abstract

Owing to the global importance of deserts for understanding climate change and biogeochemical cycles, there has been an increasing studies on arid regions since three decades. It has been identified recently that the desert dust entrained from Middle East and North Africa can aggravates rainfall over the north-western India and the adjoining countries through processes, such as, enhanced heat pumping, short-term modulation of monsoon rainfall as well as eastward advancing westerly wind in the temperate zone. The west coast of India and the adjacent Western Ghat is the second largest watershed areas for the Peninsular rivers. A glance through the data needed to test the above processes in the high monsoon rainfall regions, like the coastal Karnataka, indicates that dust raised from the Middle East can enhance rainfall even in the core of the summer monsoonal air flow, particularly during the years of "excess rainfall" as compared to long-term average of the years - 1951 to 2000. Satellite images and data from NOAA and other organizations suggest that the desert dust related data, like RGB images, aerosol optical depth, back-air mass trajectory computations, outgoing long-term radiation indicate that a close association of these parameters with the dense monsoon clouds, that yielded high rainfall during the monsoon 2013. The annual and monsoon rainfall of the Coastal Karnataka compiled by the Climate Monitoring and Analysis of the Indian Meteorological Department, Pune, were 15% and 17% higher than the long-term average climatology of 1971-2000. However, this was not the situation during the year- 2018, although intense dust-entrainment in the Middle East and North Western India, triggered heavy rains in Northern India as well as south-western India during the pre-monsoon and beginning of the monsoon season, rainfall substantially reduced during the August and September months, leading to a drought-like situation where the seasonal and annual rainfall were much below the long-term average. In the current scenario, deserts, particularly in the Middle East are under the influence of westerlies with scanty rainfall have a greater impact on the desiccation of inland water bodies and water budget, particularly for the West Asia, Middle East and North East African countries. It appears that the scenario will worsen in the event of global warming.

Accelerated volume loss in glacier ablation zones of NE Greenland, Little Ice Age to present

Jonathan Carrivick¹, Clare Boston²

¹University of Leeds, Leeds, United Kingdom, ²University of Portsmouth, Portsmouth, United Kingdom

Abstract

Mountain glaciers at the periphery of the Greenland ice sheet are a crucial freshwater and sediment source to the North Atlantic and strongly impact Arctic terrestrial, fjord and coastal biogeochemical cycles. In this study we mapped the extent of 1848 mountain glaciers in NE Greenland at the Little Ice Age (LIA). We determined area and volume changes for the time periods LIA to 1980s and 1980s to 2014 and ELAs. There was at least 172.76 ± 34.55 km³ volume lost between 1910 and 1980s, i.e. a rate of 2.61 ± 0.52 km³ yr⁻¹. Between 1980s and 2014 the volume lost was 90.55 ± 18.11 km³, i.e. a rate of 3.22 ± 0.64 km³ yr⁻¹, implying an increase of ~ 23 % in the rate of ice volume loss. Overall, at least ~ 7 % of mass loss from Greenland mountain glaciers and ice caps has come from the NE sector.

Abstract

The highest parts of the Dinaric Mountains (northeastern Mediterranean region), known for their karst-dominated landscape and humid climate, were glaciated during the late Pleistocene. Bosnia and Herzegovina is considered as one of the main black spots in the Dinaric Mountains from the glacial chronological point of view, as quantitative age data were completely missing. In this work, we present the first attempt to date moraines in the Dinaric Mountains using cosmogenic ^{36}Cl surface exposure dating method, and evaluate the ages in the light of regional geomorphological and climatic context. We focus on three areas in southern Bosnia and Herzegovina, i.e. Velež (1969 m asl), Crvanj (1920 m asl) and Čvrsnica (2226 m asl) mountains. Thirty-two samples were collected from moraine boulders from the lowest and largest lateral moraines and hummocky moraines on these three mountain massifs. The moraine boulders, corrected for 40 mm ka^{-1} bedrock erosion age, yielded ^{36}Cl ages of Last Glacial Maximum ($22.7 \pm 3.8 \text{ ka}$) for Čvrsnica, Oldest Dryas ($14.9 \pm 1.1 \text{ ka}$) for Velež, and Younger Dryas ($11.9 \pm 0.9 \text{ ka}$ and $13.2 \pm 1.8 \text{ ka}$) for Crvanj and Čvrsnica respectively, considering the oldest boulder age obtained from each moraine as the most representative time of moraine emplacement. The dated moraines mark the largest extent of glaciers in the study areas, which have been reconstructed to $\sim 28 \text{ km}^2$ for Velež and $\sim 24 \text{ km}^2$ for Crvanj, having a mean equilibrium line altitude at 1388 m and 1541 m, respectively. The magnitude of glaciation along with the equilibrium line altitudes is exceptional in terms of the Lateglacial evidence elsewhere in the northeastern Mediterranean region. It is very likely that the boulder ages reflect complex exhumation and denudation histories; therefore future work is needed to better understand these processes and their influence on the cosmogenic exposure dating approach in a karstic landscape. As the entire country of Bosnia and Herzegovina lack any previous knowledge on the timing of glaciations, the correlation of the age data are quasi impossible. However, our results provide a new dataset, and present a relevant contribution towards a better understanding of the glacial chronologies of the Dinaric Mountains. This work was supported by TUBITAK 118Y052 and Istanbul Technical University (MGA-2017-40540) projects.

The structural glaciology of the Svínafellsjökull snout: Implications for ice dynamics and debris transfer

Ailsa Guild^{1,2}, Emrys Phillips², David Evans¹, David Roberts¹

¹University of Durham, Durham, United Kingdom, ²British Geological Survey, Edinburgh, United Kingdom

Abstract

Since the Little Ice Age (LIA) the overall retreat of Svínafellsjökull has been punctuated by several readvances resulting in the development of a complex suite of large to small-scale, concentric to saw-tooth moraines on the foreland. Between c. 1970 and 2000, the position of the margin has remained relatively stable, with retreat being dominated by downwasting and a lowering of the glacier surface. However, since 2000 the recession of Svínafellsjökull has been occurring at an accelerated rate resulting in a pronounced thinning of its terminal zone. This research presents data to investigate the structural response to this pronounced thinning of the terminal zone both spatially and temporal, and the impact this has on the glaciological landform record.

The structural architecture of Svínafellsjökull has been investigated by detailed mapping and analysis of the deformation structures (fractures, banding) exposed on the glacier surface using historical vertical aerial photographs, supplemented by field survey and unmanned aerial vehicle aerial photography. Variation in the orientation, length, density and morphology of the crevasses has revealed that Svínafellsjökull can be divided into two main zones: (i) an extensive upper zone which exhibits a relatively simple radiating/fan shaped fracture pattern, a locally well-developed network of supraglacial meltwater channels and a prominent light and dark coloured ogive/Forbes banding; and (ii) a structurally more complex lower zone occupying the lower reaches of the glacier. The regular view of the movement of non-surging valley glaciers is that they move as a single 'plug flow' with the entire glacier body moving 'en-masse' down valley. Although initial results suggest that the structure of the upper part of Svínafellsjökull can be interpreted in this way, the complex lobate morphology of its marginal zone does not fit with simple radiating crevasse pattern typically associated with the spreading of a single piedmont lobe. The structurally complex nature of the marginal zone of Svínafellsjökull indicates that it comprises of three independent, lobate flow units.

Changes in the structural configuration of the lower reaches of Svínafellsjökull have an impact on the landform record preserved within its forefield. The most recently formed moraines at Svínafellsjökull display saw tooth or crenulated pattern in plan form. Geomorphological mapping of the forefield reveals that the pre-LIA limits are arcuate in shape with the switch to a saw tooth pattern of moraine crests having occurred during the 1980-90s (c.f. Everest *et al.*, 2017). This could suggest that the lobate style of flow at the margin of Svínafellsjökull was established during the late 1980s as the glacier retreated from this major readvance limit. To conclude, this research demonstrates that the landform record within Svínafellsjökull's forefield reflects changes in the structural architecture of the marginal zone of the glacier.

Insights into the influence of stepped topography on glacier retreat rates from an abandoned lobe of Skálafellsjökull, SE Iceland

Robert Storrar¹, Marek Ewertowski², Aleksandra Tomczyk², Jon Bridge¹, Naomi Holmes¹, Andrew Jones¹, Matt Bowker¹, Jamie Gordon¹, Shannon Harewood-Malone¹, Will Twigg¹

¹Sheffield Hallam University, Sheffield, United Kingdom, ²Adam Mickiewicz University, Poznan, Poland

Abstract

Glaciers do not retreat at a uniform rate dictated solely by climate. Climate signals are interspersed with more location-specific signals, which may be influenced by factors including (but not limited to) glacier hypsometry, underlying geology, ice albedo and underlying topography. We use detailed Unmanned Aerial Vehicle imagery to produce a high resolution Digital Elevation Model and aerial orthophoto to map the glacial geomorphology of the abandoned foreland of a former high elevation secondary lobe of Skálafellsjökull, an active temperate outlet glacier of the Vatnajökull Ice Cap in SE Iceland. We combine this mapping with lichenometric dating and sedimentology to provide insights into the effect of stepped upland topography on glacier retreat rates.

Many of the glaciers in SE Iceland have been intensively studied over the last 50-100 years and numerous publications document their retreat in response to climate warming. However, most of this work has concentrated on the piedmont lobe termini which flow(ed) onto the somewhat flat outwash plains produced during the Holocene. The response of glaciers in more topographically complex areas is less well understood, but is important because many glacierized areas that are undergoing retreat, such as glaciers around the periphery of Greenland and Svalbard, lie over such terrain.

Skálafellsjökull provides a useful analogue because the glacier sits over a series of dyke-controlled bedrock steps. Whilst the main snout of Skálafellsjökull has retreated across a flat outwash plain, a subsidiary lobe of the glacier previously extended over part of the higher-altitude stepped topography during the Little Ice Age, and has now almost completely disappeared from this area. The lobe flowed over four relatively uniform topographic steps. We reveal the detailed geomorphology of this abandoned lobe, which comprises arcuate and saw-tooth moraine ridges at the distal ends of the steps, and flutings at the proximal ends, and we provide lichenometric ages for the retreat of the glacier from 1890 to 1945, and historical margin positions from a series of aerial photographs and satellite imagery from 1945 to the present day.

P-3820

Topographic controls on plateau icefield recession: insights from the Younger Dryas Monadhliath Icefield, Scotland

Clare Boston¹, Sven Lukas²

¹University of Portsmouth, Portsmouth, United Kingdom, ²Lunds universitet, Lund, Sweden

Abstract

Plateau icefields are a common form of mountain ice mass, frequently found in mid-latitude to high-arctic regions and increasingly recognised in the Quaternary record. Their top-heavy hypsometry makes them highly sensitive to changes in climate when the ELA lies above the plateau edge, allowing ice to expand significantly as regional ELAs decrease, and causing rapid recession as climate warms. In light of predicted future climate warming, it is important to understand the controls on plateau icefield response to climate change in order to better predict recession rates, with implications for water resources and sea-level rise. Improving knowledge of controls on glacier recession also has the potential to enable palaeoclimatic information to be extracted from the Quaternary glacial record. We use the distribution of moraines in a formerly glaciated setting to examine how topographic controls augment the response of a former icefield to climatic amelioration towards the end of the Younger Dryas. We find that overall valley morphology influences the style of recession, through microclimatic and geometric controls, with bed gradient affecting moraine spacing. In addition, ice masses reconfigure as recession progresses, because transection valleys and ice divide migration could alter the expected response based on hypsometric distribution. We also identify the potential for thresholds or tipping points during recession, resulting in a non-linear and spatially variable ice mass response to changes in climate.

The geomorphology of Svínafellsjökull and Virkisjökull-Falljökull glacier forelands, southeast Iceland

Jeremy Everest¹, Tom Bradwell^{1,2}, Lee Jones³, Leanne Hughes³

¹British Geological Survey, Edinburgh, United Kingdom, ²University of Stirling, Stirling, United Kingdom, ³British Geological Survey, Nottingham, United Kingdom

We present a detailed, 1:10,500-scale, surficial geology and glacial geomorphology map of Svínafellsjökull and Virkisjökull-Falljökull glacier forelands in southeast Iceland. The map depicts the landsystem imprint of Holocene glacier fluctuations, volcanogenic outburst floods, and recent (post-1990) climate-induced rapid ice-front retreat. The map is based on field survey data in combination with 2012 airborne LiDAR data, 2009-2012 terrestrial LiDAR data and 2007 colour aerial photography. The base DEM for the glacial and topographic information is compiled from an ice-cap wide airborne LiDAR dataset. The mapped glacial landforms are dominated by sequences of recessional moraines laid down in the mid Holocene, the Little Ice Age, and the last ~100 years; the state of landform preservation generally decreasing with age. In addition, expansive glaciofluvial outwash plains (sandar) stretch from the glacier margins to the present-day coastline. Interspersed with glaciofluvial sedimentation associated with typical ice-marginal retreat sequences is key geomorphological evidence of high-magnitude volcanogenic outburst floods (jökulhlaups) associated with the eruptions of Öraefajökull in 1362 and 1727 CE. Other notable geomorphic features include saw-tooth moraines at Svínafellsjökull; flutes at both glaciers; and a large, recent, supraglacial rockfall at Virkisjökull-Falljökull. Ice-front retreat from a prominent re-advance moraine in ~1990 has accelerated since ~2005 leaving a rapidly evolving buried-ice landscape in front of Virkisjökull-Falljökull – including an ice-cored esker, a large ice-floored (supraglacial) lake, numerous actively forming kettle holes and subterranean ice caverns. This map could act as a 'reference frame' for geomorphologists studying the temporal evolution of glacial landform-sediment assemblages – the products of currently rapid deglaciation in southeast Iceland.

P-3822

Pervasive cold-ice within a temperate glacier - implications for glacier thermal regime, sediment transport and foreland geomorphology
