Quartz is one of the primary rock-forming minerals during the rock cycle and is relatively resistant to weathering during transport. Compared to the heavy zircon, it has a much lower density, which means that it can be easily transported over long distances during aeolian processes, and can thus be potentially indicative for the relatively distal source areas. The major advantage of using quartz for provenance analysis is that it is the major component of the Asian dust and it travels with the bulk of the sediments. Therefore, provenance analysis based on quartz grains will provide more complete information about the dust sources and travel history of the sediments, compared to that of zircon. In this study, we introduce a new approach based on *in-situ* trace element analysis of detrital quartz, using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) to characterise the provenance of the Chinese aeolian loess and Red Clay deposits. Three trace elements in quartz: Li, Sc and Ti are analysed. The comparison of trace elements in quartz between desert sand of the potential source areas, the Quaternary loess and late Miocene-Pliocene Red Clay has yielded results that are consistent with zircon U-Pb ages. The results indicate Qaidam Basin has a similar trace element distribution in the quartz to that of the Quaternary loess of the Mangshan Plateau and also suggest a possible dust supply from the Taklimakan Desert to the Baode Red Clay. This study sheds new light on the application of *in situ* quartz trace element analysis by LA-ICP-MS in tracking the sources of the bulk of wind-blown sediments.

The Central Andes primary dust sources of the Chaco-Pampean loess (South America)

Daniela M. Kröhling

CONICET , Santa Fe , Argentina. Universidad Nacional del Litoral , Santa Fe, Argentina

Abstract

The loess of the Chaco-Pampa Plain (Argentina) is the most extensive and voluminous dust archive in the Southern Hemisphere, providing mineralogical, physical and chemical information on transported dust. The Pampean Aeolian System (PAS) generated during the Last Glacial Maximum (LGM), represents the largest Quaternary aeolian system of South America (ca. 600,000 km²), forming by a loess belt and a sand sea. Stratigraphic and sedimentological studies of Pampean loess units have been applied to understand the provenance of dust. The grain-size trend in SW-NE direction, the mineralogical association, and the geochemical data are indicators of multiple sources of the LGM loess. Some geomorphological units of the Central Andes were identified and characterized as the main primary sources. Dust emission of key areas of the Andes and the characteristics of their dust sink region in the Late Quaternary sedimentary archives (loess, wetlands and soils) were investigated. A significant geomorphological control on dust emission is observed. Field studies on representative areas, the installation of sediment sampling towers linked to a meteorological station, and GPR surveys have enhanced the understanding of surface process geomorphology on present-day dust sources identified by other authors using remotely sensed products. The hyper-arid Altiplano/Puna Plateau, ca. 1,500 km long and 300 km wide and with an average elevation of ca. 4,100 m a.s.l., is one of the main dust sources of the Central Andes, also being a present active area of dust. It comprises extensive sedimentary basins that are internally drained, formed by ignimbritic rocks and volcanic calderas. Tectonic depressions are occupied by Quaternary dry lakes (playas), alluvial fans, sand dunes, outwash plains and hypersaline lakes. The Southern Puna Plateau (25°-27°S; 68°30'-66°30'W) shows impressive Late Quaternary aeolian landforms as the largest megaripples on Earth, gravel dunes, yardangs and aeolian scars indicating a NW-SE wind direction. Particularly, the Purulla depression (NW Argentina) represents a unique natural laboratory for the evaluation of the dust exported to the lowlands, with a registered net loss of ca. 4 m of volcanoclastic sediments and ignimbrites. Salt pans of Puna also show large evidence of deflation process during the Holocene. Other important dust areas in South America are the arid Southern Central Andes and North Patagonia (Western Argentina). Silt-producing mechanisms as frost weathering, glacial grinding and fluvial comminution, mainly in the Andean upper basin of the Bermejo-Desaguadero-Salado fluvial system during the LGM, generated large volumes of clastic sediments that were transported by meltwaters along the eastern Andean piedmont and spreading out in terminal sand flats, ephemeral streams and wide alluvial plains. Their deposits were deflated by SW winds to the Pampa region. Changes in dust emission and mobilization reflect the occurrence of different processes.

The paleogeography of the Danube Deep-Sea Fan, NW Black Sea

Andrei Briceag¹, Gabriel Ion¹, Mihaela Melinte-Dobrinescu¹, Dan Vasiliu², Naliana Lupascu²

¹National Institute of Marine Geology and Geo-ecology, GeoEcoMar, Bucharest, Romania. ²National Institute of Marine Geology and Geo-ecology, GeoEcoMar, Constanta, Romania

Abstract

During the Holocene, the Black Sea basin suffered a major shift from a fresh water environment to a brackish one, which is mirrored in the biotical turnover. The transition of the Black Sea from an inland lake to a marine basin during the last glacial/deglacial episode is still generating debates. In Black Sea basin deeper parts, i.e., below 200m water depth, Ross and Degens (1974) recorded three stratigraphic units (from young to old): Unit 1 (the microlaminated coccolith ooze, deposited under marine conditions), Unit 2 (the sapropel mud, corresponding to a brackish, anoxic phase), and Unit 3 (the lacustrine lutite deposited during the freshwater or oligohaline stage).

The Danube Deep-Sea Fan is one of the most developed deep-sea sedimentary structures in Europe (Panin & Jipa, 2002). In 2018, in the framework of the uBiogas Project (24PCCDI/2018), several cores were acquired from the Danube Deep-Sea Fan area for investigating the processes that led to the formation and accumulation of methane. In this study, high resolution microfaunal analyses coupled with sedimentological and calcium carbonate (CaCO₃) ones, were performed on two gravity cores, MN183_3_GC_1 (401cm long) and MN183_8_GC_1 (376.5cm long), revealed changes that occur in the Black Sea from the Last Glacial Maximum through the transition to the present day semi-enclosed marine basin.

The cores were collected from two secondary canyons situated to the east of the Danube Canyon, from 655,7 (MN183_3_GC_1) and 1315m water depth (MN183_8_GC_1). In both studied cores, three stratigraphic units were identified: the youngest Unit 1 (Coccolith Mud), Unit 2 (Sapropel Mud) and the oldest Unit 3 (Lacustrine lutite). The glacial cold period is marked by the presence of the cold-water ostracod species. The cores contain a reddish-brown clay and silt interval belonging to the post-glacial melt-water pulse of the Heinrich Event 1. In the upper part of the cores, in Unit 1, a brackish ostracod assemblage, with low diversity and abundance was identified. This interval is characterized by the presence of polyhaline ostracods with Mediterranean origin. The ostracods from this assemblage tolerate salinities comprised between 17-21‰ and characterize a sub-littoral environment.

The aim of this study is to decipher the paleoenvironmental and paleoecological conditions by the integration of the fossil record with the CaCO₃ values. Detailed micropaleontological studies, based on ostracod and foraminifera analyses, are also presented herein.

Sratigraphy and neotectonic structure of Lower Pleistocene deposits in the NW Taman Peninsula (Azov Sea, Eastern Europe)

Sergey Sokolov^{1,2}, Alexey Tesakov¹, Pavel Frolov^{1,3}

¹Geological institute RAS, Moscow, Russian Federation. ²Russian State Geological Prospecting University n. a. Sergo Ordzhonikidze (MGRI-RSGPU), Moscow, Russian Federation. ³Laboratory of Macroecology and Biogeography of Invertebrates, Saint-Petersburg State University, Saint-Petersburg, Russian Federation

Abstract

The eastern part of the Taman Peninsula at its northern coast is known to host a uniquely rich large mammal site of Sinaya Balka with remains of many dozens of southern elephants and giant rhinos elasmothers unearthed. This site is exposed in a displaced sedimentary block lacking a geological context. Studied by generations of researchers for over a century the site is still enigmatic in its origin, structural, and stratigraphic position. Recent field study (2017-2018) produced new data on geology and paleontology of this important area of Quaternary deposits. According to our model, the sedimentary sequence observed in the coastal cliff is a series of discontinuous blocks separated by faults frequently camouflaged by mud volcano clays. The blocks show differing facies structure. The sequence can be divided into three units. Two upper units overlie the lower unit 1 with angular unconformity. Units 2 and 3 shows a stratigraphic gap at their boundary. The strata of unit 1 in the NW block dip towards NW contrary to the SE block that dip into the opposite direction. The dip angle is increasing to the SE. The upper formations are nearly horizontal.

New paleomagnetic data showed that unit 1 with predominant reversed polarity and an interval of normal polarity can be correlated to Matuyama Chron immediately before the Olduvai Subchron. Records of small mammals (*Allophaiomys deucalion*, *Lagurodon arankae*, *Mimomys* cf. *pliocenicus*, *Pitymimomys pitymyoides*, *Ellobius kujalnikensis*), molluscs (*Teodoxus* sp., *Fagotia esperi*, *F. acicularis*, *Parafossarulus* sp. (opercula), *Bithynia* sp. (opercula), *Lithoglyphus* sp., *Viviparus* sp., *Limax* sp., *Dreissena polymorpha*, *Margaritifera arca*, *Bogatschevia* ex gr. *sturi*, and a very important find of *Apsheronia* cf. *propinqua*) and palynology enable the correlation of this section with the late Gelasian – early Calabrian (1.8–2.1 Ma).

The base of the second unit shows normal polarity (?Jaramillo) capped by reversely magnetised sediments. The biostratigraphic content of this unit with large and small mammals (*Allophaiomys* ex gr. *pliocenicus*), freshwater molluscs, and palynology indicates a middle-late Calabrian (0.78–1.4 Ma) time interval. The dislocated Sinya Balka locality of large mammals we correlate to unit 2. The age of the unit 3 we estimate as middle Pleistocene.

Combination of fluvial and coastal records of the southern Black Sea basin to reveal sea-level changes during the late Pleistocene

Mehmet Korhan Erturaç¹, Eren Şahiner², Steven L. Forman³, Nizamettin Kazancı⁴

¹Sakarya University, Department of Geography, Sakarya, Turkey. ²Ankara University, Institute of Nuclear Sciences, Ankara, Turkey. ³Baylor University, Department of Geosciences, Waco, USA. ⁴Ankara University, Department of Geological Engineering, Ankara, Turkey

Abstract

The global sea level changes during the middle-late Pleistocene is well documented by using direct evidence or multi-proxy data from various data resources distributed worldwide. This global sea-level curve is used to correlate the regional data to decipher other influences, such as tectonic settings. The history of the changing levels of the Black Sea is rather more complicated phenomena, considering its wide catchment extending to the Eurasia and also its connection to the global ocean via narrow and shallow gateways such as the Bosphorus and Dardanelles straits. As a result the resolution of the Quaternary sea level curve for the Black Sea is comparably low.

During the Last Glacial, there are two major reported drops of the Black Sea level, post-Karangatian (MIS4) and Neoeuxinian (MIS2-Holocene) and in between Surozhian (MIS3) high stand. The latest episode of this history, the abrupt rise at the early-middle Holocene, is also well-known and have a remarkable impact on the prehistoric societies.

We aim to build up a luminescence chronology of the terrestrial records gathered from the southern Black Sea domain such as fluvial terraces (e.g. Sakarya, Yeşilirmak and Filyos Rivers) and coastal dunes (Karasu and Sinop). The initiation and termination of depositions are discussed in order to maintain a correlation to the Black Sea level curve during the late Pleistocene and beyond.

Circumnavigating the complexities of radiocarbon dating the Late Quaternary evolution of the Black Sea Basin

Michael Grant¹, Justin Dix¹, William Symons², Chuang Xuan¹, Alistair Monteath¹, Jon Adams¹

¹University of Southampton, Southampton, United Kingdom. ²CGG, Llandudno, United Kingdom

Abstract

Since the 1990s, the Black Sea basin has been the subject of multiple hypotheses and studies relating to its Late Quaternary hydrological development, including the much-publicised claims for a catastrophic flooding event. One of the principle causes for the disparity in hypotheses relates to the complexity of obtaining reliable chronologies for the sequence of events since the Last Glacial Maximum. Radiocarbon dating, mainly of shells, has been used as the main source of dating in most studies but it is well-recognised that reservoir ages, critical to robust calibration, have fluctuated markedly over time due to a complex interplay of riverine run-off, changes in catchment, evaporation and precipitation of the basin, and changes in water depth and circulation patterns. The dating uncertainties generated are frequently a source of the contradictions between the timing of key events from different researchers. To circumvent these problems, a non-radiocarbon-based chronology on sediment cores from the Bulgarian shelf, in the western Black Sea basin, has been produced. This provides an independent assessment of the timing of Late Quaternary hydrological events within the Black Sea basin against which radiocarbon calibration approaches can be tested.

This study is part of the Black Sea Maritime Archaeology Project (MAP), which took place between 2015-2018. Extensive geophysical surveying covering >2000km², coupled with 92 piston and vibrocores cores, has provided unprecedented levels of detail of this area of the Black Sea shelf. Core chronologies covering the last 30ka have been determined using a combination of palaeomagnetism, tephrochronology and radionuclide dating (²¹⁰Pb and ¹³⁷Cs), coupled with geochemical and biostratigraphic analysis. The results demonstrate the presence of both visible and cryptotephra within the western Black Sea basin, extending the northern distal range of some Late Quaternary Mediterranean eruptions and providing isochrons. The palaeomagnetic results demonstrate the great potential of using this technique for dating the Late Quaternary sediments of the Black Sea basin with good replication of palaeomagnetic signals in multiple cores and close correlation to the tephra isochrons.

Age of raised marine terraces of the eastern Mediterranean, Turkey, determined by amino acid racemization and electron spin resonance dating

Ufuk TARI¹, Okan Tüysüz², John F. Wehmiller³, Darrell S. Kaufman⁴, Bonnie A.B. Blackwell⁵

¹Department of Geological Engineering, Istanbul Technical University, 34469, Maslak, Istanbul, Turkey. ²Fina Energy Company Inc., 34662, Istanbul, Turkey. ³Department of Geological Sciences, College of Earth, Ocean, and Environment, University of Delaware, Newark, 19716, DE, USA. ⁴School of Earth Sciences and Environmental Sustainability, Northern Arizona University, Flagstaff, 86011, AZ, USA. ⁵Department of Chemistry, Williams College, Williamstown, 01267-2692, MA, USA

Abstract

The coastal area in the eastern Mediterranean Basin presents a deformed system of raised coastal deposits, some of which have been tectonically affected. This deformation has produced several stacked marine terraces due to successive tectonic movements and Quaternary sea-level fluctuations at elevations ranging from 3 and 175 m in this region. Here, molluscs from terrace deposits were dated using standard electron spin resonance (ESR) dating. Then, amino acid racemization (AAR) values measured from marine molluscs are demonstrated to be an important aid to correlations and chronology of raised marine terrace deposits in the study area. For molluscs *in situ* in the terraces, the ESR ages ranged from ~ 8 to ~ 214 ka are consistent with the aspartic (Asp) and glutamic acid (Glu) racemization values in shell samples in spite of significant differences occur between species at the taxonomic level. This is also the first established amino-stratigraphical sequence from marine terrace sites in this study and their combination with ESR dating. The results allowed corroborating the age of some studied sites, the general amino-stratigraphical framework for the raised marine terrace deposits was confirmed with ages between Marine Isotopic Stage (MIS) 2 and MIS 7. The amino-zones from oldest to youngest found along eastern Mediterranean coast support the reliability of the ESR ages, as well as compatible with the mean values for the amino-zones established in the western Mediterranean coasts. On the basis of our study, we conclude that the results of AAR dating can be used widely for the reference the geochronological investigation and/or effective diagenetic temperature in different areas of the Mediterranean realm.

Molluscs of the genus *Corbicula* as climatic and stratigraphic markers

Pavel D. Frolov^{1,2}, Alexey S. Tesakov¹, Alexey A. Bondarev³

¹Geological institute of Russian Academy of Science, Moscow, Russian Federation. ²Laboratory of Macroecology and Biogeography of Invertebrates, Saint-Petersburg State University, Saint-Petersburg, Russian Federation. ³Omsk regional branch of Russian Geographical Society, Omsk, Russian Federation

Abstract

Bivalves of the genus *Corbicula* are well known markers of warm climate. The mean air temperatures in modern habitats of *Corbicula* in Central Asia range from 13 to 16°C. Normally *Corbicula* cannot stand water temperature drops to 0°C for more than a week. *Corbicula* occurred several times in the fossil record of Eastern Europe. The first, late Gelasian entry is recorded in the North Caucasus as *Corbicula* aff. *jassinensis*. Widespread sites of *Corbicula* *apscheronica* are known in late Early Pleistocene (Calabrian) of Azerbaijan, Stavropol, and Kerch (Andrusov, 1923; Semenenko, 1987). The genus went extinct in the south of Eastern Europe by mid Calabrian.

First records of *Corbicula* in Western Europe are known from Early Pleistocene. *C. fluminalis* is recorded in early and late Gelasian sites of France, Netherlands, and East Anglia. And from Cablarian (Bavelian) of the Netherlands (Meijer, Preece, 2000).

In south of Western Siberia and in the foothills of the Altai Mts, *Corbicula* occurs in a narrow stratigraphic range at the end of Gelasian (Popova, 1981; Zykin, 1991). The finds are attributed here to *C. tibetensis* and *C. ferhanensis*, that possibly dispersed from Central Asia (Zykin, 2012). In the Baikal region, the end Gelasian warm spell also showed a dispersal of the genus (as *C. praebaikalensis*) to the headwaters of the Lena River (Logachev, Popova, 1962).

The next extensive northward migration of *Corbicula* occurred during warm interglacials of the mid Middle Pleistocene (Holsteinian, etc.). The northern boundary of the range of this mollusc in the mouths of the Kama and Irtysh rivers reached 55-60° N, being 10-15° further north from its modern range. In Eastern Europe *Corbicula* is present in Holsteinian sediments in the Black and Azov seas regions. Likewise, the last appearance of *Corbicula* in NW Europe occurred at MIS11-7 (Meijer, Preece, 2000). The reliable presence of *Corbicula* in the middle latitudes of Eurasia during the Eemian (MIS5) interglacial has not been supported by unambiguous records.

The two waves of northward dispersal of *Corbicula* in Early and Middle Pleistocene represent the most important climatic and stratigraphic benchmarks, invaluable for deciphering the bioclimatic history of Northern Eurasia. The taxonomic position of the fossil forms of this genus needs a revision. The modern extensive invasion of *Corbicula* is mainly connected with human activity.

Legacy-based targets for restoration of the tropical montane forests of northern Ecuador

Nicholas Loughlin^{1,2,3}, William Gosling^{3,2}, Encarni Montoya^{4,2}

¹Northumbria University, Newcastle Upon Tyne, United Kingdom. ²The Open University, Milton Keynes, United Kingdom. ³University of Amsterdam, Amsterdam, Netherlands. ⁴Institute of Earth Sciences Jaume Almera, Barcelona, Spain

Abstract

Conservation and restoration efforts that aim to return an ecosystem to a desirable past state require a designated target against which success may be measured. Records of past ecological change, preserved in sedimentary archives can provide empirical data of ecosystem dynamics over periods beyond that of observational studies, offering a range of potential reference conditions. Here we identify possible restoration options for the tropical montane forest of the Andean-Amazonian corridor based on varying degrees of landscape and vegetation modification through time. Human disturbance of the landscape is viewed along a gradient of impact from a pre-human arrival tropical montane forest through to the intensely managed cultural landscape created by pre-European indigenous peoples. Ecosystem dynamics, vegetation composition and structure are characterised through three periods corresponding to an ancient (pre-human arrival), historic (indigenous land-use) and modern landscape (cattle farming), in order to provide restoration ecologists and resource managers information on various past reference states. In this study we propose that, following the depopulation of the indigenous American people (c. AD 1600), the mature and structurally functional montane forest that was established after ~ 130 years of forest recovery represents the most practical target for restoration efforts looking to re-establish a 'near-natural' vegetation community. The ability of palaeoecology to register long-term ecosystem change and vegetation response to ecosystem drivers can offer advice to conservation and restoration projects in landscapes that have undergone extensive and prolonged human impact.

Abstract

In Amazonia, most palaeoecological reconstructions have been dependent on pollen records from lake sediments. Unfortunately, the scarcity of such sites has hampered our understanding of the impact of Holocene climate change and pre-Columbian land use upon Amazonia's forests. Phytolith analysis, however, has the potential to circumvent this problem because, unlike pollen, phytoliths are well preserved in soils and can thus serve as an alternate, or complementary, proxy for reconstructing vegetation histories. Furthermore, unlike pollen, soil phytolith records provide comparable spatial resolution to 1 ha plot-scale ecological studies, enabling direct comparison between ecological and palaeoecological data. This PhD project addresses the following questions regarding Amazonian Bolivia:

1. What was the spatial scale of drought-induced forest die-back during the middle Holocene?
2. What is the relative importance of climate versus edaphic factors in controlling the dry forest-savanna boundary?
3. How does the mid-late Holocene fire regime compare between different types of tropical forest in the context of climate change and human land use?
4. How did pre-Columbian land use compare between fluvial and interfluvial rainforest settings?

Phytoliths, stable C isotopes and charcoal were analysed from 1 m soil-pit profiles from 1 ha plots from different types of forest across lowland Bolivia to create vegetation and fire histories extending to the middle Holocene, when the climate was drier than present. Selected sites are: (a) 'El Tigre' – inter-fluvial rainforest, Pando; (b) Tumichucua – fluvial rainforest at archaeological ring-ditch site, Pando; (c) Ottavio – dry forest/savannah boundary, Chiquitania; (d) Santa Cruz Botanic Garden dry forest – ecotone with Chaco-scrub.

Radiocarbon dates and stable C isotope data are pending, but previous studies suggest the soil profiles extend to ca. 6 ka BP. Preliminary findings:

1. The El Tigre site in Pando shows continuous presence of rainforest throughout the record, constraining the scale of mid-Holocene drought-induced forest die-back to within 650 km of the present-day rainforest ecotone at Noel Kempff Mercado Park (NE Bolivia).
2. The Ottavio plot also shows dry forest dominance throughout the 1 m profile, demonstrating resilience of dry forest to increased drought, and showing that edaphic factors are more important than climate in controlling the dry forest-savanna ecotone in Chiquitania.
3. Fire activity is lowest at the El Tigre interfluvial rainforest site (low flammability) and highest at the Tumichucua fluvial rainforest archaeological site (high anthropogenic burning), supporting the model of highest Pre-Columbian human impacts in fluvial settings.
4. Although palms are likely to have been an important resource for humans through the Holocene, as they are today, we find no relationship between palm abundance and human population density across space (Tumichucua versus El

Tigre) or time (mid-Holocene to present). 5. Despite construction of ring-ditches at Tumichucua, there is no evidence for significant pre-Columbian deforestation.

First palaeoecological evidence of Buffaloes husbandry and rice cultivation in the Kerinci Seblat National Park in Sumatra, Indonesia

Christina Setyaningsih¹, Hermann Behling¹, Asmadi Saad², Lyudmila Shumilovskikh¹, Supiandi Sabiham³, Siria Biagioni¹

¹Georg-August University of Goettingen, Goettingen, Germany. ²University of Jambi, Jambi, Indonesia. ³Bogor Agriculture University, Bogor, Indonesia

Abstract

Rice is one of the most important subsistence, however evidence of the origin and domestication of rice cultivation is still scarce in Indonesia. This study aims to trace the beginning of rice cultivation and buffalo husbandry in Sumatra, Indonesia. We carried out palaeoecological multi-proxy analysis of pollen and spores, non-pollen palynomorphs (NPPs) and macro-charcoal analysis on a sediment core from the swamp forest of Danau Bento (DB) in the Kerinci Seblat National Park (KSNP). Our results provide first evidence of buffalo husbandry in the Kerinci since at least 4300 years ago, in line with the migration of the Austronesians to Sumatra. NPPs and pollen results indicate the existence of grassland around the site until about 3200 cal B.P, which was used for buffalo grazing and not for rice cultivation. The rise of Poaceae about 2500 cal B.P suggests the beginning of rice cultivation in the swamp contemporary with a decline in grazing as shown by the NPPs. However, this phase lasted only few centuries until ca. 2100 cal B.P. Following the decline of rice cultivation, the swamp remained in use as a grassland for grazing.

Abstract

The Sago palm (*Metroxylon*) is an important food (starch) source across its range from Southeast Asia, New Guinea and the Pacific Islands. In Papua New Guinea *Metroxylon sagu* is cultivated in lowland tropical freshwater swamps, where it is a major staple food for around 10% of rural villages. The economic and cultural significance of sago in lowland PNG is immense, but the extent to which human populations have managed sago in the past is poorly understood. Here I review pollen and phytolith records from freshwater swamplands in the northern and southern lowlands (0-800m altitude) of Papua New Guinea and present a new record from Lake Kutubu in the Southern Highlands. The evidence shows the presence of *Metroxylon sagu* in association with lowland swamp forest disturbance (fire related) by at least 5000 yr BP, though it appears to undergo expansion in area planted after 1500 yr BP. This suggests that these environments were being managed for the production of sago at a time when swamp forests in the highlands of PNG were also rapidly declining in extent due to clearance for horticulture/agriculture. The links between past climate change and ENSO-related climate variability and food production in the New Guinea tropics will be discussed.

O-3138

Ancient wetland agroecosystems based on multiproxy excavation and LiDAR Imagery of the Maya tropical forest

Timothy Beach, Sheryl Luzzadder-Beach
University of Texas at Austin , Austin, USA

Abstract

Key hallmarks of indigenous alteration and adaptation of tropical forests were wetland agroecosystems. These occur and occurred in the tropical forests of South America, Africa, and East Asia, adapting local and regional environments and possibly influencing global climate over the Holocene. This paper synthesizes and presents new geoarchaeological and paleoecological records of wetland field complexes based on soil stratigraphy, geochemical, and pollen records. We compare perennial and seasonal ancient Maya wetland field complexes created from 3000 to 1000 years ago. Both areas have tropical forest vegetation with little evidence for human alteration since the Early Post Classic Maya period, about 1000 years ago. We present chronological and stratigraphic evidence of paleosols, sedimentation, and field formation. Our methods include AMS dating, typical soil analyses, magnetic susceptibility, XRF/XRD, pollen, and isotopic and elemental geochemistry of sediment sequences and water chemistry. Ancient farmers built the perennial wetland field and canals in the coastal plain of Belize sometime in the Maya Late Classic and these lasted until 1000 years ago in the Maya Terminal and Post Classic. Based on new Lidar imagery, possible wetland fields appear in many upland sinks of Belize and Guatemala's Peten. The paper presents these new LiDAR surveys with the first excavations into these possible canals and fields from the 2018 and 2019 field seasons. We interpret the extent, timing, formation of these fields compared with the large body of evidence we have produced for the perennial wetland field systems based on two decades of soil geomorphology, water chemistry, and archaeological study. We will thus compare multiple scales of long-term environmental change and multiple drivers of landscape formation over the early "Anthropocene" in these Neotropical fluvio karst depressions.

O-3139

The high dynamism of Western Amazonian lowlands: a long-term view of the vegetation communities of Yasuní National Park (Ecuador).

Encarni Montoya¹, Rommel Montúfar², Carmen X. Luzuriaga³, Valentí Rull¹

¹Institute of Earth Sciences Jaume Almera (ICTJA-CSIC), Barcelona, Spain. ²Pontificia Universidad Católica del Ecuador, Quito, Ecuador. ³Universidad Tecnológica Equinoccial, Quito, Ecuador

Abstract

Since the first pollen diagram presented in 1916 by von Post, the study of the vegetation long-term (>50 years) dynamics through the use of palynology has spread worldwide. However, this increment in the number of analyses has been patchy, with locations densely studied and other areas with still limited knowledge, as it is the case of the tropics. For instance, South American tropics and specially the lowlands (*Amazonia sensu lato*), represents a region largely understudied, thus limiting obtaining accurate information of the plant communities' dynamics of such an ecologically and economic important area. Some of the reasons for this low density of available studies are the difficulty of arriving and exploring the study area or the finding of suitable locations. Among the problems for finding suitable records, western Amazonia has been highlighted as a very geomorphologically active location, preventing the development of long, continuous, sediments spanning several thousand years without a sedimentary gap or hiatus. Here we present a Holocene sequence of western northern Amazonian lowlands, in the Ecuadorian Yasuní National Park. The sequence (PATAM25_B16, 0°41'07.1''S-76°25'58''W, 217 m asl), spans the last 6000 years, and pollen, non-pollen palynomorphs, and charcoal analyses have been performed. The beginning of the record is characterised by the presence of some disturbance indicators such as *Cecropia*, and Asteraceae and Anacardiaceae. Around 5000 years ago, the forest was characterised by high abundances of Urticales, Araliaceae, *Virola*, *Sterculia* and *Mimosa*. Other rainforest elements became important around 3000 years ago, including *Acalypha*, *Alchornea* and Malpighiaceae. Finally, the modern forest composition was established during the last millennium, with important contributions from *Hyeronima*, *Geonoma/Euterpe*, *Iriartea*, *Ficus*, and more recently, *Machaerium* and *Mauritia*. The results show the continuous presence of a rainforest, but with a high dynamism changing the abundance of the dominant taxa several times during the last 6000 years. In this sense, the forest with a higher evenness is the present-day one, established during the last millennium. It is suggested that the changes in the vegetation were primarily driven by geomorphological activity including changes in the drainage system, as well as human occurrence, which could have been only sporadic in the study area. Today, the study site is inhabited by Waorani indigenous, and it is subjected to oil extraction activities. The high dynamism of the forest and the unidirectional trends of the taxa shown in this record highlight the importance of studying in more details the trends of the current vegetation in order to secure the present and future ecosystem services of such unique location. Examining the Role of Natural and Anthropogenic Fire Activity on the Biogeographic Distribution of the Amazonian Rainforest Ecotone (ARE)

³University of Exeter, Exeter, United Kingdom. ⁴University of Reading, Reading, United Kingdom. ⁵University of Utah, Salt Lake City, USA

Abstract

Amazonian rainforest ecotones (AREs) are vegetation transition zones from rainforest to seasonally dry forests and savanna woodlands. AREs are vital ecosystems that play an important role in rainforest speciation, harbor high-levels of habitat heterogeneity (*beta* diversity), and provide migration corridors that allow species to shift geographic ranges in response climate change. Increased human activity has caused AREs to be one of the most heavily exploited and most threatened ecosystems in the Amazon. Fire plays an integral role in maintaining the biogeographic distribution of AREs. Synergies between direct human activity and indirect climate change impacts threaten to accelerate forest transformation through positive feedback loops by increasing future fire susceptibility, fuel loads and fire intensity. In the upcoming century, a reduction in annual precipitation in the region is expected in response to deforestation and reduced evapotranspiration, while natural- and human-caused ignitions are projected to increase fire in AREs. The combined results will likely drive the expansion of savanna woodlands at the expense of rainforest vegetation. To date, however, the long-term factors driving fire in AREs remain poorly understood because of the challenge of disentangling the effects of prolonged climatic variability and over 7,000 years of human land-use in the AREs. Thus, the long-term role of fire in shaping the biogeographic distribution of Amazon ecotones remains elusive. To address this issue, an interdisciplinary framework incorporating fossilized macrocharcoal (>125 μm) and stable carbon isotopes from large (>20km²; for regional paleofire reconstructions) and small lakes (< 5km²; for local scale paleofire reconstructions) traversing the Bolivian ARE are compared with existing palaeoclimatological and regional archaeological data to investigate the potential natural and anthropogenic drivers of fire activity since the Last Glacial Maximum (LGM ; ca. 21,000 cal BP). Together these records indicate an expansion of C₄ grasslands in the ARE during the LGM. Despite the presence of drought and fire adapted C₄ vegetation, fire is at its lowest point which is attributed to cooler temperatures and decreased fuel connectivity. C₄ grasslands are gradually replaced by in C₃ woody vegetation during the early Holocene coupled with an increase in fire activity around the smaller lake basins while fire activity remains low around larger lake basins. These data suggest the higher sensitivity of small basins to detect changes in local-scale paleofire activity. However, during the mid-Holocene (~6,500 cal yr BP) the small basin charcoal records become asynchronous despite similar regional climate conditions in the Bolivian lowlands. Increased evidence of human occupation during this period combined with intensified crop cultivation, may potentially explain the increased heterogeneity of local-scale fire regimes, further contributing to the biogeographic distribution and diversification of AREs in the Bolivian Amazon.

Exploring the climate of South Africa during the Extended LGM: lessons from proxy evidence

Jennifer Fitchett

University of the Witwatersrand, Johannesburg, South Africa

Abstract

Located at the transition between the mid-latitudes and the sub-tropics, southern Africa has a climatic dichotomy between zones of winter- and summer-rainfall. The latitudinal extent of the winter-rainfall zone during the Extended Last Glacial Maximum (LGM), the regional changes in rainfall amount, and the extent of the temperature depression remain points of contentious debate, spanning divergent disciplines of palaeosciences. The synoptic scale shifts in the latitudinal position of the westerly belt, a function of the expansion of Antarctic sea ice and the contraction of the tropical Hadley Cell, represents the greatest driver of regional to local scale climatic changes during the extended LGM in South Africa. The accurate determination of precipitation seasonality for a given location is important in inferring the concurrent shifts in mean annual precipitation, water availability and temperature. While previous interpretations of precipitation seasonality during the LGM have relied heavily on the geomorphological record, more recent analyses have involved more continuous palaeoclimatic reconstructions utilising interpretations of more complex measures of water availability inferred from isotopes, pollen, diatoms and fossil rodents. These methods represent developments in proxy interpretation, which are necessarily highly location specific in their application, yet contain significant overlaps with the reconstruction of concurrent temperature and rainfall changes which present challenges in quantifying the changes for individual climate variables. Critical reflection of their validity, both in determining the contemporary validity of such proxies, and the potential for long-term seasonal reconstruction is thus essential. This paper outlines the current understanding of palaeoclimates during the extended LGM in South Africa on the basis of proxy evidence including pollen, minerogenic microfossils and micromammalian remains, considering the spatial and temporal heterogeneity in the regional record.

Environmental change at high altitude sites in southern Africa during the last glacial maximum

Stephanie Mills^{1,2}, Timothy Barrows^{1,3}, Mike Morley⁴, Keith Fifield⁵

¹University of Wollongong, Wollongong, Australia. ²University of Plymouth, Plymouth, United Kingdom. ³University of Portsmouth, Portsmouth, United Kingdom. ⁴Flinders University, Adelaide, Australia. ⁵Australian National University, Canberra, Australia

Abstract

Southern Africa is located at the junction of three of the world's major oceans and is affected by subtropical and temperate circulation systems, making it ideal for the study of past environmental change. Cold climate landforms present at high altitude sites allow for the timing of cold events to be determined through dating and for the reconstruction of past climatic conditions at the time of their formation. In addition, archaeological evidence from high altitude sites allows us to explore how humans reacted and adapted to environmental change during the last glacial maximum.

Here we summarise work that has been undertaken at high altitude sites in Lesotho and the Eastern Cape Drakensberg, and we present new ages for the timing of glaciation in Lesotho based on surface exposure dating using ^{Cl-36}. In Lesotho, geomorphological evidence in the form of moraines at a number of sites dated to the last glacial cycle attest to cold temperatures at the time of their formation. Glacier reconstructions, including steady-state mass balance and flow dynamics, suggest that temperatures during this time were approximately 6 °C colder than present, consistent with other proxy records from southern Africa. The occurrence of glaciers at these high altitude sites in Lesotho suggest a seasonal shift towards cold-season precipitation. In comparison, high altitude sites in the Eastern Cape Drakensberg retain no evidence for glaciation, however there is widespread evidence for periglacial activity down to an elevation of 1700 m a.s.l. Periglacial deposits dated to the last glacial cycle corroborate a 6 °C temperature depression during this time.

Archaeological evidence suggests that humans were present in the highlands at ~24 ka, despite the evidence of reduced temperatures and arid conditions at this time. Lesotho would have been attractive to hunter-gatherer populations due to the perennial surface water availability, in contrast to many regions of the sub-continent. The period ~23-17 ka is, however, represented by low frequencies of radiocarbon ages in the archaeological record, suggesting that hunter-gatherers reduced visits to the high Drakensberg during this time as a result of particularly cold conditions. Sustained reoccupation commenced after 17 ka, however the Eastern Cape appears to have remained unoccupied during this period, possibly reflecting climatic heterogeneity across southern Africa at this time.

Last Maximum Glacial records in the Rio Blanco basin (32° S), Argentinean Central Andes.

Stella Moreiras

CONICET, Mendoza, Argentina. Universidad Nacional de Cuyo, Mendoza, Argentina

Abstract

Throughout the Andes, the glacier history reveals that glaciers had a maximum extension during the Last Glacial Maximum (LGM) and the Late Glacial, with rather consistent ages of ca. 31–18 ka BP and 18–12 ka BP from Alaska to Southern Chile (Clapperton, 2000). Diachronic intervals of glacier advances have been determined for the humid tropical Andes, the Central Andes of Argentina and Chile, and the Patagonian Andes (Zech et al., 2008). However, a regional glacial chronology is not yet fully established for the Central Andes. Late glacial advances were distinguished both in the subtropical Andes (Espizúa, 1999; Espizúa, 2004; Zech et al., 2005; Zech et al., 2007) and Patagonia (Rabassa et al., 2011), where drifts identified between ~36°-39°S have been interpreted as LGM in age. However, climatic archives show a complex pattern of timing and even antiphase climate responses in the arid Central Andes (Grosjean et al., 2003; Font and Chiesa, 2015). Knowledge about timing is severely limited in this region due to the scarcity of organic material for radiocarbon dating.

In the Blanco River Basin (BRB), a number of ambiguous Quaternary glacial stages have been proposed (Corte, 1957; Polanski, 1958, 1965; Wayne, 1981; Wayne and Corte 1983). Wayne (1981) proposed at least four main glaciations along the BRB that would have reached very low altitudes near the confluence of the Mendoza River valley (1400 masl). Assuming temporal correlations with Northern Hemisphere Glaciations and using relative dating techniques (e.g., soil development, loess thickness, block weathering degree, and preserved morphology) a tentative chronology for glacial deposits was suggested (Wayne and Corte, 1983). The Vallecitos Glaciation, evidenced by moraine deposits (Vallecitos I) and moraines related to fossil rock glaciers (Vallecitos II) located above (2600 to 3400 masl) were assigned to the Late Pleistocene. The authors proposed a speculative age of 17–22 ka BP for Vallecitos I and 12–16 ka BP for Vallecitos II.

This work presents the first numerical cosmogenic ages of glacial deposits from the eastern slope of the Plata peak (6200 masl) along the BRB (32°S). Surface boulders on the top of moraines were sampled for Be10. Obtained ages fit very well with local stratigraphy and regional paleoclimate evidence. The Loma de los Morteritos moraine II (3000 masl) was dated to ~25,000 years, while ages of ~8,000 and ~12,000 years were found for the Angostura II deposit (~3300 masl). These ages could be evidencing the Last Glacial Maximum (LGM) period for this region.

Annually-resolved (varved) record of ice sheet–climate interaction at the onset of the Last Termination in central Patagonia (46.5°S)

Jacob Bendle, Adrian Palmer, Varyl Thorndycraft, Ian Matthews

Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom

Abstract

Records of former ice sheet behaviour have proven vitally important in understanding the southern mid-latitude terrestrial response to climate variability during the Last Glacial Maximum and Last Termination (35–15 ka ago), with key studies contributing to conceptual models of ocean–atmosphere dynamics during this interval, such as the nature of wind belt and Southern Ocean frontal migration. Such records have relied primarily on cosmogenic nuclide exposure dating of glacially-transported boulders and/or luminescence dating of outwash sands to constrain past glacier dynamics. While effective, the resultant archives may be fragmentary or biased towards periods of glacier stability (e.g. moraine construction) and are typically limited to millennial-scale chronological precision.

By contrast, varved sediment sequences accumulated in former proglacial lakes offer the potential to develop continuous, annually resolved records of past glacier dynamics during periods of climatic change. Here we utilise a ~1000-year duration varve record from Lago General Carrera (Chile)–Buenos Aires (Argentina; 46.5°S) to reconstruct the retreat behaviour of a major Patagonian Ice Sheet outlet glacier between ~18 and 17 ka. The annual incremental record is tied to the calendar-year timescale via tephrochronology and offers unprecedented insights into the interplay between southern mid-latitude glacier and climate variability at centennial (i.e. through ice-margin position changes) and sub-centennial (i.e. through glacier ablation and sediment flux changes) temporal resolution.

Using annual sediment flux (varve thickness) data (and through comparison with regional palaeoclimate records and modelling data) we infer that distinct changes in ice lobe retreat dynamics coincide with several major climate shifts, namely an abrupt migration or weakening of the Southern Westerly Winds at ~18.0 ka, followed by a lagged oceanic and atmospheric warming associated with the propagation of hemispheric climate anomalies through the oceanic bipolar seesaw. Under this background of centennial scale glacial change, we also detect significant interannual to decadal cyclicity in the thickness of annual sediment layers (varves). The identified cycles are suggestive of El Niño–Southern Oscillation (ENSO) and/or Southern Annular Mode (SAM) influences on regional ice sheet ablation rates, likely through controls on Southern Westerly Wind strength and/or location and regional solar radiation receipts. This new evidence hinting at climate teleconnections between the tropics and the southern mid-latitudes at the onset of the Last Termination is consistent with reconstructions of coupled ocean-atmosphere frontal shifts at that time, and some climate model simulations that predict enhanced ENSO variability during this time period.

Abstract

The SHeMax (The LGM in the Southern Hemisphere) project seeks to develop a greater understanding of the timing, duration and nature of the LGM in the Southern Hemisphere. It is centred on the period 35-15 ka, encompassing the termination of the last glacial cycle, and the traditionally accepted timing of the global LGM (24-18 ka). Emerging evidence suggests that instead of being a relatively short event centered on 21 ka, the LGM in the Southern Hemisphere may have been an extended period of time, with an early onset at 35-30 ka. It has also been suggested that the LGM was not uniformly cool and dry but may have been characterized by millennial-scale variability.

New Zealand's unique physiography, and position spanning the middle latitudes of the Southern Hemisphere produces a dynamic climate, with teleconnections to a range of tropical and polar climate processes. In New Zealand, evidence for an extended LGM period was initially recognised through pollen-based palaeovegetation records, glacial evidence, and aeolian quartz sequences. These archives indicated that glacial conditions prevailed across most, if not all, of New Zealand during the interval 29–18 ka, much longer than the 'traditional' timeframe of 24-18 ka. This interval was subsequently dubbed the 'Last Glacial Coldest Period' (LGCP). Variations in pollen spectra, supported by other proxies (beetles, chironomids and plant macrofossils) provided for further subdivision of the LGCP into a series of 3 stadial and 2 interstadial events, which correspond reasonably well with the timing of terminal moraine formation from around New Zealand at ca. 28 ka, ca. 22 ka and ca. 18 ka.

In this presentation, we draw together proxy climate and environmental records derived from speleothems, lacustrine sediments, peat sequences, glacial sediments and moraines, and ocean sediment cores from the New Zealand region to illustrate the latest in our understanding of the climate and environmental variability over the SHeMax timeframe. We link our records chronologically through various dating approaches, including cosmogenic isotopes, tephrostratigraphy, Uranium-Thorium and radiocarbon. We focus on three particular events during the timeframe: 1) the onset of the LGM; 2) the period of maximum cooling; and 3) Termination 1. We compare and contrast how these events were captured across the different proxies, in terms of both timing and magnitude, and assess how variations in timing and magnitude between proxies can be interpreted in terms of the different climate and environmental drivers to which each proxy was responding.

¹ANSTO, Sydney, Australia. ²Uni of Griefswald, Griefswald, Germany. ³Uni of Queensland , Brisbane , Australia

Abstract

Recent debate on mid-latitude New Zealand glaciation has focused on reconstructing paleo-climate conditions leading into the (global) Last Glacial Maximum and subsequent deglaciation dynamics during the last termination. Paleo-environmental evidence coupled with reliable glacial chronologies confirms significant differences from that observed in northern hemisphere signatures of glacial change. The New Zealand glacial record does not show glacial readvance and strong cooling commensurate with Younger Dryas timing (~11.7-12.9 ka) and many lake pollen records suggest a minor cooling or hiatus in warming during the period from ~14.5 – 12.0 ka that is more commonly associated with the Antarctic Cold Reversal (ACR) (~14.7 - 13.0 ka). The Arthur's Pass Moraine complex at 950 masl, deposited by an alpine glacier advancing out of the Otira Valley splaying east and westward over the divide of the Southern Alps in New Zealand, exhibits a full post-LGM glacial chronology. We have determined paired ^{10}Be and ^{26}Al exposure ages from 58 greywacke samples taken from all major moraines. Calculated exposure ages (using accepted local NZ production rates) show that the Arthur's Pass moraine system spans a period of 19.5 ka to 12.0 ka with mean recessional moraine ages in chrono-stratigraphic sequence. The overall timing of deglaciation after peak LGM conditions is similar to the glacial systems we have dated in the Rakaia, Waimakariri and Rangitata Valleys. The Misery sequence shows ice retreat at the end of the ACR and no major advance during the YD period. Multiple cores from two intermorainal bog (Lances and Misery Tarns), separated by ~1 km and constrained by the terminal Dobson and Misery moraines, have been recovered for paleo-climate study. Basal glacial silts and organic matter have provided radiocarbon ages representing a minimum age for glacial retreat. Combined with the Misery moraine cosmogenic concentrations, new ^{10}Be and ^{26}Al production rate calibrations can be made for New Zealand to improve exposure age accuracy.

Abstract

The Antarctic Peninsula is undergoing accelerated environmental changes in response to changing climate patterns over the last decades. In this context, understanding the calendar of deglaciation is crucial to frame past changes with recent trends. To this purpose, nunataks are excellent areas to examine the mechanisms and rates of glacial retreat during the deglaciation process as well as environmental dynamics during the paraglacial phase, particularly vegetation colonization.

In January 2017 we collected 26 samples from three (paleo)nunataks (Chester, Cerro Negro and Clark), composed of basaltic rocks, in the Byers Peninsula (South Shetland Islands, Antarctica), a 60 km² ice-free area in this archipelago where our knowledge of the spatio-temporal pattern of deglaciation was only based on a few radiocarbon dates from basal lacustrine sediments. Samples from polished surfaces at different elevations from the top to the base of these three volcanic plugs were selected for ³⁶Cl surface exposure dating.

The data show evidence that glacial thinning already started during the Last Glacial Maximum, with the tops of nunataks becoming ice-free between 26 and 19 ka. A first stage of massive deglaciation occurred until 17-16 ka, when the highest parts of the nunataks in the Byers Peninsula were deglaciated. A relative stability of the ice cap occurred until 12-11 ka, followed by another massive glacier retreat with rapid ice thinning that exposed the land surface of the central plateau of Byers by 8-5-7.5 ka. This is also in agreement with lake records that also showed evidence that the Chester and Cerro Negro hills were no longer isolated nunataks by that time. Despite the fact that the eastern fringe of nunatak Clark is still connected with the Rotch dome glacier, the deglaciation followed a similar pattern, with its western side becoming ice-free by 7.5 ka. Small glacier advances were recorded during the Late Holocene.

These new data on the deglaciation of currently ice-free areas in the South Shetland Islands opens new perspectives for vegetation colonization of ice-free areas in the Antarctic Peninsula as well as for the interior of the continent. The first ice-free areas appeared much earlier than known to date, which has major implications for the diversity of species and its distribution.

Stable carbon isotope analysis on fossil *Cedrus* pollen shows climatic aridification in Morocco during the last 5000 years

Benjamin Bell¹, William Fletcher¹, Henk Cornelissen¹, Helen Grant², Peter Ryan¹, Christoph Zielhofer³

¹The University of Manchester, Manchester, United Kingdom. ²Centre of Hydrology and Ecology (CEH), Lancaster, United Kingdom. ³Leipzig University, Leipzig, Germany

Abstract

Quantitative climate reconstructions from pollen typically rely on empirical relationships between pollen abundances or assemblages and climate, such as the modern analogue technique. However, these techniques may be problematic when applied to fossil sequences as they, for example, cannot separate anthropogenic from climatic influence on pollen assemblages.

On the other hand, geochemical analysis of pollen allows quantitative relationships to be established with environmental and climatic conditions which directly influence the pollen geochemistry. Stable carbon isotope analysis on fossil pollen allows for reconstruction of moisture availability and aridity conditions. This approach is based on well documented plant physiological responses to moisture stress and is therefore independent from vegetation composition.

We reconstruct mid- to late-Holocene aridity in the Middle Atlas, Morocco, using stable carbon isotope analysis on isolated fossil *Cedrus* pollen. *Cedrus atlantica* (Atlas cedar) is an endemic tree found across North Africa, growing in sub-humid and semi-arid mountainous environments. It has been present in the region throughout the Holocene and Late Glacial period. As an early autumn pollinating tree where pollen develops over the summer months, it is an ideal species for reconstruction of summer aridity in Morocco, and indeed North Africa.

We find that there has been a general long-term trend of increasing summer aridity in the region during the last 5000 years. Pollen records show a gradual decline of *Cedrus* forest during the late-Holocene which follows the increase in summer aridity. Our findings indicate that climate has become drier, confirming the mid- to late-Holocene aridification trend, as seen elsewhere in the western Mediterranean, using a novel proxy for this region. The findings also help to resolve the often conflicting signals of climate change interpreted from pollen assemblages alone, while this technique has good potential for wider application in similar environments.

Abstract

The Villarquemado palaeolake sequence provides a unique palaeoenvironmental record from the western Mediterranean Basin spanning the interval from the end of MIS6 to the late Holocene. The pollen and sedimentological record from Villarquemado provides qualitative information about changes in temperature seasonality and moisture conditions. Here we use Weighted Averaging Partial Least-Squares (WA-PLS) regression to derive quantitative reconstructions of winter and summer temperature regimes, expressed in terms of the mean temperature of the coldest month (MTCO) and growing degree days above a baseline of 0° C (GDD₀) respectively. We also reconstruct a moisture index (MI), the ratio of annual precipitation to annual potential evapotranspiration, taking account of the effect of low CO₂ on water use efficiency. We reconstruct a relatively rapid summer warming at the beginning of MIS5. Summers are relatively cold during MIS4 and MIS2, but there are intervals in MIS3 (and, counterintuitively, also at the beginning of MIS 2) characterized by summers as warm as during the warmest phases of MIS5 or the Holocene. However, MIS3 is not significantly warmer in winter than other intervals during the glacial, and indeed there is a gradual decline in winter temperature from MIS4 through MIS3 to MIS2. The ecophysiological effects of changing CO₂ concentration through the glacial cycle has a significant impact on reconstructed MI. Conditions become progressively more humid during MIS5 and MIS4 is also relatively humid, while MIS3 represents the most arid phase of the glacial. The highest values of MI are reconstructed during the deglaciation and there is a pronounced increase in aridity during the Holocene. These changes largely reflect orbitally-controlled changes in climate and its seasonality, but the record also provide insights into superimposed millennial-scale climate variability and its impact on vegetation dynamics.

¹University of Wollongong, Wollongong, Australia. ²University of Cologne, Cologne, Germany. ³British Geological Survey, Nottingham,, United Kingdom. ⁴National and Kapodistrian University of Athens, Athens, Greece. ⁵University of Pisa, Pisa, Italy. ⁶National and Kapodistrian University of Athens, Athen, Greece. ⁷British Geological Survey, Nottingham, United Kingdom. ⁸University o Nottingham, Nottingham, United Kingdom

Abstract

Due to the lack of appropriate analytical methods, high-resolution studies on the frequently non-linear interplay between climate, vegetation, and anthropogenic activity that severely impact the landscape through geological history are challenging. To address this, catchment-wide erosion processes have been quantified by means of novel uranium (U) isotope analyses on a lacustrine sediment succession from Lake Ohrid (FYROM, Albania) on the Balkan Peninsula. The new proxy is applied using the same material from which the climatic and environmental history has been inferred by means of conventional proxy analyses, such as pollen (for vegetation development and paleoclimate), carbon isotopes (for soil development), and (bio-)geochemical data (for soil development and paleoclimate). The comprehensive understanding of catchment-wide erosion processes and detrital matter delivered to the lake, as inferred from uranium isotopes, also helps to better understand the paleoclimate signal recorded in the sedimentary archive.

Uranium isotopes ($(^{234}\text{U}/^{238}\text{U})$ activity ratio) determine the time that has elapsed since physical and chemical weathering have formed silt and clay-sized detrital matter as the $(^{234}\text{U}/^{238}\text{U})$ activity ratio decreases in fine-grained grains $<63\mu\text{m}$. Deep weathering horizons, where fine-grained detrital matter is produced close to the regolith-bedrock interface, consequently have lower ratio $(^{234}\text{U}/^{238}\text{U})$ activity ratios than shallow soil horizons. Consequently, a lower $(^{234}\text{U}/^{238}\text{U})$ ratio in sedimentary deposits indicates shallow erosion, while a higher ratio reflects deep erosion.

A consistent pattern of soil erosion in response to rapid climate variability is inferred for the Late Glacial and Early Holocene, with shallower erosion (sheet wash) prevailing during cold and dry periods such as the Younger Dryas. Humid (and warmer) time intervals (Bølling/Allerød and Early Holocene) are characterized by deeper erosion, such as gully erosion. A pronounced shift in uranium isotope compositions indicates that stabilization of hillslopes by vegetation crossed a threshold at the Early to Mid-Holocene transition ($\sim 8,300$ cal a BP), preventing deep erosion of thin soils in the catchment of Lake Ohrid. Hillslope stabilization and the threshold in catchment erosion are not mirrored by soil development over time, as inferred from carbon isotopes and elemental ratios. Human land use during the Late Holocene is reflected by reduced soil development.

Abstract

A new sediment core from Padul wetland (Granada, southern Iberian Peninsula) provides a long and continuous paleoenvironmental record of the last ~200,000 years. This study aims to reconstruct the regional vegetation and local paleoenvironmental signal of the last two glacial-interglacial cycles from the southern Iberian Peninsula and the western Mediterranean region. Pollen analysis from this core shows orbital-scale vegetation oscillations (mainly forced by precession and eccentricity) pointing into insolation as the principal factor controlling vegetation changes at this latitude. Lake level reconstruction based on palynological data showed that local paleoenvironmental changes seems to be related to precipitation/evapotranspiration balance, and therefore, to changes in regional climate conditions. In addition, high siliciclastic/detrital input in the wetland carried from Sierra Nevada range have been related to enhanced soil weathering/erosion during regional aridity and lower forest cover recorded by the arboreal pollen data. Therefore, the combination of different proxies have provided good information not only about regional vegetation but also about detrital input and lake level evolution in the wetland during the last ~200 kyr.

O-3152

Trends and anomalies in the Mediterranean palæoarchive

Belen Martrat

Spanish Council for Scientific Research, Institute of Environmental Assessment and Water Research (IDÆA-CSIC),
Barcelona, Spain

Abstract

The demise or flourishing of societies as a simple reaction to climate is never a fully satisfactory explanation. Predictable long-term trends facilitate adjustment of civilizations, and interactive processes of cultural and technological transformation become predominant factors. Nevertheless, societies may recall anomalies, i.e. prominent departures from previous average conditions, frequently with local particularities and hard to predict. In the Mediterranean context, an anomaly could be a period of sustained cold/wet summers or exacerbated cold/dry winters.

In this study, a compilation of Mediterranean sites is used to determine interactions between atmospheric, marine, cryosphere and terrestrial climate elements. These records allow us to identify climatic structures and discuss interhemispherical connections at multi-decadal resolution over the last two deglaciations and interglacials and over the past glacial.

None of anomalies recorded was an exact reproduction of the others because patterns of spatial and temporal evolution of the climate elements involved were never identical. However, some common features can be identified in their development:

- Firstly, anomalies can contain an abrupt warming event (e.g. as much as +4°C in few centuries), commonly in the middle of their progression
- Secondly, even when early cold conditions are registered, the maximum wind strengthening, aridity take place after the warming event, during a cooling phase as rapid as the warming; periods of scarcity of continental ice near the north Atlantic do not necessarily imply a more stable climate; in fact, quite the opposite, as some of the most extreme rapid cooling events occurred under these climate conditions.
- Thirdly, the warming event establishes a climate shift from one state to another, which differs depending on the relative occurrence of the anomaly with respect to precessional oscillation. The most prominent anomalies occur during periods around perihelion passage in NH spring equinox, in line with maximum extent of ice sheets, preceding deglacial processes. Anomalies linked to acceleration of the increase in ice volume accumulated on land, occur close to perihelion passage in the NH winter solstice. During such anomalies (for instance, 117200 years ago or 115300 years ago or 2800 and 700 years ago; Tzedakis et al., 2018, NATURE COMM.; Martrat et al., 2014, QUAT. SCI. REV.), climate change making an impact on societies cannot be ruled out completely. For instance, the most notable aspect of climate during the Little Ice Age (Abram et al., 2016, NATURE; McGregor et al., 2015, NATURE GEO.) was its great year-to-year variability: extreme events, prolonged droughts during the winter and spring seasons and then deluges or catastrophic floods during late summer and early autumn; severe winters, advances of high mountains glaciers. Other events happening around perihelion passage in the NH autumn equinox or summer solstice share complex characterisation, and appear implicit in predictable long-term trends.

Abstract

Sea surface temperature reconstruction (SST) over the last millennia in the Mediterranean area represent an important challenges to document the possible link of past climate variability on the rise and fall of ancient civilizations. In addition, the last report of the Intergovernmental Panel on Climate Change (IPCC 2018) underlines the requirement to assess climate feedbacks during past episodes of moderately warmer (1.5°C-2°C) conditions. Within this framework, we present the reconstruction of the SST anomaly over the last five millennia based on the Mg/Ca ratios measured in the planktonic foraminifer *Globigerinoides ruber* from the sediment core SW104-ND11 extracted in the western part of Sicily Channel (water depth 475 m, central Mediterranean Sea). This new generated SST record is compared with previous published SST records reconstructed from Alboran Sea, Minorca Basin, Aegean Sea and from a north Hemisphere temperature reconstruction. This exercise brings the basses to discuss the regional impact of the most recent episode of apparently warmer conditions than present in the social-economical development of the Mediterranean region.

According to the Mg/Ca *G. ruber* SST record, the Late Holocene maximum temperatures (22.7°C) were reached at ca. 424 CE during the Roman period, after an overall warming trend that started at ca. 3300 BCE and was punctuated by several abrupt short term oscillation. After the Roman period, the Mg/Ca *G. ruber* SST record shows a cooling trend reaching the minimum temperature (18.2°C) at ca. 1673 CE, during the Little Ice Age. During the last three centuries the Mg/Ca *G. ruber* SST record shows warming trend to present day (20.3°C). The comparison of the studied record with other SST records, based in both Mg/Ca and alkenone proxies from several areas of the Mediterranean basin, supports homogeneous warm conditions at regional scale between from 100 BCE to 500 CE, and documents the occurrence of a distinct warming phase of ca. 2°C at the beginning of the Roman Period that led to the so called “Roman Climatic Optimum”. This period corresponded to an important demographic increase during the Roman Empire. At ca. 600 CE a cooling phase is recorded, which age corresponds to the Late Antique Little Ice Age (LALIA) event; after this event, the SST Mg/Ca *G. ruber* reconstruction documents the onset, at ca. 1180 CE, of the well-known Medieval Warm Period. The cooling associated to the Little Ice Age event occurred between 1320 CE and ca. 1850 CE with an anomaly of ca. 2°C vs negative values. The studied record of Sicily Channel ends with a turnover from ca. 1850 CE to 2014 CE vs a warming phase of ca. 1°C probably associated to the onset of the Industrial Period/Modern Warm Period. This research was financially supported by NEXTDATA and ERC-TIMED 525 (683237) projects.

⁵Department of Environmental Chemistry IDAEA-CSIC, Barcelona, Spain. ⁶Universitat de Barcelona, Barcelona, Spain

Abstract

During MIS 12 deglaciation the Earth underwent the loss of a wide continental ice sheet in the Northern Hemisphere, which was larger than during the last glacial maximum. In order to clarify the timing, origins and dynamics of the freshwater entrance during this glacial Termination, eastern-western Mediterranean gradients were studied through a quantitative study of the planktonic foraminifera assemblages carried out in two cores: ODP 977 and KC01B.

Additionally, the isotopic composition of surface water ($d^{18}O_{sw}$) was calculated using the calcite shell measurements of *Globigerina bulloides* and *Neogloquadrina pachyderma* dextral. These values have been corrected for ice volume and sea surface temperature (SST), the latter calculated using the artificial neural networks (ANN) method.

In general, low isotopic values were found in both basins during the whole deglaciation period. However, three episodes with maximum abundances of polar planktonic foraminifer species - *Neogloquadrina pachyderma* sinistral and *Turborotalita quinqueloba* - are highlighted in the record. Those episodes are associated with Mediterranean freshening events since they correlate to decreases in the $d^{18}O_{sw}$. Although major freshening events in the Mediterranean are described in the literature as a result of the release of Laurentian icebergs and the consequent entry of melt-waters through the Strait of Gibraltar, our study points also to the disruption and melting of the European reservoirs in the first part of the deglaciation, from both Fennoscandian and British ice sheets. The intervals with larger isotopic drops in the eastern Mediterranean indicate a possible extra source of fresh water from the southern Alps and the Apennines, melting through the Po River, and/or Black Sea outflows.

According to our planktonic foraminifer assemblages, before MIS 11 begins there is a sharp warming in the Mediterranean and an increase in $d^{18}O_{sw}$, reaching values similar to those at present.

The exceptional flash flood in Central Bohemia in May 1872: really so strong event?

Libor Elleder¹, Jakub Krejčí¹, Jan Daňhelka¹, Stanislav Racko², Jolana Šírová¹, Ladislav Kašpárek³

¹Czech Hydrometeorological Institute, Praha, Czech Republic. ²Czech Hydrometeorological Institute, Praha, Slovakia.

³T. G. Masaryk Water Research Institute, Praha, Czech Republic

Abstract

The flash flood occurring on May 25, 1872 ranks among the most extreme events recorded within the Czech Republic. The causative torrential rain affected approximately 2000 km². A corresponding intensity of precipitation observed incidentally at two sites exceeded 200 mm in 3-8 h. The consequent flood caused tremendous damages to ponds, houses, and infrastructure and resulted in a temporary collapse of transport especially due to a total break of trains operation. The flood led to approximately 240-300 fatalities according to various sources. An extent of the total area affected reached approximately 2000-3000 km² representing an unusually large scale for such a type of flood. The intensive rain and inflow caused for Czech territory the biggest rupture of a water reservoir in Mladotice so far. The respective Mladotice pond held very likely more than 5 million cubic meters of water before its rupture. With a delay of 2 to 3 days, a substantial saturation triggered a massive landslide blocking the Mladotice water stream and creating a new water body named the Odlezly Lake. The flood event motivated elaboration of at least 5 scholarly papers already between 1872 and 1875. Accordingly, this flood presents for Czech hydrologists an outstanding example of such an incredible magnitude until now. The flood in 1872 and drought in 1874 led directly to establishing the Hydrological service of the Czech Kingdoms in 1875. Hitherto, we have no comparison for such extreme flood including recent floods occurring in 2002, 2010 and 2013. The flood peaks exceeded other historical or recent floods by at least 1-2 m. As there were no regular hydrological observations including precipitation measurements available for the affected areas before 1883, the prevailing data source comprise documentary sources and their relevant interpretations. The aim of our study is to explain in a more detail the course of this flood and a number of indeterminate circumstances during the flood. An important question was an effect of the collapse of approximately 100 ponds and a role of the collapsed sizeable Mladotice pond. These phenomena were partly explained by newspapers and chronicles describing an incredibly rapid increase of water level at a relatively large number of sites. We have completed a hydraulic estimation of peak discharges at major profiles. In our research we used the Agualog hydrological modelling system. The hydrological modelling enabled us to complete and check the reliability of observed causative precipitation for the affected area and peak flow rates at the Beroun and Prague municipalities. This flood is of crucial importance for the Prague flood protection system. The main reason being a short time span of 22 hours between the beginning of causative rainfall and occurrence of maximum flood flow rate at Prague.

O-3156

Identification of extraordinary floods in the Late Holocene fluvial deposits of the Copiapó River (southern Atacama Desert, Chile)

Tatiana Izquierdo, Ai-ling Rivera, Manuel Abad
Universidad de Atacama, Copiapó, Chile

Abstract

After the last two extreme hydrometeorological events that caused large floods in the southern Atacama Desert, March 2015 and May 2017, knowledge of extreme event patterns has become necessary for understanding disaster risk and strengthening disaster risk governance. Although extremes are an intrinsic characteristic of the hydrological regime in this arid region, short gauge records difficult their characterization and the paleohydrological study of the fluvial Quaternary sequences can be used to address this issue. With this aim, we have first focused in two outcrops located in the Lower Copiapó basin, upstream and downstream of the Angostura sector. Here, the valley, which drains at this point a catchment area of 18,000 km², narrows and incises the Palaeozoic bedrock forming a 10.5 km long canyon. Mean annual discharge rate in the study area, near its mouth, is 0.43 m³/s. Despite this low value, extraordinary floods with peaks discharges more than 500 times the mean occur (240 m³/s in the March 2015 event).

In Angostura, a low bench with multiple flood units was recognized. Upstream the canyon deposition of suspended sediment and bedload occur controlled by the constriction while downstream, changes in the valley geometry result in a reduction of the flow velocity. At the base of section A (upstream), a relatively thick (80 cm) calcareous tufa level, related to a paleowetland environment, appear overlaid by 5 flood units. The deposition period for these flood units is well constrained: 1) 1390 – 1445 AD below the tufa; 2) 1628 – 1803 AD above flood unit 1; and 3) March 2015 flood unit 5. Section B can be separated in four sets. The lower set comprises two flood units, interbedded between shale and peat deposits, consisting of fine sands with rizolites. The second set contains four successive flood units of silty sand while the third set includes only one event. Finally, in the uppermost set three flood units appear consisting of silty sand with undulated and upper plane bed horizontal lamination as well as fluid scape structures. Set one ranges from BC 541 – 370 to BC 234 – 66 and denotes wetter conditions than present ones. The base of set four has been dated as 1810 – 1839 AD. The paleodischarge estimation of the three more recent flood units will allow increasing the extreme event discharge record to the beginning of the 19th century what combined with the analysis of the historical record will help reconstructing the paleoflood history of the arid Copiapó basin.

Spatio-temporal variability of modern sediment composition in Baker fjord (Chilean Patagonia, 48°S): A pre-requisite for paleohydrological reconstructions

Benjamin Amann¹, Elke Vandekerkhove¹, Brian Reid², Sebastien Bertrand¹

¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium. ²Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Coyhaique, Chile

Abstract

Fjord sediments, like fluvial and lacustrine archives, are increasingly recognized as accurate recorders of past and current hydrological variability. Fjords exhibit particularly high sediment accumulation rates (>3cm/year), allowing for high-resolution hydroclimate reconstructions. Nevertheless, accurately interpreting fjord sediments in terms of past changes in hydrology requires a comprehensive understanding of the variables that affect the composition of the sediment. In this context, we conducted a spatial and temporal study of the relations between sediment composition and particle size in Baker Fjord (Chilean Patagonia, 48°S), and we compare our results to the discharge of Rio Baker; the main source of sediment to the fjord and Chile's largest river. Grain size, major and selected trace elements, biogenic silica, carbonate content and bulk organic geochemistry (TOC, $\delta^{13}\text{C}$, $\delta^{15}\text{N}$) were compiled from: (i) 13 surface grab sediment samples collected along a proximal-distal transect in the proximal part of the fjord (i.e. with increasing distance from the river mouth); and (ii) from a sequential sediment trap with 24 samples integrated over an entire year with a bi-weekly resolution. These data are then compared to daily precipitation, temperature, and discharge from local stations (Caleta Tortel meteorological station and Rio Baker Bajo Ñadis gauging station, respectively). We show that: (i) magnetic susceptibility significantly depends on mean particle size ($r = 0.84$, $p < 0.01$, $n = 24$); (ii) particle size skewness strongly reflects river discharge seasonality, with positive values (towards fine grains) in summer, typical of proglacial sediment input (grain size mode = $5\mu\text{m}$), whereas negative skewness (towards coarser grains) is recorded in winter, reflecting a reduced influence of glacial meltwater and a higher sensitivity to short and intense rainfall events (grain size mode = $15\mu\text{m}$); and (iii) total inorganic carbon content of detrital origin peaks during rainfall events independently of grain size changes. These findings are being tested against an additional year of sedimentation (sequential sediment trap retrieved in Feb. 2019), and they will serve as a basis towards the production of long, accurate and high-resolution records of hydrological variability from fjord sediments, including reconstructions of precipitation, floods, and glacier mass balance (meltwater input).

A 1000-year-long documentary record of the lower Yellow River ice-jam floods and its climatic implications

Yi Wang^{1,2}, Shi-Yong Yu³, Wen-jia Li³

¹School of Global Studies, Department of Geography, University of Sussex, Falmer, Brighton, United Kingdom.

²Department of Earth System Science, Tsinghua University, Beijing, China. ³School of Geography, Geomatics, and Planning, Jiangsu Normal University, Xuzhou, Jiangsu, China

Abstract

The Yellow River floodplain is a low-lying landmass, which is remarkably susceptible to excessive precipitation and prone to floods. Therefore, it has a strong association with calamity and has traditionally been regarded as “China's sorrow.” Also, given its immense ecological, societal, and economic importance, the Yellow River floodplain contributes significantly to human welfare, which has colloquially known as the birthplace of Chinese civilization. Therefore, a deeper understanding of flooding frequency in this area is especially important for the assessment of socio-economic risks associated with future climate changes. The late 20th century contained a number of catastrophic floods in the lower Yellow River, which has exerted devastating impacts on the human livelihood. However, the long-term context of apparently anomalous flooding events witnessed in recent decades has received very limited attention.

To better understand the nature, evolution, and driving mechanisms of river floods, it is widely recognised that the instrumental time series should be placed within a longer time framework. Here we present a 1000-year-long documentary record of ice-jam floods of the lower Yellow River by compiling flooding events in terms of levee breaches and overflows during the early spring months as documented in official dynamic histories. A time series with a yearly resolution was formed by using a binary expression with “1” denoting the presence and “0” the absence of flooding event for a year. The flood frequency is computed by convolution with a 31-year-wide window. Our results reveal an increasing frequency of ice-jam floods since AD 1855 when an avulsion occurred, and the river shifted northward to its current channel. As the occurrence of the ice-jam floods is essentially induced by a deepened temperature gradient between the inland and maritime region in the lower Yellow River area during the early spring months (January-March), we ascribe the increasing frequency of ice-jam floods to the prolonged negative phase of ENSO (i.e., La Nina). Our finding implies the global teleconnection of terrestrial hydrological systems to the ENSO cycles.

Meandering river dynamics in response to glacial-interglacial cycles

Jasper Candel¹, Bart Makaske¹, Niels Kijm¹, Maarten Kleinhans², Joep Storms³, Jakob Wallinga¹

¹Wageningen University & Research, Wageningen, Netherlands. ²Utrecht University, Utrecht, Netherlands. ³Delft University of Technology, Delft, Netherlands

Abstract

Meandering rivers are usually associated with active meandering processes. However, many meandering rivers are relatively laterally stable, and can have very complex planforms. We show that these rivers became autogenically constrained within their self-formed, heterogeneous floodplain, by a reconstruction of the Late-Glacial to Holocene planform evolution of a small meandering river; the Dommel River in The Netherlands. Here we combined coring, ground-penetrating radar (GPR), optically stimulated luminescence (OSL) dating and radiocarbon (¹⁴C) dating. The Dommel River developed a complex sinuous planform with very limited lateral migration due to insufficient flow strength to erode its self-formed cohesive banks, which largely consist of oxbow channel fills and counterpoint deposits. We compared data on river energy, bank strength and planform complexity of 48 rivers from around the world, which confirmed that complex planforms occur where rivers are constrained within their self-formed cohesive banks. This self-constraining of rivers is initiated once river energy decreases, which occurred to many rivers in temperate regions during the transition from a glacial to interglacial period. Due to better preservation of cohesive deposits compared to non-cohesive deposits, the required energy needed to break out of the self-constraining tendency increases over time. Self-constraining thereby enhances resilience of the system. The river is able to escape from the self-constraining tendency if river energy increases to such an extent that the threshold for erosion of cohesive bank material is crossed, such as during the transition from an interglacial to a glacial period. Our study provides a novel explanation for meandering planforms and meandering dynamics and their responses to climatic changes.

Identifying late Quaternary pluvial episodes beyond MIS 5 in south-eastern Australian highlands using single-grain quartz and feldspar luminescence dating

Xiao Fu^{1,2}, Tim Cohen^{2,3}

¹School of Earth Sciences, Zhejiang University, Hangzhou, China. ²GeoQuEST Research Centre, School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia. ³ARC Centre of Excellence for Australian Biodiversity and Heritage, University of Wollongong, Wollongong, Australia

Abstract

Fluvial sediments in Australia provide important archives for assessing late Quaternary flow regime changes. In south-eastern Australia abundant evidence exists of enhanced runoff conditions (relative to today) throughout and beyond the last full glacial cycle. These include palaeochannel deposits and fluvial terraces which have been interpreted as evidence for pluvial episodes and enhanced flow regimes. The hydrological setting in the east of the Great Dividing Range is characterised by a series of smaller coastal-draining catchments (< 1000 km²) surrounded by larger basins, such as the Hunter and Shoalhaven extending to the west of the great escarpment and with areas > 5000 km². Previous studies mostly focused on small basins or concentrated on late Pleistocene or Holocene alluvium; fewer studies have investigated the much larger catchments containing drainage areas above the escarpment (on the tablelands), despite preserving antecedent fluvial landforms of much greater antiquity. Recently, a single-grain (SG) optically stimulated luminescence (OSL) study on three fluvial terraces in the upper Hunter catchment showed that extreme fluvial aggradational episodes in the catchment are mainly correlated with glacial or stadial periods since MIS 6 (Fu et al., 2019), in contrast with records from northern Australia and inland rivers draining west from the Great Dividing Range. Further confirmation and understanding of this regional pattern requires more chronological studies on fluvial archives in these large coastal draining catchments.

This study presents the latest OSL dating results of several previously undated or partially-dated fluvial terraces in the Shoalhaven and upper Hunter catchments, namely the Larbet terraces, the lower and upper Mayfield terraces, and the Razorback terraces. SG quartz and/or SG K-feldspar dating were applied to fluvial sediments collected from these terraces. These include several challenging samples in terms of luminescence dating, exhibiting complex luminescence properties (especially for quartz), and/or strong bioturbation, and/or are close to signal saturation. A comparison between SG quartz and feldspar equivalent dose distribution was used to assess the extent of bleaching for individual samples and to select the most reasonable dose population for age estimation (for bioturbated samples); new statistical models were also used to provide more reliable chronologies for samples near saturation. Our dating results, for the first time using SG data, extend the fluvial sedimentary record in south-eastern Australia to Marine Isotope Stage 8. These new chronologies, together with previously published data, continue to suggest that enhanced river valley aggradation in the south-eastern Australian highlands took place mostly during glacial or stadial periods throughout the late Quaternary rather than during peak interglacial episodes. Phases of valley-floor aggradation in south-eastern Australian highland are inferred to be a function of increased sediment supply during the cold periods in the late Quaternary, resulting from strong periglacial activities in the adjacent Australian highlands.

Using depositional architecture and luminescence dating to understand the genesis of the Lower Tejo and Lower Thames terraces

Pedro P. Cunha^{1,2}, David R. Bridgland³, Peter Allen⁴, Mark J. White⁵, Jan-Pieter Buylaert⁶, Andrew S. Murray⁷
¹MARE, Coimbra, Portugal. ²University of Coimbra, Coimbra, Portugal. ³Department of Geograph, Durham, United Kingdom. ⁴Essex Field Club, Durham, United Kingdom. ⁵Durham University, Durham, United Kingdom. ⁶Centre for Nuclear Technologies, Technical University of Denmark, Risø Campus, Roskild, Denmark. ⁷Aarhus University, Risø DTU, Roskilde, Denmark

Abstract

The Thames and Tejo terrace stratigraphies have long histories of research, with an enviable profusion of Palaeolithic artefact content in both valleys and copious fossils in interglacial Thames sediments in the valley downstream of London. Thus biostratigraphy is a well-established basis for classification of the lithostratigraphical sequence in the Thames, along with the trace-fossil value of artefact assemblages in both systems. In the Thames this has provided clear indications of the marine isotope stages (MIS) represented, especially in the post-MIS 12 record in the Lower Thames.

Chronological control in the Lower Tejo has relied on geochronological methods, notably OSL and ESR, with ranges up to 300 and 900 ka, respectively.

In order to provide further temporal constraint for boundaries of depositional architecture within the Thames sequence, comparable with data from the Tejo, improved numerical geochronology is required, this being a prime aim of the authors. In both river systems a combination of published and targeted new dates, principally of luminescence type (quartz-OSL and K-feldspar post-IRIR₂₉₀) is used to constrain episodes of deposition and, by means of proximity, of incision.

A key aim is to identify and compare the prime drivers of fluvial activity in these systems (set against background uplift): climate change *versus* sea level (not that these are fully independent of one another).

Abstract

With the development of high-throughput sequencing technologies in the recent years, there has been a growing number of projects using environmental DNA (eDNA) technologies in environmental, ecological and conservation research and broad areas of Quaternary science.

We will present the first results of the “GEN-EX - Metagenomics of Extreme Wave Events” pioneer project, which is developing high-throughput, metagenomic sequencing techniques to identify foraminifera assemblages (key bioindicators in tsunami and storm deposits), and to unravel their cryptic diversities in onshore extreme wave deposits from their DNA remains.

The project has sampled tsunami deposits from coastal peat sections at three sites on the Shetland Islands, UK (Dury Voe, Garth Loch and Maggie Kettle's Loch), dated to approximately 1.5, 5.5 and 8 ka BP, respectively. By applying classical micropalaeontological techniques, no foraminiferal tests have been found in any of the tsunami deposits analysed to date, whilst inter- to subtidal offshore source deposits show moderate to high foraminiferal concentrations, indicating likely post-depositional dissolution of foraminifera in the onshore tsunami deposits, i.e. a massive loss of information.

The first DNA results are very promising. In the laboratory using stringent precautions to avoid extraneous contamination, foraminiferal DNA has been successfully extracted from palaeo- and modern sediments and also from individual foraminifera. After extensive Polymerase Chain Reaction (PCR) optimisation, amplification of the D1–D2 region of the Large ribosomal Subunit (LSU; 18S) ribosomal DNA from modern individuals has been successfully achieved.

Currently foraminifera are an underrepresented taxonomic group in genetic databases such as GENBANK and BOLD. Thus, Sanger DNA sequencing is in progress to allow us to construct a reference database. For the first time, sequences available to deposit in this database are presented, including our methodology protocols for DNA sample treatment and for the development of custom nuclear DNA primers, which are specific to the target taxonomic group.

All molecular analyses have been complimented by an integrative and comparative approach utilising geoscientific techniques such as micropalaeontological analysis (foraminifera), grain-size distribution, CT scanning, multi-sensor core logging and geochemical analyses.

¹National Institute of Geological Sciences, University of the Philippines Diliman, Quezon City, Philippines. ²Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore. ³Department of Geography, Tokyo Metropolitan University, Tokyo, Japan

Abstract

The 1976 Mw 8.1 Moro Gulf earthquake, which occurred on the shallow portion of the subducting slab along the Cotabato Trench in northern Celebes Sea, produced a tsunami with reported tsunami wave heights of up to 9 m. Among the worst-hit areas in southern Philippines include the province of Zamboanga del Sur where the height of tsunami waves reached up to 5 m. This unprecedented event resulted to thousands of casualties and millions worth of damage in the coastal communities bordering Moro Gulf. In order to gain insight on the potential of Cotabato Trench to generate large magnitude tsunamigenic earthquakes, our study conducted sediment sampling in the coastal areas of Pagadian City and Tukuran, Zamboanga del Sur to find potential geologic evidence of past tsunami events. Test pits, auger, and the handy geoslicer were used to observe the subsurface stratigraphy of coastal plains and mangrove swamps up to 1.5 m deep. The sedimentary structures observed in the stratigraphy, i.e. parallel laminations, heavy mineral laminations, and erosive base overlain by coarser sediments, are similar to the descriptions of tsunami deposits in Asia, such as the 2011 Tohoku and 2004 Indian Ocean tsunamis. The sediments collected from the subsurface were also compared to nearshore, fluvial, and terrestrial samples to further understand the sedimentary environment. Satellite imageries from Landsat were also used to interpret if the changes in sediment sizes are influenced by anthropogenic activities. The sediment samples vary in sizes from mud to very coarse sand. The composition is generally detrital grains such as mica, quartz, diorite, andesite, pumice, and other volcanic and pyroclastic rock fragments. While additional analyses are needed to confirm if the sedimentary characteristics are related to a tsunami event, this study is the first to report the characteristics of coastal sediments in northern Celebes Sea, particularly in the Moro Gulf region.

Storm-wave movement of megagravel, and formation of imbricated boulder ridges: evidence from Froude-scaled wave-tank experiments

Rónadh Cox¹, Louise O'Boyle^{2,3}, Frederic Dias⁴, Jacob Cytrynbaum¹

¹Williams College, Williamstown MA, USA. ²Queens University, Belfast, United Kingdom. ³ABCO Marine, Lisburn, United Kingdom. ⁴University College, Dublin, Ireland

Abstract

Coastal boulder deposits (CBD) are supratidal clastic deposits that include isolated boulders, small clusters, and extensive ridge systems built of stacked, imbricated clasts. Individual boulders can weigh many 10s to 100s of tonnes. They are emplaced by waves along steep rocky coasts. Some are on cliffs as high as 50m above high water, and others are found at the back of shallowly dipping coastal ramps, up to 250 m inland of the tide line. They occur worldwide, but some of the best examples occur on the west coast of Ireland. An outstanding question about these deposits is whether storm waves can produce the structured and imbricated boulder ridges that are characteristic of CBD, or whether they are the signatures of tsunamis.

We carried out Froude-scaled 1:100 wave tank experiments, using a JONSWAP spectrum to simulate realistic storm conditions, with H_s ranging from 10-14 m (scaled equivalent). Model boulders (441-1075t scaled equivalent) were situated on a cliff-top platform (10 m a.s.l. scaled equivalent), and we examined both the movement of individual blocks and the formation of boulder clusters and ridges on the platform. We ran multiple tests, varying boulder size and configuration. Wave gauges at several locations in the tank recorded water surface elevation, and video footage captured wave parameters and wave-boulder interactions that are difficult to measure at full scale.

Overtopping waves did not disperse cliff-top boulders, but tended to deposit them in clumps and ridges, with imbrication and geometry matching coastal boulder deposits, indicating that storm waves can and do form imbricated boulder ridges. The majority of boulder displacements were caused by a small subset of the incident waves, the key to boulder transport being development of a high velocity bore. The largest waves are not necessarily the most effective: instead, wave-front steepness just before cliff impact seems to control the strength of post-collapse cross-platform flow. Waves that approached the cliff unbroken, had a front slope angle in the range 15°-25°, and were taller than the cliff, generated the most powerful bores. These waves moved very large boulders with masses in excess of those predicted by existing hydrodynamic equations.

Pluri-decadal to annual storm-induced geomorphic processes on the Valahnúkur coastal boulder ridge, SW Iceland

PIERRE STEPHAN^{1,2}, David Didier³, Ronan Autret^{1,2}, Samuel Etienne⁴, Bernard Fichaut^{1,2}, Serge Suanes^{1,2}

¹CNRS, BREST, France. ²Université de Bretagne Occidentale, Brest, France. ³Université du Québec à Rimouski, Rimouski, Canada. ⁴PSL, EPHE, Dinard, France

Abstract

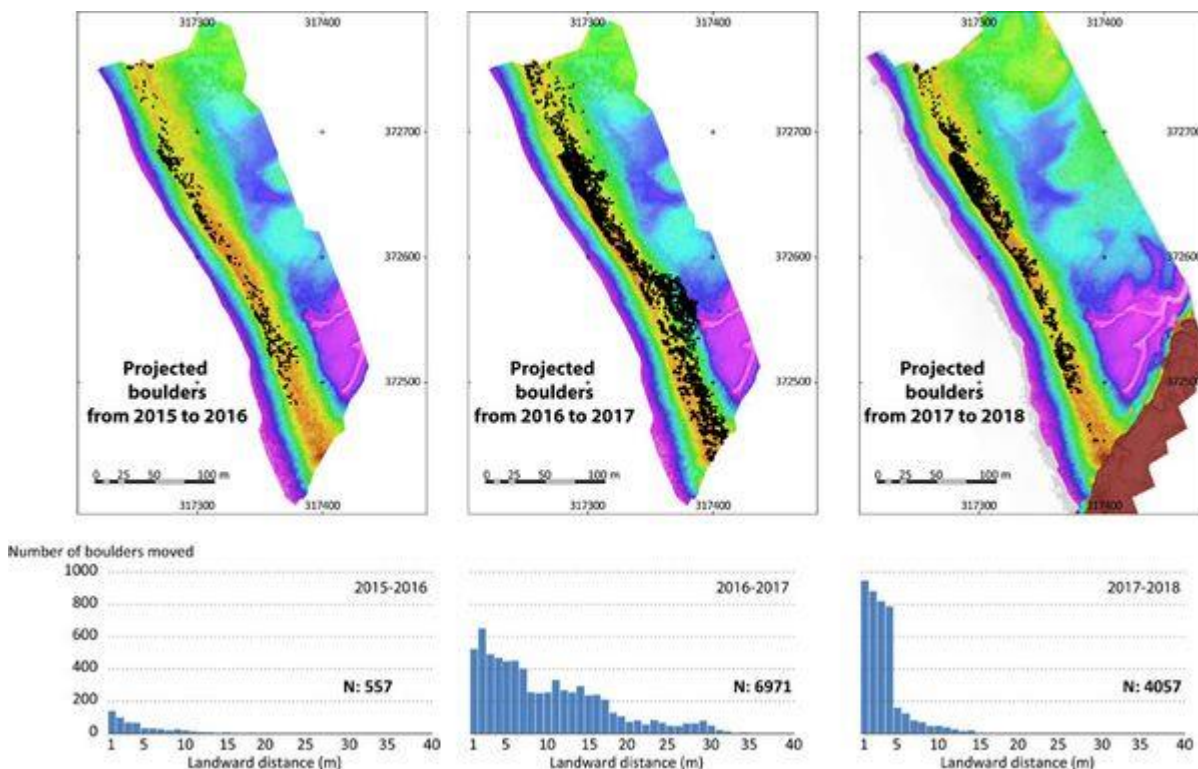

While recent studies highlighted the great mobility of boulder beaches related to the impact of storm waves, numerous researches are still needed to better understand the morphodynamic of coastal boulder accumulations and to better interpret fossil boulders deposits. This paper provides original data about storm-induced geomorphic processes and their impact on the Valahnúkur boulder ridge (figure 1). The study site is located west of the Reykjanes Peninsula, in the south-west of Iceland.

Firstly, the historical evolution of the boulder ridge was reconstructed from a set of aerial photographs between 1978 and 2010. Photographs were geometrically corrected and georeferenced according to the standard procedure to quantify the shoreline changes. Secondly, four kite and drone surveys were realized yearly between May 2015 and May 2018. The Digital Elevation Models (DEMs) produced using Structure-from-Motion photogrammetry were compared to deduce the morphological changes. Four orthophotographs were analyzed to quantify the movement of boulders. Hydrodynamic conditions were reconstructed using wave buoy and tide gauge measurements. Storminess was first assessed using a POT method. The extreme morphogenetic events were recognized using the 98th percentile of the significant wave height. The storm duration was estimated using the 75th percentile to define the start-time and the end-time of storm events. Wave runup were calibrated from the analysis of a wave/swash motion data set acquired by video monitoring.

The historical analysis of shoreline change shows a significant landward retreat of the ridge during the last 40 years. The Highest rates of retreat are recorded in the northern part of the barrier where a large washover fan was formed during the 1990s and reactivated in the 2000s. This suggests a set of overwash events and the episodic flooding of the boulder ridge, probably during major storm events. The southern part of the barrier also shows high migration rates suggesting sediment transfers from the beachface to the back-barrier.

The annual topo-morphological survey indicates various morphological responses according to the frequency and magnitude of winter storm events. From May 2015 to May 2016, the swash processes were dominant. The mobility of boulders was moderate (N=557) and restricted to the beachface (figure 2). These changes were attributed to fair weather conditions during the winter. The period from May 2016 to May 2017 was dominated by overwash processes. The results highlighted a crest reworking and a landward projection of high number of boulders (N= 6971) due to several intense winter storm events associated with high water levels. From May 2017 to May 2018, the morphodynamic regime was dominated by overtopping processes. Despite the large number of boulders moved (N=4057), the sediment transfer was limited to the crest line. These changes can be attributed to three storm events associated to moderate water levels.

Modern and historical tropical cyclone and tsunami deposits at the coast of Myanmar

Dominik Brill¹, Katharina Seeger¹, Felix Reize¹, Kay Thwe Hlaing², Martin Seeliger³, Anna Pint¹, Kyaw Kyaw⁴, Frauke Kraas¹, Helmut Brückner¹

¹Universität zu Köln, Köln, Germany. ²University of Yangon, Yangon, Myanmar. ³Universität Frankfurt, Frankfurt, Germany. ⁴University of Mawlamyine, Mawlamyine, Myanmar

Abstract

Myanmar's coast is prone to flooding by both tropical cyclones (TCs) and tsunamis from multiple sources. However, although TCs (e.g. TC Mala 2006 and TC Nargis 2008) and tsunamis (2004 Indian Ocean Tsunami) repeatedly caused flooding during the last decades, the temporal restriction of existing records limits the robustness of regional long-term frequency-magnitude information. While there is only a single historical tsunami in AD 1762, associated with a major rupture of the Rakhine segment and with inconclusive information with regard to its impact at the coast, that provides data beyond the instrumental record, sediments of past flooding events might allow to extend it to much longer time periods.

So far, very limited research on coastal flooding deposits has been conducted in Myanmar. This study presents results of a field survey along Myanmar's western (Rakhine) and eastern (Thanintharyi) coast. To provide a local reference for the sediment characteristics and preservation potential of TC and tsunami sediments, onshore deposits of 2006 TC Mala and 2008 TC Nargis were documented. Both events formed sand sheets with landward extents of up to ~100 m or washover fans in back-barrier areas. Significant flooding by the 2004 tsunami was only reported at the eastern coast, where it is reflected by a thin sand sheet identified in a paddy field. However, at most sites the flooding deposits display a very poor preservation potential. After only a few years most evidence is already overprinted by soil formation that probably obliterates all differences to sandy subsoils within decades.

Only where sand sheets extend into swales or back-barrier depressions characterized by the deposition of terrestrial fine sediments during the rainy season, preservation may potentially allow for detection after longer time periods. In the swales of a beach-ridge plain at the west coast, distinct marine sand layers predating the TCs and tsunami in the early 2000s were identified. A combination of luminescence, radiocarbon and ¹³⁷Cs dating points to 1982 TC Gwa and an unrecorded TC in the 1950s as the most likely candidates. Comparison with the complete historical TC record indicates that the archive is only sensitive to TCs of category 4 (or higher) with landfall directly in or a few tens of kilometers north of the study area. While the presented TC records are restricted to the last 100 years, luminescence ages of the beach-ridges indicate that the swales landward of the one investigated in this study might provide TC information for at least the past 700 years.

Sedimentary and erosional features caused by hurricane Irma

Michaela Spiske¹, Jessica Pilarczyk^{2,3}, Stephen Mitchell³, Robert Halley⁴

¹Universität Basel, Basel, Switzerland. ²Simon Fraser University, Burnaby, Canada. ³University of Southern Mississippi, Stennis Space Center, USA. ⁴I-Guana Farm, Cedaredge, USA

Abstract

The 2017 Atlantic Hurricane Season drew renewed attention to the need for storm risk assessment as it was the costliest season on record. Irma was the strongest recorded hurricane to form in the Atlantic Ocean and reached the northwestern Caribbean Islands as a category 5 hurricane on Sept 5th 2017.

A post-hurricane survey was conducted on Anegada (British Virgin Islands). The project takes advantage of pre-event field data collected on Anegada in earlier years that allows for a detailed comparison of pre- and post-Irma data. Irma passed ca. 35 km south of Anegada. Maximum wind speed on Anegada was ~256 km/h, related maximum offshore wave heights were ~17 m. Irma had a surprisingly weak storm surge of <3 m as indicated by wrack lines and overwash deposits. The small surge may be explained by the fact that Irma's eyewall passed south of the island and winds were mainly shore parallel. Thus, even though a category 5 hurricane, very close to the island, Irma does not represent the worst-case scenario for a storm on Anegada.

Substantial coastal erosion occurred on Anegada's north shore. A steep erosional scarp of about 1 to 1.5 m height and a retreat of the coastline by several meters were documented. While erosion dominates the northwest and central north shore, depositional evidence is present along the northeastern and southern shore. Thick faintly laminated sand sheets that cover beach sand have a max. thickness of ca. 35 cm. Deposits are massive and well-sorted carbonate sands. Small washover lobes that contain shell hash have sediment thicknesses of 5 cm. The deposits contains *Homotrema rubra*, a red foraminifer that bleaches predictably following detachment from the reef. The relatively high concentration of vibrantly colored *Homotrema* suggests that the majority of sediment was freshly sourced from the fringing reef. Furthermore, a pre-existing coast-parallel coral rubble ridge was entirely reworked. Cobbles and boulders were moved several meters in landward direction. Few cobbles were washed into the sea, moved shore parallel towards the west and transported back onto the coastal platform.

The depositional and erosional evidence of Irma differ significantly from features left by historical tsunami that breached the coastal dunes and transported sand and large living corals several hundreds of meters on land. The deposits of the 1755 Lisbon tsunami revealed key differences in their sediment provenance as they contain reef crest foraminiferal assemblages with a contribution of offshore planktics, whereas the Irma deposits are characterized by reef flat to reef crest assemblages.

Abstract

Frequent storm surges often cause catastrophic impacts on human lives and the global economy; however, these phenomena are not well understood. In this study, a regional storm reconstruction is performed based on a grain-size analysis and stratigraphic modelling of the accelerator mass spectrometry radiocarbon dates of benthic foraminifera from two neighbouring lagoon cores from Lingyang Reef in the Xisha Islands located in the northern South China Sea of the western Pacific. The dating results from the lagoon cores reveal a ~3500-year depositional history. Three different depositional units are recognized based on a time series of distinct grain-size variations that correspond to the following three stages of storm activity: intense and frequent storms from ~3500 to 3100 cal yr BP and ~1800 cal yr BP to present and weak and infrequent storms from ~3100 to 1800 cal yr BP. A high sedimentation rate is observed from ~2800 to 2600 cal yr BP in both cores, and it was likely caused by a slump deposit associated with a tsunami event. In addition, grain-size variability may be associated with changes over time caused by the synchronous Asian monsoon and may also be correlated with climate records retrieved from the ice cores from Greenland; thus, this variability could indicate pervasive global climatic teleconnections. The overall temporal patterns of the isolated coral branches and shells from the sediment sequences are well correlated with the high sea surface temperatures in the western tropical Pacific. We suggest that increasing sea surface temperatures in the future may lead to more intense storm activity in the western Pacific warm pool as the planet warms.

Human-environment interactions since the latest Pleistocene west of the subtropical Andes (31°-32° S), South America.

César Méndez¹, Antonio Maldonado², Amalia Nuevo Delaunay¹, Andrés Troncoso³, Roxana Seguel⁴, Sebastián Grasset⁵, Felipe Gutiérrez³

¹Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Coyhaique, Chile. ²Centro de Estudios Avanzados en Zonas Áridas, La Serena, Chile. ³Universidad de Chile, Santiago, Chile. ⁴Centro Nacional de Conservación y Restauración, Santiago, Chile. ⁵Universidad Autónoma de Barcelona, Barcelona, Spain

Abstract

The geographical band between 31°-32° S, from the Pacific to the Andes, lies in the southernmost part of the Semi-Arid North of Chile, south of the Atacama Desert. Multidisciplinary research in this area has exposed the potential for discussing human-environment interactions since the latest Pleistocene. This area is ideal for such assessment due to its environmental sensitivity because it lies in the margin of the northernmost area of influence of the westerlies. Also, the dominance of an archaeological record produced by mobile human groups, bestows this region of high anthropogenic sensitivity as can be examined by the different degrees of permanence/avoidance of certain spaces.

However, research efforts across the area remain uneven, therefore in need of complementing studies in those sectors left behind. The aim after a four-year period of research is to understand the relative intensity of the human traces across the landscape and evaluate if environmental changes conditioned such distribution at different points in time.

Currently, the combined pollen records in the coast and highlands provide a semi continuous climate history for the last 15,000 years. After wetter and colder late Pleistocene conditions, pollen records indicate arid phases between 7.8-6.2 ka and 3.5-2.2 ka and the wettest period within the last 2 ka. Anthropogenic dates (>430) range from 13.5 ka to modern over a 10,000 km² area (Figure 1). Such chronometric resolution, attained by long lasting archaeological programs and CRM studies, provides grounds for discussing the intensity of human occupation and comparing the human chronological signature with the available paleoclimatic data to discuss if aridity, its magnitude, and regional expression, and therefore shortages in resources, exerted pressures over human groups inhabiting this area (Figure 2).

On one hand, the coastal radiocarbon record is nearly continuous, thus indicative of a sustained human presence across the Holocene. Inland valleys, on the other hand, show a remarkable prevalence of radiocarbon records on the last 3000 years as motivated by profound changes in settlement patterns, economy and technology.

Earlier discussions suggested the hyper arid mid-Holocene conditions lead to population relocation or even demographic decrease based on region-wide radiocarbon assessments. New research efforts into previously neglected areas have yielded dates precisely within the time gap detected in earlier human records. This preliminary collation argues in favor of relocation and posits environmental change as a potential mechanism influencing the past human spatial distributions. Assessing human responses to environmental change in the margins of the desert should prove useful for the broader understanding of landscape use and its variation throughout the Holocene.

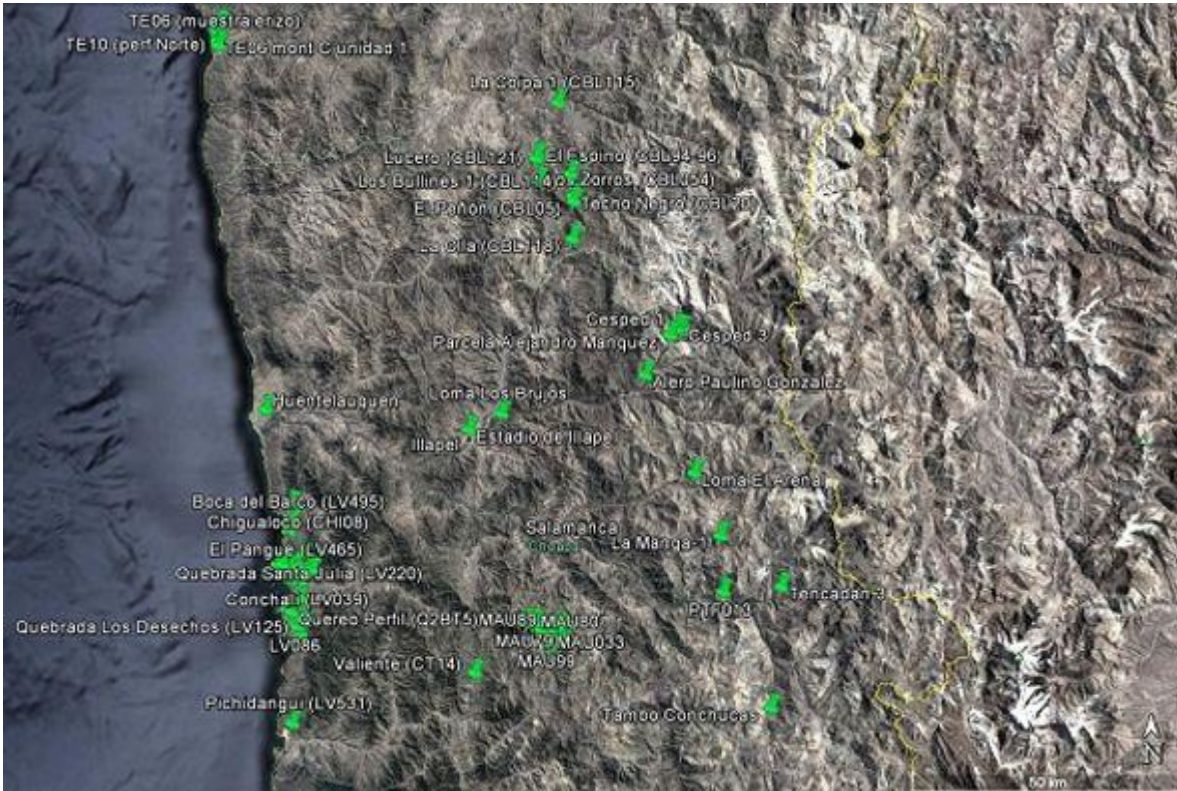

Figure 1. Distribution of dated archaeological sites between 31°-32° S.

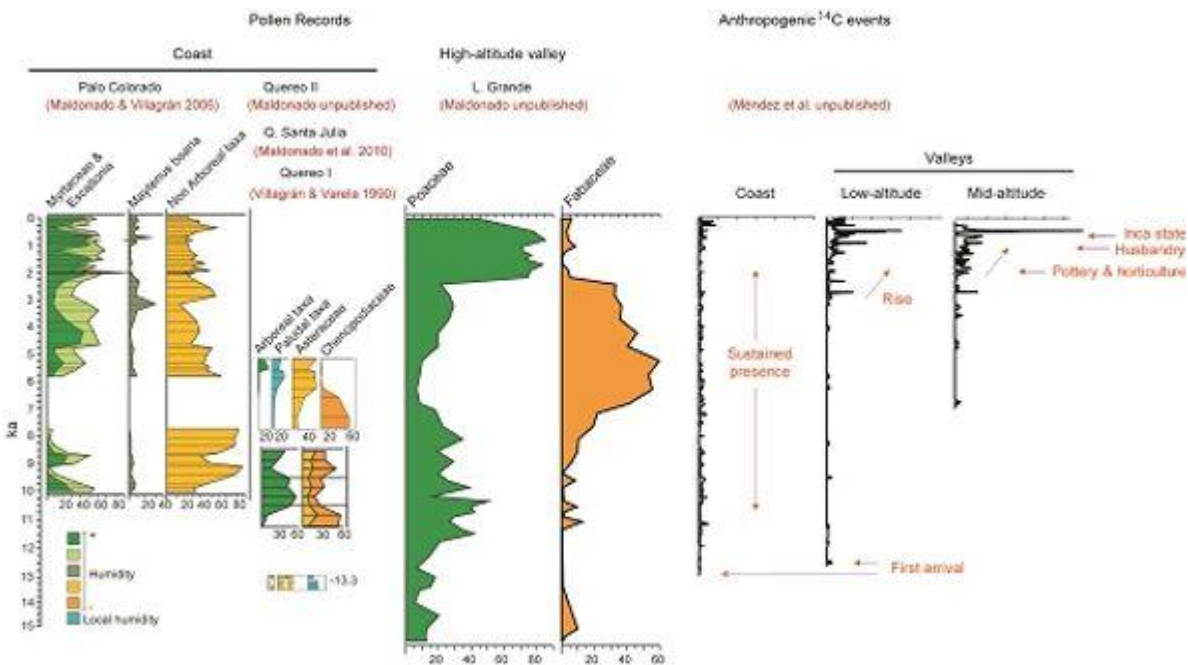

Figure 2. Comparison between pollen records and summed distributions of anthropogenic radiocarbon dates partitioned by landscape band.

The Synchrony and Magnitude of Energy Booms and Busts among Human Societies Throughout the Holocene

Jacob Freeman¹, Erick Robinson², Darcy Bird³, Jacopo Baggio⁴, Gideon Maughan³

¹Utah State University, Logan, USA. ²University of Wyoming, Laramie, USA. ³Utah State University, Logan, USA.

⁴University of Central Florida, Orlando, USA

Abstract

We conduct a comparison of the consumption of energy by human populations throughout the Holocene and statistically quantify coincident changes in the consumption of energy over space and time—synchrony—as well as amplitudes of change over multiple time scales. When populations synchronize, adverse changes in ecosystems and social systems may cascade from society to society. Thus, to develop policies that favor the sustained use of resources, we must understand both the processes that cause the synchrony of human populations and why amplitudes of change vary from society to society. Our analysis begins to fill these knowledge gaps. We document that (i) the creation of social ties that couple populations over smaller scales and (ii) much larger scale, globally convergent trajectories of cultural evolution toward more energy-consuming political economies with higher carrying capacities creates a synchrony of energy consumption among human populations throughout the Holocene. However, (iii) the magnitudes of changes in energy consumption vary from society to society. Agricultural populations unwittingly tradeoff more stable energy dynamics at small time scales for vulnerability to large booms and busts at larger time scales. Conversely, hunter-gatherers experience moderate intensity booms and busts in their economies and populations, but fewer large and small amplitude changes.

Withdrawn - Evaluating the resilience of traditional agriculture systems to climate change in the Peruvian Andes over the last 2000 years

Josephine Handley, Nicholas Branch
University of Reading, Reading, United Kingdom

Abstract

The cultural history of highland Peru suggests that once great empires, from the Early Intermediate Period through to the Late Horizon (200BC – 1533AD), supported their populations through highly innovative agricultural systems. The construction of agricultural systems, including terraces, canals, reservoirs, corrals and raised fields, transformed the morphology of the Andean landscape. This significantly increased food production and ‘risk spreading’ through complex engineering involving the movement of soil, stone and water, and the selection of appropriate cultivars, which resulted in highly sophisticated agricultural systems. The archaeological record indicates that these agricultural systems were remarkably resilient as evidenced by the apparent persistence of human occupation in many highland areas. Nevertheless, several studies have highlighted the potential impact of water stress due to enhanced climate variability during this time that led to social and economic collapse. For example, published data suggest that these systems flourished due to high precipitation (e.g. ~600-800AD), but may have been unsustainable due to drought which led to agricultural terrace abandonment (e.g. ~800-1000AD). However, the relationship between increased climatic variability and the sustainability of the agricultural systems is still poorly understood.

Despite the growing number of high-resolution records for past climate change in Peru from lakes, caves (speleothems) and ice, as well as marine records, there remains a paucity of palaeoenvironmental data documenting changing land-use patterns and vegetation succession, especially from small lakes and mires proximal to zones of intensive human activity. Palaeoenvironmental information recorded in these wetland archives provides an important insight into the sensitivity of the surrounding landscape and human environment to past climate change.

Using radiocarbon-dated sediment geochemistry, pollen, phytoliths and non-pollen palynomorphs, alongside archaeological and ethnographical evidence, we present an improved understanding of the relationship between the past agro-pastoral economy and climate change in the Peruvian Andes. We will provide new data from three study areas: Ancash Region (Santa Valley); Lima Region (Chillon Valley); Apurimac Region (Chicha-Soras Valley). Within each of these locations, we will present records from three infilled lake / mire sequences: Huarca near Yungay (Ancash); Cantamarca near Canta (Lima); Ayapampa near Pampachiri (Apurimac).

The study sheds new light on the resilience of past agricultural systems to climate change, which has implications for our understanding of the issues that govern sustainable food production in Peru at present day among rural communities employing traditional agricultural practices.

Abstract

Fluctuations in the availability of water resources represents the main factor which has modulated ecosystem dynamics, human population changes and culture in arid and semiarid regions. One of the largest high-altitude semiarid regions of South America is the Altiplano plateau in the Central Andes (~14°S-26°S). With a mean elevation of 4.000 m a.s.l. and many volcanoes up to 6.700 m a.s.l., the Altiplano has been the physical environment for the settlement of many local communities who have inhabited the region for thousands of years. Historically, human activities in the Altiplano have been strongly modulated by variations in climate, particularly water availability.

During the last decade, tree-ring research has been developed in this region allowing the reconstruction of the dynamics of water resources at annual resolution during the last millennia. In the other hand on the mountain tops of the Altiplano exists many high-altitude pre-Columbian sanctuaries which are framed within the remarkable relationship between mountains and water, which was a fundamental feature on which local cultures of the Altiplano based their complex religious beliefs related to mountains as sources of water and fertility. The existence of archaeological wood on this sites utilized as offerings and/or firewood, and the possibility to develop regional tree-ring chronologies in the area allow the tree-ring dating and the development of precipitation reconstructions. On this investigation we present a new tree-ring based regional precipitation reconstruction for the Altiplano for the last millennia, and the dating of three high-altitude sanctuaries located on mountain tops at ~6,000 m a.s.l. utilizing tree-ring widths and 14C wiggle-matching of tree-ring sequences. For the last, we utilize a recently developed regional 14C curve from the Altiplano region. The dating and occupancy of these water-related sanctuaries will contribute to a better understanding of the relationship between humans' religious beliefs and the semiarid environment that inhabited, on which century-scale dry periods are demonstrated to be a recurrent feature in the regional climate.

A palaeoecological investigation of Ancient Maya land-use strategies at low-density settlements

Adam Bermingham¹, Bronwen Whitney¹, Nicholas Loughlin¹, Sarah Metcalfe², Julie Hoggarth³

¹Northumbria University, Newcastle Upon Tyne, United Kingdom. ²University of Nottingham, Nottingham, United Kingdom. ³Baylor University, Texas, USA

Abstract

The Ancient Maya Civilisation (ca. 2500 BCE - 1500 CE) are one of the best documented past societies in Mesoamerica. Numerous high-resolution palaeoenvironmental investigations have highlighted a link between environmental degradation and the decline of the Classic Maya civilisation around the 8th century CE, occurring against the backdrop of known periods of climate instability (specifically drought). Many of these studies focus around large ceremonial centres, which may reflect the intensive agriculture that was required to support high population densities. Palaeoecological investigations from low-density sites provide an opportunity to investigate how the Ancient Maya managed their landscapes using alternative strategies, such as agroforestry and small-scale crop production. We use a combination of high-resolution pollen and charcoal records to show the local impact of the Ancient Maya on their environment from island (Basil Jones) and mainland (Laguna Esmeralda) sites. Both sites do not contain evidence of large civic architecture (e.g., temples), but show evidence for small-scale occupation by the Ancient Maya. The dominant ecosystem type of each site is seasonally dry tropical forest. A 6,000-yr sediment core from Basil Jones was extracted from a local sinkhole adjacent to a small Maya settlement. Evidence for crop production is shown with the appearance of maize pollen, which dates human occupation at the site to 2500 BCE. Pollen and charcoal data indicate there were no large deforestation events, but smaller clearances were made for the production of crops. The most notable impact on the environment is the complete clearance of palms (*Acromia* spp.) by 1700BCE. Charcoal analysis of the 6000 -yr sediment core from Laguna Esmeralda suggests that fire was not as prominent as in Basil Jones, suggesting low impact on dry forest cover, but preliminary pollen data show variations in constituent forest taxa. The results of this research highlights the importance of selecting suitable sampling locations (proximity to temple structures) to understand the heterogeneity of Ancient Maya land-use in Mesoamerica.

Abstract

Human settlement of uninhabited land masses can dramatically transform local ecosystems and its endemic biota around the world. These changes are particularly evident on islands, where human settlement usually marked a period of large-scale habitat destruction and extinctions of local flora and fauna. Historical records specify that the Azores archipelago in the North Atlantic Ocean was settled in the mid-15th century CE. The human footprint in the Azores was large and widespread: within six centuries of colonization more than 95% of the original native forests were destroyed. Paleoecological and geochemical reconstructions from the Azores have allowed us to compare ecosystem processes and dynamics before and after colonization.

To document the cultural evolution of human settlement in the Azores archipelago, we studied lake sediment records from four distant islands, located in the Western (Flores), Central (Pico and Terceira) and Eastern (São Miguel) group of islands. In particular, we investigated the role of the Medieval Warm Period and the Little Ice Age climatic periods as external driving forces for human displacement and potential triggers for cultural transformations. A suite of proxies – pollen, diatoms, chironomids, cladocerans, hydrogen isotopes, macroscopic charcoal, organic matter, inorganic composition (XRF scanning and X-ray diffractions), and lithofacies – were used to distinguish between different signals of climate change, landscape and ecosystem dynamics, and their local lacustrine responses. A comprehensive multi-disciplinary analysis of all the proxies provides strong indications that the Azores were colonized more than two centuries earlier than currently recognised. These early colonizers first reached the Central group of islands around 1100 yr CE and the Eastern group before the end of the 13th Century. The Western group was subsequently reached around 1300 yr CE. Early human activities included the introduction of domestic animals, land clearance and small-scale agriculture, and extractive forestry mostly for charcoal production. The origin of the early colonizers is further discussed during the presentation.

¹CONICET/UTN (Instituto de Evolución, Ecología Histórica y Ambiente), San Rafael, Argentina. ²UNCuyo, Mendoza, Argentina. ³CONICET (Instituto de Evolución, Ecología Histórica y Ambiente), San Rafael, Argentina. ⁴Anthropology Program and Ecology Center, Utah State University., Logan, USA. ⁵Department of Anthropology, University of Wyoming,, Laramie, USA. ⁶CONICET (IADIZA), Mendoza, Argentina. ⁷Laboratorio de Isótopos Estables en Ciencias Ambientales (CONICET), San Rafael, Argentina

Abstract

Historical records from the Subtropical Andes reveal a surprising mosaic of human subsistence strategies, ranging from intensive reliance on domestic plants to a sole reliance on wild resources. This presentation focuses on this diversity in Central West Argentina by developing summed probability distributions of radiocarbon data and stable isotope on human bone collagen for different regions in order to reconstruct and compare Late Holocene demographic and dietary trajectories. We compare the northern area, where historic farmers lived, with the southern area, where historic hunter-gatherers lived. We find just one significant difference between both areas throughout the entire Late Holocene, which occurred between 800-1100 AD. During this period, a significant positive change in demographic growth in the north was associated with an increase and abrupt drop in maize consumption. At the same time, the southern area shows a drop in demography. Stable isotopes on human bone collagen (¹³C and ¹⁵N) show a similar pattern between both areas, with values being more enriched in the north than in the south. In both areas, the inter-individual variation was high. This variation spikes when individual bone collagen $\delta^{13}\text{C}$ values cross -14‰ in both areas. Higher standard deviations suggest that individuals have more diverse subsistence adaptations when ¹³C bone collagen (maize) reached the highest values. This strategy could reflect the adaptability and flexibility of subsistence systems under highly variable environment conditions. Maize diets were unstable as a consequence of high interannual variation of climatic conditions. Subsistence that focused predominantly on maize was not viable over the long-term, and prevented high-energy extraction necessary for driving sustainable population increases.

The missing piece: late Pleistocene changes in the ecological function of mammal communities in North America

Felisa A. Smith¹, Amelia Villaseñor^{1,2}, Emma A. Elliott Smith¹, Catalina P. Tomé¹, S. Kathleen Lyons³, Seth D. Newsome¹, Thomas W. Stafford, Jr.⁴

¹University of New Mexico, Albuquerque, USA. ²University of Arkansas, Fayetteville, USA. ³University of Nebraska–Lincoln, Lincoln, USA. ⁴Stafford Research, LLC, Lafayette, USA

Abstract

By the late Pleistocene, the genus *Homo* had increased exploitation of other mammals for food and resources. As hominins became increasingly abundant and dispersed across the globe, a temporally and spatially transgressive extinction of large-bodied mammals followed; the degree of selectivity was unprecedented in the Cenozoic fossil record. The rate of extinction has only increased over time; today the conservation status of the largest mammals is precarious owing to a disastrous combination of continued hunting, habitat loss/alterations, and conflict with humans.

Recent work suggests that large-bodied species perform many essential ecosystem services, which are not fully characterized. Because biodiversity threats are ongoing, conservation biologists cannot wait for the results of long-term studies before proposing potential mitigation strategies. Yet, understanding the functional role of large-bodied mammals is essential for effective management of the remaining wild areas on Earth. Here, a paleo-perspective provides powerful insights; by studying the consequences of the catastrophic biodiversity loss at the terminal Pleistocene (ca 13 ka), we can characterize the long-term ecological effects of the loss of large-bodied animals on the rest of the mammal community.

Here, we focus on changes in morphological and isotopic dietary space of the mammal community in the Edwards Plateau, Texas before and after the megafauna extinction. Body size was estimated based on measurements of molars or post-cranial material; carbon ($\delta^{13}\text{C}$), nitrogen ($\delta^{15}\text{N}$) and/or oxygen isotope ($\delta^{18}\text{O}$) values were derived from analysis of collagen or apatite extracted from fossil materials. When available, literature values were also employed. We find that prior to the extinction, there was a diverse community of large-bodied C4 grazers, C3 browsers and mixed-feeders. The carnivore guild was more specialized and tightly linked to their prey base, especially felids who were hyper-carnivorous and ate C4 grazers, similar to their counterparts in modern African systems. Ursids (*Arctodus* and *Ursus*) regardless of body size, fell into mixed C3-C4 to pure C3 dietary isotopic ranges. Post-extinction, diversity in body size and isotopic space is lost within the mammal community, although these shifts are complex and appear to be related to both body size and trophic guild. For example, while the $\delta^{13}\text{C}$ niche space of browsers such as deer did not change, the larger bodied grazing Bison did demonstrate a shift. Moreover, a baseline shift in nitrogen appears to have influenced all surviving herbivores, which may reflect a changes in biogeochemical cycling commensurate with the loss of megafauna. We conclude that the ecological function lost with the terminal Pleistocene megafauna extinction was not restored over the Holocene.

Exploring beneficial plant-fungal symbioses in the Quaternary

Brian John Pickles¹, Corrina Thomsen², Jason Pither²

¹University of Reading, Reading, United Kingdom. ²University of British Columbia, Kelowna, Canada

Abstract

Mycorrhizal symbioses have been an important component of terrestrial ecosystems since plants invaded the land over 450 million years ago. The important contribution of these below-ground plant-fungal symbioses to nutrient cycling, carbon storage, water uptake, and protection from pathogens is receiving increasing attention. However, examination of the geohistorical interactions between mycorrhizal host plants and fungi remains a largely unstudied field of research. Our recent work on postglacial biotic interactions in North America (Pither et al. 2018) is a rare exception and suggests that certain types of mycorrhizal fungi played an important role in moderating the range dynamics of their hosts during past periods of climate change.

Here we use host pollen data, extracted from the Neotoma database, to interpolate the residence times of different types of mycorrhizal host in grid squares across North America since the last glacial maximum. The spatiotemporal heat maps produced by this method highlight locations in which specific types of mycorrhizal association have dominated, or been repeatedly excluded, over millennia. Using this information we discuss the implications of host residence times for symbiont diversity, and *vice versa*. Specifically we explore what the spatial distribution and temporal residence times of key plant genera allows us to infer us about species pools of mycorrhizal fungi.

A multi-proxy reconstruction of a terrestrial-marine linkage in the Falkland Islands

Dulcinea Groff¹, Jacquelyn Gill²

¹Lehigh University, Bethlehem, USA. ²University of Maine, Orono, USA

Abstract

The Falkland Islands (51° S) are a biodiversity hotspot for seabirds in the South Atlantic Ocean, yet little is known about how seabirds will respond to rapid climate change. Seabird guano is an important source of nutrients to the coastal grasslands that form critical seabird breeding habitat. The availability of these marine-derived nutrients is influenced by not only seabird populations, but also the marine food web. Because seabirds are sensitive indicators of climate change, we hypothesize the linkage between marine and terrestrial environments (guano inputs to grasslands) is sensitive to climate variability. Deep peat-forming coastal grasslands in the Falkland Islands provide a natural archive to assess the responses of seabird populations and terrestrial ecosystem to past climate change. We analyzed pollen, charcoal, and geochemical proxies for seabirds from a 4.76-m radiocarbon-dated peat core. Our multi-proxy reconstruction of the past 14,000 years demonstrates a terrestrial ecosystem shift occurred at ~5,000 years ago when seabird populations reached higher levels than the previous 9,000 years. The increase in seabird populations coincided with the development of a grassland ecosystem. The coastal grassland ecosystem that persisted over the last 5,000 years is largely degraded today because of introduced livestock grazing with the arrival of European settlers two centuries ago. Grassland fires, which are suppressed today, were present throughout the past 14,000 years, but most frequent when seabird nutrient inputs fueled the coastal grassland ecosystem. This shift in the terrestrial-marine ecosystem linkage coincides with well recognized records of Southern Hemisphere neoglacial cooling, such as lower sea surface temperatures on the western Antarctic Peninsula and expanded sea ice in the South Atlantic Ocean. Our reconstruction linking terrestrial-marine ecosystems suggests that Falklands coastal ecosystems respond to past cooling shifts and are a refuge for seabirds during cold periods in Antarctica. The terrestrial-marine linkage between coastal grasslands and seabirds is sensitive to climate change. Our understanding of the natural range of variability of the terrestrial marine linkage suggests that marine-derived nutrients are essential for restoring and conserving now degraded coastal grasslands.

A new paleoecological indicator for reconstructing insect outbreaks in forest ecosystems

Miguel MONTORO GIRONA^{1,2}, Hubert Morin¹, Lionel Navarro¹, Emy Tremblay¹, Anne-Elisabeth Harvey¹

¹Université de Québec à Chicoutimi, CHICOUTIMI, Canada. ²Swedish University of Agricultural Sciences, Umeå, Sweden

Abstract

Natural disturbance is one of the major topics in forest ecology. However, most paleoecological studies have only considered the influence of wildfire as an agent of disturbance, with fire history based primarily on the use of charcoal as a proxy for fire events. The frequency and intensity of insect outbreaks and their effect on the forest landscape have been neglected due to the absence of an effective proxy tool. Finding indicators able to provide insight into the impacts of past insect outbreaks is therefore essential due to the economic and ecological implications under climate change scenarios, where there is a projected change in the occurrence and severity of natural disturbances in forest ecosystems. Fossil moth (Lepidoptera) scales offer a new approach for interpreting past insect-related disturbances and assessing the interactions between climate, fire and insect outbreaks. Paleoindicators must respond to three main criteria: (1) be in high abundance, (2) allow for easy identification and (3) remain well-preserved in sediment records. We demonstrate that Lepidoptera scales are abundant in the boreal forest during insect outbreak periods. We also show that due to their chitin composition, these scales remain well-preserved throughout a 10,000-year sediment record. Furthermore, they are relatively easy to identify after being recovered from lake sediments. We will show the current research to develop the potential of this paleoindicator as well as our innovating results.

At a multi-millennial scale, various disturbances shape boreal forest stand mosaics and the distribution of species. Here, we combine macrocharcoal and plant macrofossils with our new proxy—lepidopteran scales—to describe the Holocene ecology around a boreal lake. Lepidopteran scales turned out to be a more robust proxy of insect outbreaks than the traditional proxies such as cephalic head capsules and feces. We identified 87 significant peaks in scale abundance over the last 10 000 years. These results indicate that SBW outbreaks were more frequent over the Holocene than suggested by previous studies. Charcoal accumulation rates match the established fire history in eastern Canada: a more fire-prone early and late Holocene and reduced fire frequency during the mid-Holocene. Although on occasion, both fire and insect outbreaks were coeval, our results show a generally inverse relationship between fire frequency and insect outbreaks over the Holocene.

Therefore, we introduce the needs, potential and applications of this paleoindicator in forest ecology, and the main directions for the future research. This new approach offers an important scientific advance in ecology through a much improved, higher resolution reconstruction of a major natural disturbance: insect outbreaks.

O-3180

A multi-proxy approach to advance our understanding of niches in fossil mammals

Melissa Pardi, Larisa Grawe DeSantis

Vanderbilt University, Department of Earth and Environmental Sciences, Nashville, USA

Abstract

With the prospect of climate change, conservation biologists are challenged with predicting future impacts on populations and communities of species. The fossil record provides an opportunity to study the broad array of responses to climate change in the past – conservation paleobiology seeks to apply this knowledge to inform modern conservation. Our focus is on the multidimensional nature of the ecological niche of mammals. Species have the ability to adjust ranges to remain within physiological tolerance limits within their abiotic environment, or they may adapt to changing environments. Biotic interactions also constrain the geographic ranges of species, with changing interspecific interactions additionally impacting where species are found. Here, we investigate the combined effects of abiotic factors (climate) and biotic factors (diet) on the distribution of fossil mammals, with a focus on the Quaternary. We ask if species changed diets in response to climate change in the past, and if our ability to predict the range shifts in response to climate change can be improved by including aspects of the dietary niche.

Our research program unites three separate tools that have been invaluable in understanding various aspects of both modern and ancient ecological systems: stable isotope analysis (SIA), dental microwear texture analysis (DMTA), and species distribution modeling (SDM). Individually, SDM, SIA, and DMTA are powerful tools for understanding the impacts of climate and the environment on species. SDM describes the suitable environment for a species. At the individual level, SIA and DMTA describe what resources are being used, and at population and community levels they are a tool that can describe how resources are partitioned. Integrating these techniques and applying them to the fossil record may help us gain a deeper understanding of species responses to changes in their environment.

We present a framework for integrating SDM, SIA, and DMTA, with examples from the fossil record. We explore how dietary specialization and individualism may impact niche conservatism and the ability for species to respond to climate change. A broad survey of SIA analyses finds that species tend to be fairly consistent in their dietary strategies over time. However, across strategies, individuals tend to be specialized, even within species that are considered to have broad, or mixed, diets. Species level constraints and individual specialization have implications for predictive SDM, and we present examples using the maximum entropy method.

Niche evolution and resource competition: herbivore stable isotopes reveal changing species interactions during the Late Pleistocene

Hazel Reade, Rhiannon Stevens
UCL Institute of Archaeology, London, United Kingdom

Abstract

The megafaunal extinctions that characterise the Late Pleistocene and Early Holocene periods are one of the most prominent ecological events to have occurred during the Quaternary. The pattern of extinction and survival of large and medium bodied herbivores varies between different geographical locations. The drivers behind these changes, which affected both species composition and diversity, have been extensively debated. One promising avenue of research is to look at the interaction between the different species in different environments. Stable isotope analysis ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$, $\delta^{34}\text{S}$) of the fossil record offers one such tool to do this; by providing a dietary proxy, ecological niches can be explored. Preliminary data hints at dietary shifts as a prelude to extinctions in some species, in some environmental contexts. In other contexts, no such changes are observed. Such dietary shifts have implications for understand changing patterns of interaction between different species, and possibly changing resource competition dynamics. In this paper we discuss these initial findings from Eurasian and North America contexts and discuss possible interpretations.

Modeling mammals food webs in the Orce sites: Quantitative reconstruction of prey-predator relationships for the first humans of Western Europe

Guillermo Rodríguez-Gómez¹, Manuel Salvador², Jesús A. Martín-González³, Paul Palmqvist¹

¹Universidad de Málaga, Málaga, Spain. ²University of Surrey, Guilford, United Kingdom. ³Universidad de Burgos, Burgos, Spain

Abstract

Many researchers consider that meat was a relevant trophic resource for the first hominin populations that dispersed in Europe during Early Pleistocene times. Moreover, meat availability could have conditioned human presence if we take into account the intensity of competition with other carnivores for the access to these resources. From this point of view, it is very interesting to test past ecosystems which have fossil records before and after human presence. The Early Pleistocene sites of Orce (Baza Basin, SE Spain) offer a unique opportunity to analyze the food webs of the mammalian paleocommunities in these conditions. With an age of 1.6-1.5 Ma and absence of evidence on human presence, the Venta Micena site provides the scenery before the initial peopling. In contrast, Barranco León and Fuente Nueva-3, dated at around 1.4 Ma, preserve evidence of human presence at the Baza Basin. The latter sites have provided huge large mammals assemblages with an excellent state of preservation, which has allowed carrying out a number of taphonomic, geochemical isotopic and paleoecological analyses. This has allowed contextualizing the environmental context of the first human settlements in Western Europe. For this reason, it is very interesting to reconstruct the Orce food webs for estimating how meat availability could have influenced their structure. In this study, we have applied a mathematical approach based on Leslie matrices to quantify the biomass of large mammals available to the guild of secondary consumers, including humans in Barranco León and Fuente Nueva-3, in order to analyze the pattern of meat distribution and intraguild competition. The model determines: (1) the age structures that would make stable the population of each primary consumer; (2) the distributions of individuals among body mass categories; and (3) the average biomasses that could be extracted in the long term from these populations. Finally, it distributes the ungulate meat among the secondary consumers and estimates the sustainable densities of each carnivore species. The results for Orce allowed reconstructing the food webs of the sites, which showed that meat was not the main limiting factor to hominin presence in Western Europe before 1.4 Ma.

Westerly wind variability at sub-Antarctic Macquarie Island: links to the Southern Annular Mode and Southern Hemisphere rainfall and temperature

Krystyna M Saunders^{1,2}, Stephen J Roberts³, Alan Griffiths¹, Karina Meredith¹, Christoph Dätwyler⁴, Ivan Hernandez-Almedia⁵, Christoph Butz⁴, Louise Sime³, Raphael Neukom⁴, Martin Grosjean⁴, Dominic A Hodgson^{3,6}

¹Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia. ²University of Tasmania, Hobart, Australia. ³British Antarctic Survey, Cambridge, United Kingdom. ⁴University of Bern, Bern, Switzerland. ⁵ETH Zurich, Zurich, Switzerland. ⁶University of Durham, Durham, United Kingdom

Abstract

The position and strength of the Southern Hemisphere westerly winds is important for temperature and rainfall variability from the mid- to high-latitudes of the Southern Hemisphere. They also influence Southern Ocean circulation and sea ice extent around Antarctica and are closely linked to changes in the Southern Annular Mode (SAM). While observations available since the 1950s show the winds have strengthened and shifted southwards, this period is too short to understand their natural variability, especially as stratospheric ozone depletion and rising greenhouse gases from anthropogenic activities are considered to be driving these changes. Sub-Antarctic islands, such as Macquarie Island (54°S, 158°E), are ideally situated to reconstruct changes in the westerly winds as they lie within the latitudes where the winds are strongest. Here, we reconstruct changes in westerly wind strength of the last ca. 1800 years using lake sediment records from Macquarie Island. The reconstruction involves the application of a diatom-sea spray inference model (transfer function) supported by geochemical, minerogenic and sedimentological analyses. The inference model was used to assess changes in sea spray inputs to a small, exposed lake on the western edge of the Macquarie Island plateau, where the amount of sea spray is directly related to the strength of the westerlies. The reconstruction shows close agreement with the southern South America temperature (Past Global Changes) and SAM reconstructions for much of the last millennium, with the main feature being a decrease in wind strength ca. AD 1450 that coincides with a decrease in temperature at many sites around the Southern Hemisphere and transition to a more negative SAM phase. The combination of a modern climatological framework for understanding Macquarie Island's current climate together with modelling and palaeoclimatological reconstructions of the westerlies, demonstrates that changes recorded at Macquarie Island are representative of wind, rainfall and temperature across the mid- to high-latitudes of the Southern Hemisphere.

⁵Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

Lakes are some of the most biodiverse, yet vulnerable, ecosystems on the planet. In Australia, the driest inhabited continent on earth, permanent lakes are relatively rare. By contrast, K'gari or Fraser Island, the largest sand island in the world, has a large number of permanent lakes and represents one of the few lake districts on the continent. The lakes of K'gari/Fraser island are remarkable because many are perched above the regional water table where an impermeable layer separates them from the sand below. They are one of the reasons why the island is listed as a UNESCO World Heritage site.

Holocene sediment sequences have now been analysed from at least six lakes on K'gari/Fraser Island. It appears that there was marked aridity on the island from c. 8000 to 5000 ka BP. Some lakes dried completely at a time previously thought to be characterised by humid climates in the Australian subtropics. Interestingly, in some sequences there is little to no physical evidence of drying which is recorded as a hiatus in the accumulation of highly organic, acidic, lake sediments.

The mid-Holocene dry phase recorded on K'gari/Fraser Island contrasts with evidence from North Stradbroke Island, a similar sand island which also has perched lakes, approximately 150 km to the south. As a result, there is strong potential to infer the Holocene regional climatology of the Australian subtropics at small spatial scales from these records.

Lastly, our study highlights a largely unrecognised vulnerability of lakes on K'gari to drying and indicates a need to better understand their hydrology and response to projected future climate change.

Antarctic ice sheet surface mass balance over the last millennium: a comparison between climate models and ice-core reconstructions

Quentin Dalaiden¹, Hugues Goosse¹, François Klein¹, Jan Lenaerts², Max Holloway³, Louise Sime³, Liz Thomas³

¹Université catholique de Louvain, Louvain-la-Neuve, Belgium. ²University of Colorado Boulder, Boulder, USA. ³British Antarctic Survey, Cambridge, United Kingdom

Abstract

Improving our knowledge of the spatial and temporal variability of the Antarctic Ice Sheet (AIS) Surface Mass Balance (SMB) is crucial to reduce the uncertainties of past, present and future Antarctic ice sheet contribution to sea level rise. Here, we show that the Global Climate Models (GCMs) simulate relatively well the current AIS SMB, but also the temporal variations over the last two centuries, including the large positive SMB trend since around 1960 AD as shown in ice cores data. The climate models suggest a strong regional positive correlations between AIS surface temperature and SMB, which is not evident in the reconstructions. Additionally, this correlation is stronger than that between delta O 18 and surface temperature at regional scale, which suggests that SMB can be used to reconstruct surface temperatures. When constraining the isotope-enabled model results with SMB and delta O 18 observed in the ice cores through a data assimilation procedure, the resulting surface temperature reconstruction outperforms the reconstruction based on the statistical method from PAGES2k, which is based on only delta O 18 (Stenni et al. 2017). Indeed, the correlation between the observed surface temperatures (1958--2010 CE) and our reconstruction is 0.73 against 0.57 for the statistical reconstruction. This is particularly true for the East Antarctica, where the observational uncertainties are large. This confirms that the use of other proxies and not only the delta O 18 allows improving the reconstruction, but also the relevance of data assimilation which allows to consider different proxies. Finally, we present an AIS SMB reconstruction over the last two centuries showing 1) large variability in SMB trends at regional scale; 2) large SMB increase (0.82 Gt year⁻²) in West Antarctica over the last decades, which is consistent with the recent reconstruction of Medley et Thomas (2018).

O-3186

Long-term demise of Subantarctic glaciers modulated by meridional shifts in the Southern Hemisphere Westerlies

Jostein Bakke¹, Oyvind Paasche²

¹University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, Bergen, Norway

Abstract

The recent accelerated loss of land ice and ice-shelves on the Antarctic Peninsula demonstrates a high sensitivity with respect to regional and large-scale climate drivers. To place the recent observed changes in the context of past natural shifts, it is paramount to reconstruct and reproduce past long-term glacier variability in the subantarctic zone and establish linkages to potential climate drivers. Here, we present a new high-resolution reconstruction of the extent of three cirque- and tidewater glaciers on South Georgia (SG, 54°S, 36°W). The reconstructions, which cover the past 14 000 years, combine lake multi-proxy lake sediment analyses with cosmogenic nuclide exposure dating. The analysis documents a dynamical behavior with glaciers on South Georgia shrinking since the Antarctic Cold Reversal (ACR, 14.5-12.8 Ka) and throughout the Holocene, in phase with glaciers on the Antarctic Peninsula and in part with Patagonia. Post ACR Equilibrium-Line-Altitude (ELA) variations correspond to a gradual warming of 1-1.5 °C, in accordance with recent ice core reconstructions. We hypothesize that orbital forcing and recent CO₂ changes and ozone depletion have caused an intensification of the Southern Annular Mode (SAM) which contributed to summer warming, the retreat of the subantarctic glaciers during the Holocene, and to the recent complete disappearance of Hodges Glacier on South Georgia, respectively.

Non-linear ice sheet behaviour in the Ross Sea driven by oceanic variability during the Holocene

Richard Selwyn Jones¹, Ross Whitmore², Andrew Mackintosh², Kevin Norton², Shaun Eaves², Jamey Stutz²

¹Durham University, Durham, United Kingdom. ²Victoria University of Wellington, Wellington, New Zealand

Abstract

Many outlets of the Antarctic ice sheet are experiencing terminus retreat, dynamic thinning and mass loss. This ice loss is predicted to accelerate for several regions of Antarctica in response to oceanic warming. Crucially, the observational record is short, restricting our ability to understand complex and non-linear responses. Longer-term records are therefore required to better understand patterns, mechanisms and drivers of ice sheet retreat, and to distinguish trends from decadal-scale variability.

We investigated the Holocene history of outlet glaciers in the western Ross Sea. Today, this region has the coldest continental shelf waters and so these marine-terminating outlets should be relatively insensitive to changes in ocean temperature. New cosmogenic-nuclide (¹⁰Be) surface-exposure data from Mawson Glacier, collected in elevation transects above the modern ice surface, reveal that rapid thinning occurred at ~6–8 ka. This is broadly coeval with new ages of grounding-line retreat at ~6 ka, as well as rapid surface lowering recorded at nearby Mackay Glacier at ~7 ka. Our data also show that a moraine formed near to the modern ice margin of Mawson Glacier at ~0.8 ka, which, together with other ice elevation data, indicates that glacier terminus positions likely oscillated during the Late Holocene. We then used time-dependent ice-flow modelling to evaluate the mechanisms of outlet glacier change in this region. We find that 1) the accelerated thinning of outlet glaciers resulted from local grounding-line retreat through overdeepened basins irrespective of the forcing applied, 2) the glaciers were unaffected by increased accumulation and/or glacial isostatic adjustment, and 3) ocean temperature variability during the Holocene can best explain the recorded outlet glacier history.

Our work demonstrates that non-linear ice sheet retreat was typical of Antarctica's marine-based margins during the last deglaciation, and that glaciers in the western Ross Sea were closely coupled to oceanic and topography-induced perturbations near their termini throughout the Holocene.

Abstract

For the last decades, paleoclimate studies in Patagonia have emphasized a high Holocene variability, strongly controlled by the intensity and latitudinal position of the Southern Westerly Wind (SWW). In this study we analyze the sedimentological and geochemical record of Lake Jeinimeni to document environmental and climate variability over the last centuries in North East Patagonia. At Present the lake setting is characterized by cold and steppic conditions with less than 300 mm by year of precipitation, mainly as snow. The core LJe14B (46°50'S, 72°00'W, 161 cm) was drilled in 2014 with an UWITEC gravity corer at a water depth of 60 m. The sediment is purely terrigenous with a low organic matter content (mean 2.5%) of allochthonous origin (mean C/N 16.7). Visual description, scopix radiographies and thin section observation evidence that the sediment is finely laminated, made by light brown clayey silts and fine sands with 17 centimetric coarser layers and 2 glass shard-rich tephras. ²¹⁰Pb and ¹³⁷Cs data demonstrate that the upper 17 cm of the core covers the last century with an average sedimentation rate of 1.3 mm/yr. The 2 tephras are consistent with recent eruptions of the Hudson volcano in 1991 and 1972AD, respectively. All chronometers are consistent with the annual deposition of the background fine sediment. A total of 766±60 varves are counted within 150 cm of sediment, the bottom part of the core being not investigated since scopix radiographies do not evidence any laminations. The 17 massive coarse layers were considered as one event and were therefore removed from the age model. A multivariate statistical analysis done on the core scanner XRF data allows to decipher 3 groups of samples. The first group, close to Principal Component (PC)1 axis, corresponds to argillaceous Al-rich layers. The second is distributed along PC2 axis and co-varies with Zr and Rb. It coincides with the plurimillimetric sandy-layers observed in the core and probably represents flood-like events related to snow melting. The third group of samples is made by the pluricentimetric sandy and gravely layers that interrupt the background fine sedimentation. They correspond to massive erosional events due to watershed perturbation. The evolution of PC1/PC2 ratio probably record flood-like events, bringing to the lake variable detrital supplies according to the precipitation rate. Our study site, the Lake Jeinimeni, allows to document environmental and climate variability in Patagonia over the last centuries. By combining sedimentological and geochemical proxies, the varved lacustrine sequence reveals recurrent coarse detrital supplies attributed to floods. The time-series record will be compared with regional paleoclimate reconstructions derived from Patagonian archives to decipher between local and regional climate influences. This research is funded by WBI-Chile cooperation project and Fondecyt 1120765.

Abstract

The temperature of the Southern Ocean is dependent on factors including the temperature of the atmosphere and upwelling water, shifts in the position of the Antarctic Circumpolar Current and the southern westerly winds, and the amount of heat transported northwards by the Atlantic Meridional Overturning Circulation (AMOC). Over recent decades, a slowdown of the AMOC has led to heat accumulating in the subsurface of the Southern Ocean, while surface waters poleward of 50°S have cooled, particularly in the Pacific sector (Armour et al., 2016; Jones et al., 2016). Given the scarcity and short length of Southern Ocean temperature records (Jones et al., 2016) palaeoclimate reconstructions can be used to investigate if the observed patterns are outside the range of natural variability and how temperature has varied in response to past changes in the climate system.

We present a diatom-based sea-surface temperature reconstruction from core KH-10-7 COR1GC, sampled from the western Indian sector of the Southern Ocean (54°16.04'S, 39°45.98'W), which was produced using the Modern Analogue Technique. The record spans from 14.2 to 1.0 ka BP (calibrated kiloyears before present) and has an average resolution of 60 years, allowing an improved understanding of the millennial-centennial variability since the deglacial. The record shows that temperatures varied in parallel with atmospheric temperatures over Antarctica, supporting synchronous changes in ocean and atmospheric temperatures across the southern high latitudes. Temperatures were low during the Antarctic Cold Reversal and gradually increased during the Younger Dryas (13-11.8 ka BP) to reach higher and stable values during the early Holocene (11.8-8.7 ka BP). Subsequently, cooler and variable conditions prevailed. The results support that during the Younger Dryas a slowdown in the AMOC along with rising atmospheric CO₂ levels caused the inferred warming of the Southern Ocean. A cool interval at 8.2 ka BP may be a southern hemisphere response to the '8.2 event' seen in records primarily in the northern hemisphere.

Abstract

The IntCal19 radiocarbon calibration curve has been constructed from carefully screened ¹⁴C and calendar age data using a newly developed Bayesian framework. New data include ¹⁴C measurements of the U-Th dated Hulu cave speleothem back to 54ka cal BP, late glacial tree-rings from New Zealand and Europe, and thousands of decadal and single year tree-rings from around the world. It also includes the extension and revision of the Lake Suigetsu varve counts. In addition, floating series of glacial age tree-rings have been wiggle-matched to the ¹⁴C calibration data. A GCM ocean model has been used to estimate marine reservoir age changes over time. The new curve compares well to other independently dated records such as wood buried by the Campanian Ignimbrite. IntCal19 provides more robust atmospheric ¹⁴C values and uncertainties than IntCal13 particularly for calendar ages older than 12ka cal BP.

Statistical methodology for the IntCal19 radiocarbon calibration curves: bespoke Bayesian splines with errors-in-variables

Timothy Heaton¹, Maarten Blaauw², Paul Blackwell¹, Christopher Bronk Ramsey³, Paula Reimer², E. Marian Scott⁴

¹University of Sheffield, Sheffield, United Kingdom. ²Queen's University Belfast, Belfast, United Kingdom. ³University of Oxford, Oxford, United Kingdom. ⁴University of Glasgow, Glasgow, United Kingdom

Abstract

A high-quality radiocarbon calibration curve requires not only precise and accurate calibration data but also a rigorous and reliable statistical approach to create the calibration curve and uncertainty bands. The available calibration data have several unique features that we need to both recognise and incorporate in the curve development. These include features such as:

- the radiocarbon measurements may relate to single-year tree-rings or annual sediment layers while others represent 5-20 years;
- for older time periods, the calendar ages of our calibration data are estimates with associated uncertainties (e.g. U/Th dating, varve counting, or climate tie-pointing to otherwise dated archives);
- calendar ages may even be unknown (e.g. a floating series of tree-ring ^{14}C measurements);
- offsets may exist between sets of radiocarbon measurements in different materials, due to reservoir ages or dead carbon fractions which may also be unknown.

If we ignore these aspects of the data then the final curve would be neither robust nor accurate and would underestimate the variability. However, at the same time we also wish to have a method that is neither so complex nor slow to run that it does not allow us to investigate the robustness of the curve to individual data points, data sets or modelling assumptions.

In this talk we present the new methodology used for the creation of the IntCal19 calibration curves. Our approach aims to address all the features described above while also enabling us to investigate the sensitivity of the curve to changing assumptions. The curve itself is estimated using Bayesian regression splines with the addition of bespoke modelling to incorporate the uncertain calendar ages, blocking and offsets. Curve creation is performed within an MCMC sampler using parallel tempering to improve mixing.

O-3192

The evolution of past marine radiocarbon reservoir ages according to simulations

Martin Butzin¹, Timothy Heaton², Peter Köhler¹, Gerrit Lohmann¹

¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany. ²University of Sheffield, Sheffield, United Kingdom

Abstract

Marine radiocarbon records are important constituents when reconstructing the atmospheric radiocarbon history prior to the continuous tree-ring period. However, marine radiocarbon records are frequently fragmentary in space and time, and their reservoir age (i.e., their isotopic depletion compared to the atmosphere expressed as radiocarbon age) is only weakly constrained through observations. Ocean radiocarbon cycle circulation models can provide a valuable tool to assess the evolution of past reservoir ages. Here, we present results of reservoir age simulations contributing to the construction of the most recent radiocarbon calibration curve, IntCal19, applying the LSG ocean general model forced with various climatic background conditions and with atmospheric radiocarbon changes according to the Hulu Cave speleothem record. We discuss the spatiotemporal evolution of reservoir ages during the past 54000 years. As an update of previous work (Butzin et al., 2017, doi:10.1002/2017GL074688), we find reservoir ages varying between 500 and 1400 ¹⁴C years in the low- and mid latitudes and reservoir ages exceeding 3000 ¹⁴C years in the polar oceans. Our results are broadly in line with available marine radiocarbon reconstructions, with the caveat that these records typically originate from continental margins, marginal seas, or tropical lagoons which are not properly resolved by our model. This problem will be overcome by the next generation of radiocarbon-equipped ocean circulation models featuring global multiresolution meshes.

Abstract

Terrestrial plant macrofossils from the lake sediment record of Lake Suigetsu, Japan, taken in 2006 (SG06) provide the only quasi-continuous direct atmospheric record of radiocarbon covering the last 50 ka cal BP (Bronk Ramsey et al. 2012). New high precision data are now available on U-Th dated speleothems covering the same time range (Cheng et al. 2018). In addition a new varve-based chronology has also been published for SG06 based on extended microscopic analysis of the sediments and improved algorithms for interpolation (Scholaut et al. 2018). Here we reanalyse the radiocarbon dataset from Suigetsu based on the new varve counting information and the constraints imposed by the speleothem data so that the Suigetsu dataset can be used to help in the construction of the next IntCal calibration curve. Comparison of the speleothem and plant macrofossil records provides insight into the mechanisms underlying the incorporation of carbon into different types of record and the relative strengths of different types of archive for calibration purposes.

Abstract

The radiocarbon calibration curve, IntCal, is a key dating tool in paleosciences. It provides a chronological framework for a wide range of disciplines studying environmental and cultural changes during the past 50,000 years which is crucial for our understanding of their dynamics. Tree-rings directly record atmospheric ^{14}C at their time of growth and can be absolutely dated via dendrochronology making them ideal archives to build a calibration curve. However, these high quality records are only continuously available back to $\sim 14,000$ years before present. Prior to this, IntCal relies on ^{14}C data from archives that do not provide the same quality in terms of timescale and (in the case of marine and speleothem records) do not directly reflect atmospheric ^{14}C . However, occasionally trees beyond the current continuous record are being discovered and these “floating” tree-ring records can provide snapshots of past atmospheric ^{14}C variability. The challenge lies in establishing their absolute chronology.

Ice cores have become invaluable tools for linking “floating” tree-ring chronologies to an absolute timescale. ^{10}Be , a cosmogenic radionuclide produced in a similar way as ^{14}C , is stored in the ice and provides a unique comparison record. Pattern-matching of floating ^{14}C records to ice core ^{10}Be can thus guide us in establishing a timescale for the tree-ring records, characterize past atmospheric ^{14}C variability and test and improve the radiocarbon dating calibration curve.

We will show examples of how ice core ^{10}Be records can be used to link floating tree-ring chronologies to an absolute timescale over the entire range of the radiocarbon dating method, and discuss the implications for the radiocarbon dating calibration curve.

Abstract

Radiocarbon (^{14}C) dating allows us to better understand the human past and the carbon cycle. The technique's success relies on very precise measurements of ^{14}C activity in carbonaceous material remains. Independently-dated biological materials that exhibit annual layers, such as tree rings, are necessary for a precise reconstruction of the atmospheric ^{14}C , as radiocarbon ages do not represent exact calendar dates. Ongoing efforts to optimize the ^{14}C timescale have produced calibration curves back to 50 kyrs BP. Nevertheless, several gaps still remain. While it is well established that during the Holocene atmospheric ^{14}C signatures have varied between the Northern Hemisphere (NH) and Southern Hemisphere (SH) through the inter-hemispheric offset, there is still little data to better define intra-hemispheric offsets for the last 70 years. The intra-hemispheric offsets define the ^{14}C geographical division known as zones NH1, NH2, and NH3 for Northern Hemisphere, and SH1-2 and SH3 for Southern Hemisphere. Currently, the ^{14}C geographical divisions, zones SH1-2 and SH3, are basically defined using data from eastern SH sites (New Zealand, Australia, and Indonesia). Consequently, the ^{14}C boundary between zones SH1-2, SH3, and NH3 over South America and Africa at lower latitudes are defined based on the mean position of the Inter Tropical Convergence Zone (ITCZ). To overcome a dearth of suitable ^{14}C records at lower-latitudes, we selected six tree species across the Amazon basin and Central Africa (i.e., Ecuador, Peru, Bolivia, Brazil and Cameroon). The main goal of this project is to extend the observational record by developing annually-resolved atmospheric post-AD1950 ^{14}C data using cellulose material from dendrochronologically-dated tree rings across the ITCZ mixed band. These newly developed datasets will be used to model observed ^{14}C gradients of each species/site for backtracking air-mass parcels to better constrain the new global atmospheric $^{14}\text{CO}_2$ global distribution map. Additionally, we will develop isotopic synoptic maps based on both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ tree-ring series to examine spatial and temporal patterns of carbon cycle changes that can influence ^{14}C spatial distributions. The project showcase will be discussed and preliminary results will be presented.

Abstract

Connecting calendar ages to ^{14}C ages (i.e. constructing a calibration curve) is mainly based on ^{14}C samples that can also be dated via independent methods. However, comparison of ^{14}C data to other records such as cosmogenic radionuclide data from ice cores can provide tests of the quality of the ^{14}C data and its calendar age determinations. Here we will discuss how such additional information can aid the identification of uncertainties in ^{14}C records and the improvement of the calibration curve.

The direct incorporation of such information into the calibration curve is challenging as it delivers only partial information (e.g. the placement of a floating tree ring sequence within a section of non tree ring data) possibly leading to an inhomogeneous calibration record. We will discuss how this issue will be addressed in the upcoming IntCal update. Furthermore, we will investigate how floating tree ring sequences on ice core time scales agree with the new ^{14}C data from measurements on U/Th-dated speleothems from Hulu cave in China and discuss unresolved differences that are possibly related to our limited understanding of carbon cycle influences on the atmospheric ^{14}C concentration during the last glacial period.

The glacial history of NW Greenland during the last 50,000 years

Anne Sofie Søndergaard¹, Nicolaj Krog Larsen^{1,2}, Jesper Olsen³, Kurt Kjær²

¹Department of Geoscience, Aarhus, Denmark. ²Natural History Museum of Denmark, Copenhagen, Denmark.

³Department of Physics and Astronomy, Aarhus, Denmark

Abstract

Knowledge about the glacial history of the Greenland Ice Sheet and its dynamic response to past climate variability is important to put the current changes into context. However, there are areas in Greenland where only little knowledge about past ice marginal fluctuations are available. One of these areas is NW Greenland, an area where ice sheet models show deglaciation sometime during Early Holocene, but limited field studies have been carried out.

In this study we aim at illuminating the glacial history of NW Greenland, combining results from three study areas; Melville Bay, the Qaanaaq area and Inglefield Land. We use ¹⁰Be and in-situ ¹⁴C exposure dating of boulders on moraines and bedrock as well as radiocarbon dating of reworked marine molluscs and subfossil plants.

Radiocarbon ages of reworked marine molluscs and subfossil plants show a smaller than present day ice extent during MIS3 between 42.2 to 30.6 cal ka BP as well as during late Holocene from 3.7 cal ka BP until 1.0 cal ka BP being in accordance with other findings from northwest and northeast Greenland (Farnsworth et al. 2018; Larsen et al. 2018).

¹⁰Be ages of boulders on moraines and bedrock show a large scatter of ages from 11 ka in Melville Bay to 93 ka in Inglefield Land, yielding low erosion rates and ¹⁰Be from previous exposures in several of the samples. Thus, in-situ ¹⁴C measurements will be carried out in order to constrain the glacial history in areas affected by inheritance. The trend so far points towards the areas away from fast flowing ice being the most affected showing the importance of ice bed properties when using a method as exposure dating.

Overall, preliminary results from our three study areas show a dynamic glacial history but also highlights difficulties when using a method as exposure dating in NW Greenland, possibly due to a cold based less erosive ice. With the new age constraints, we expect to gain further knowledge about the overall glacial history of NW Greenland, one of the least explored parts of Greenland. We will discuss the new age constraints in relation to existing climate records as well as already published glaciation ages from NW Greenland.

Disintegration of a local ice cap: patterns of ice recession during the Last Glacial-Interglacial Transition in the Wicklow Mountains, Ireland

Lauren Knight^{1,2}, Clare Boston¹, Harold Lovell¹

¹University of Portsmouth, Portsmouth, United Kingdom. ²University of Worcester, Worcester, United Kingdom

Abstract

We present a geomorphological assessment of the extent and dynamics of glaciation in the Wicklow Mountains, Ireland, during the Last Glacial Interglacial Transition (LGIT; ~ 20 – 11 ka BP). Until now, work in the area has focused upon a local ice cap which was confluent with regional ice at the Last Glacial Maximum (LGM; ~ 25 ka BP), but little information exists on subsequent ice retreat in response to climate amelioration during the LGIT. Our contribution investigates ice dynamics during and after the transition from an ice cap to topographically restricted mountain glaciation. We identify that initial ice cap recession was characterised by rapid retreat and large-scale disintegration. The geomorphological record indicates that ice masses only stabilised once they were topographically constrained within valleys. We also recognise the establishment of three distinct landsystems in the Wicklow Mountains following the fragmentation of the LGM ice cap: (1) the large north-eastern sector of the region hosted a mountain icefield with multiple outlet glaciers; (2) a small plateau icefield existed in the central sector, with several outlet glaciers; and (3) several individual valley glaciers persisted in the south-western sector. Each of these landsystems record sustained retreat and subsequent stabilisation during the LGIT, prior to the Younger Dryas. Two-dimensional reconstructions of ice dynamics indicate variations in recession patterns throughout the region. Based on our ice margin reconstructions and the limited published dates for the region, we suggest that following the retreat of regional ice after the LGM, the local ice cap was relatively stable until the start of the LGIT (~20 ka BP). Following this, ice experienced sustained thinning and ice margin retreat until ~ 17 ka BP. By this point, ice was topographically restricted and the three aforementioned landsystems were established. A period of ice margin stabilisation occurred before further persistent retreat until ~ 15 ka BP, by which ice had retreated into the upper reaches of valleys. It is likely that the plateau icefield and most of the mountain icefield had disappeared by ~15 ka BP, when the outlet glaciers of both landsystems had detached from their central accumulation areas and experienced sustained retreat. Following this, some small cirque glaciers experienced minor readvance before ice recession continued. The geomorphological record indicates that limited cirque glaciation was re-established during the Younger Dryas.

Abstract

Numerous efforts to understand glacier response to abrupt climatic events naturally focus on moraines. An often employed assumption is that moraines formed at stationary glacier configurations, but for a more comprehensive understanding we need continuous and high-resolution records of retreat, re-advances, and standstills, which glacial varves uniquely provide. The reliability of varves as chronometers hinges on cross correlating many sites and independent age control.

We present such a varve record from glacial Lake Agassiz that is both reproducible across multiple sites and independently dated. This 1200 varve-year time series documents Laurentide Ice Sheet (LIS) margin retreat during the late Younger Dryas (YD) at around 23 m/yr. In addition, the varves span a prominent end moraine (the Hartman), which is typical for those on the Canadian Shield, being composed of sand and gravel and deposited by sub-aqueous discharge along the ice margin. The Hartman moraine was created during general ice retreat and formed within a time window of less than 200 years. A 45-year period of thicker varves within this period is our favored interpretation for the duration of moraine building. The moraine dates to the YD/Holocene transition (ca. 11,600 cal yr BP). This varve time series begins 7-km north of an older moraine, the Eagle-Finlayson, but our record does not yet span this older moraine, so its timing and period of formation remain poorly constrained.

This Lake Agassiz varve record is similar to that from the Baltic Ice Lake in southern Finland, which documents steady ice retreat north from the Salpausselkä I moraine and formation of the Salpausselkä II moraine near the end of the Younger Dryas. Similar to the Eagle-Finlayson and Hartman moraines, the Salpausselkä I and II moraines are ice-marginal, sub-aqueous deposits of sand and gravel. Cooler temperatures during the latter half of the YD stadial were not enough to stop ice retreat along the LIS bordered by Lake Agassiz, nor the FIS ice margin bordered by the Baltic Ice Lake. The similar timing and mode of formation between the moraines in Lake Agassiz and the Baltic Ice Lake suggests that they may have similar climatic forcing mechanisms. Our ability to test potential teleconnections between the LIS, FIS, and ice core records during the late glacial, particularly as they relate to abrupt climate change, would be greatly improved by developing additional well-dated and cross-correlated varve thickness data sets from North America.

A spatially-restricted Younger Dryas plateau icefield in the Gaick, Scotland

Benjamin Chandler¹, Sven Lukas², Clare Boston¹

¹Department of Geography, University of Portsmouth, Portsmouth, United Kingdom. ²Department of Geology, Lund University, Lund, Sweden

Abstract

Producing three-dimensional palaeoglaciological reconstructions of discrete ice masses has been the focus of many glacial geomorphological studies in the Scottish Highlands over the past 15 years or so. Despite this, understanding of the extent, style and timing of Quaternary glacier fluctuations in Scotland remains incomplete. This is exemplified by the enigmatic and contentious Gaick (or Gaick Plateau), a dissected upland plateau in the Central Grampians. Previous studies of the glacial sediment-landform assemblages in this area have resulted in widely-differing and conflicting interpretations, although the 'generally-accepted' model is one of extensive plateau icefield glaciation during the Younger Dryas (~12.9–11.7 ka). We present the results of renewed, systematic geomorphological and sedimentological investigations in the Gaick. Using a glacial landsystems approach, morphostratigraphic principles and 'glacierisation threshold' analysis, we establish that the area experienced only spatially-restricted plateau icefield glaciation during the Younger Dryas. Our glacierisation threshold analysis shows that topographic variations from west to east across the area, combined with a steep projected increase in the regional equilibrium line altitude (and a concomitant decrease in precipitation), would have precluded the development of an icefield across the whole area. Our revised interpretation contrasts starkly with the widely-held view that the Gaick was covered by an extensive plateau icefield during the Younger Dryas. We use the geomorphological evidence, together with surface profile modelling, to produce a three-dimensional reconstruction of a ~42 km² Younger Dryas plateau icefield. This newly-reconstructed icefield is then used to derive palaeoclimatic variables for the Younger Dryas and assess regional climate trends across Scotland during that period.

The dynamic response of debris-covered Himalayan glaciers to Late Holocene climate change

Ann Rowan¹, Duncan Quincey², David Egholm³, Bryn Hubbard⁴, Josephine Hornsey¹, Katie Miles⁴, Evan Miles², Martin Kirkbride⁵

¹University of Sheffield, Sheffield, United Kingdom. ²University of Leeds, Leeds, United Kingdom. ³Aarhus University, Aarhus, Denmark. ⁴Aberystwyth University, Aberystwyth, United Kingdom. ⁵University of Dundee, Dundee, United Kingdom

Abstract

Glaciers in the monsoon-influenced central Himalaya last advanced during the regional Little Ice Age around 500 years before the present day. The dynamic behaviour of many of these large mountain glaciers during and after this period was strongly influenced by the accumulation of supraglacial rock debris supplied from rapidly eroding hillslopes. Rapid debris export during late Holocene advances created topographic barriers to further glacier expansion, causing debris-rich glaciers to expand vertically rather than horizontally. Supraglacial debris accumulation during the subsequent period of negative mass balance caused extensive glacier tongues to be preserved at lower elevations than would be possible for clean-ice glaciers, as in regions with active tectonics such as the Himalaya, debris layers are commonly thicker than a few centimeters and substantially reduce ablation by insulating the glacier surface from the atmosphere and incoming solar radiation.

Understanding the response of these large mountain glaciers to climatic change therefore requires quantifying the feedbacks between ice flow, debris transport and mass balance. We used higher-order numerical modelling of ice flow and debris transport to unravel the behaviour of the world's highest glacier, Khumbu Glacier in Nepal, during the Late Holocene and through the present day, to investigate how supraglacial debris influences the response of Himalayan glaciers to climatic change and to predict their future evolution. Numerical modelling was evaluated against observations of past glacier geometries from moraine positions, remotely sensed data spanning the last 50 years, and present day mass balance and dynamics from field monitoring as part of the EverDrill high-elevation debris-covered glacier drilling project. Results from this numerical modelling predict glacier mass loss of only 10% by 2100 CE and illustrate the differing behaviour of debris-covered glaciers compared to clean-ice glaciers.

A decade of glacier and landscape change: high resolution monitoring at the British Geological Survey Glacier Observatory, Virkisjökull-Falljökull, SE Iceland

Jez Everest¹, Bergur Bergson², Andrew Black³, Tom Bradwell⁴, Heiko Buxel¹, Andrew Finlayson¹, Verity Flett⁵, Leanne Hughes⁶, Lee Jones⁶, Alan MacDonald¹, Jon Mackay⁶, Louise Maurice⁷, Brighid Ó Dochartaigh¹, Benedikt Ófeigsson², Emrys Phillips¹, Gunnar Sigurðsson², Oddur Sigurðsson², Paul Wilson⁸

¹British Geological Survey, Edinburgh, United Kingdom. ²Veðurstofa Íslands, Reykjavik, Iceland. ³University of Dundee, Dundee, United Kingdom. ⁴University of Stirling, Stirling, United Kingdom. ⁵Scottish Environmental Protection Agency, Edinburgh, United Kingdom. ⁶British Geological Survey, Nottingham, United Kingdom. ⁷British Geological Survey, Wallingford, United Kingdom. ⁸Geological Survey of Northern Ireland, Belfast, United Kingdom

Abstract

The BGS Observatory at Virkisjökull-Falljökull has carried out continuous survey and monitoring since 2009, in order to characterise processes ongoing in the glacier catchment in response to changing climate. Multi-year datasets include: meteorology; glacier, proglacial and groundwater hydrology; glacier flow and surface ablation; glacier seismicity; annual LiDAR surveys; and multiple GPR, meltwater chemistry, structural glaciology, dye-tracing, ablation, and mapping survey campaigns. Thus we believe this is one of the broadest scope, multidisciplinary projects of its kind.

Our key findings relate to processes of deglaciation, in terms of glacier ablation, flow and reorganisation, and meltwater production, storage and transport, plus the impacts of deglaciation on landscape evolution, and surface and groundwater hydrology. Our data also help to parameterise new glacier-hydrological modelling.

Project highlights include:

The transition from proglacial debris-covered ice zone to ice-marginal lake has seen the ephemeral development of classic proglacial geomorphology, followed by equally rapid geomorphological degradation. We propose this model of proglacial evolution is now common across Iceland and evidence of similar transitions can be seen in the glacial geological record worldwide.

The upper active section of Falljökull still flows, but has detached from, and is being thrust over, its stagnant lower section. The reduction in active length of Falljökull over recent years has allowed rapid re-equilibration to regional snowline rise. Globally other steep outlet glaciers may respond similarly to mass balance changes by rapidly adjusting their active length in response to recent atmospheric warming.

Ice and snowmelt dominate summer riverflow, but significant flow also occurs in winter due to glacier icemelt and rainfall. The influence of groundwater discharge increases during winter and forms a small (15–20%) consistent source of baseflow to the river. Storms give rise to similar hydrological responses across all seasons reflecting a highly efficient permanent glacial drainage system.

Large volumes of proglacial groundwater storage are actively recharged by local precipitation and strongly influenced by individual precipitation events. Significant glacial meltwater influence on groundwater occurs within 500m of the outlet river, where there is active recharge from river losses. Predicted future changes in glacier

coverage and precipitation are likely to increase the significance of groundwater storage in proglacial aquifers for water resources and maintaining environmental flows.

Numerical modelling of glacier-hydrological processes, ground-truthed with river discharge and ablation data have indicated that meltwater volume and river discharge are highly influenced by changing glacier hypsometry. Although the river flow regime characteristics (flow magnitude, timing and variability) are sensitive to climate change, the response is moderated by melt and glacier-hydrology processes. This has consequences for uncertainty quantification in glacial meltwater modelling projections.

We would now like to build on our many collaborations borne from this project, and explore new research partnerships based on a decade of data.

Abstract

Glaciers respond to a shift from cool to warm climate by various forms of mass loss (melting, calving) and general ice-marginal retreat. This response has been widely observed in modern systems and has also been reconstructed from past deglaciations. An under-studied mechanism of glacier mass-loss in a changing climate exhibits an opposite ice-marginal response to warming. On a short timescale, glacier ice margins re-advancing rapidly, yet unsustainably, resulting in a pronounced draw-down of ice throughout the system. Unlike a traditional advance associated with positive mass balance this re-advance results in significant volumetric loss. While to an extent this process can be observed at present, the palaeo-record of such a process is harder to disentangle owing to limited palaeo-climate records and fragmented reconstructions.

Widespread, asynchronous glacier re-advances during the Late Pleistocene and Holocene have been identified around Svalbard. Glacial deposits are contemporaneous with reconstructions of warm water and air masses arriving to the region and the time-transgressive deglaciation of the Svalbard-Barents Sea Ice Sheet. We propose that unsustainable glacier re-advances were a key and previously un-acknowledged mechanism for net mass-loss and the degradation of the former ice sheet. Conceptually, this process does not exhibit a constant rate nor synchronous mode of mass loss, but potentially a more effective means of ablation given an extended period of time, as climate shifts from glacial mode to inter-glacial mode.

Late Quaternary Caspian Sea evolution recorded through clay minerals, Nd isotopes and palynology

Alina Tudryn¹, Suzanne A.G. Leroy², Samuel Toucanne³, Yuri A. Lavrushin⁴, Olivier Dufaure¹, Serge Miska¹

¹GEOPS, Univ. Paris-Sud, CNRS, Université Paris-Saclay, Orsay, France. ²Mediterranean Laboratory of Prehistory Europa-Africa, Aix Marseille Univ, CNRS, Minist Culture, LAMPEA, UMR 7269, 5 rue du Château de l'Horloge, Aix-en-Provence, France. ³Institut Français de Recherche pour l'Exploitation de la Mer (IFREMER), Unité de Recherche Géosciences Marines, Plouzané, France. ⁴Geological Institute (GIN), Russian Academy of Sciences, Moscow, Russian Federation

Abstract

We present the results of clay mineral, Nd and palynological analyses applied to sediments from the Caspian Sea. Analyses were performed on two sediment cores that were collected in the middle basin (SR-9418 GS20, water depth of 479 m and Sh7, water depth of 749 m) during a cruise that took place in 1994 as a part of the multidisciplinary study of the Caspian Sea, conducted by a Russian-French team, and a cruise of the Shirshov Institute of Oceanology in 2010. Sediments were already studied for sedimentological, magnetic, geochemical and biological parameters (Chalié et al. 1997; Jelinowska et al., 1998,1999; Boomer et al., 2005; Leroy et al., 2000,2007,2010,2013,2014; Pierret et al., 2012; Tudryn et al. 2013,2014;2016). Both cores present Late Pleistocene and Early-Mid Holocene sediments. The late Pleistocene part of both cores consists of detrital rich and carbonate poor material while Holocene sediments are dominated by carbonaceous mud.

Our results show that during the last deglaciation, the Caspian basin collected meltwater and fine-grained sediment from the southern margin of the Scandinavian Ice Sheet via the Volga River. It induced the deposition of characteristic chocolate-colored illite-rich sediments (Chocolate Clays) that originated from the Baltic Shield area according to Nd data (Tudryn et al., 2016). This supply started probably at ~22 cal kyr BP, led to the Early Khvalynian transgressive stage(s) and Chocolate Clays deposition in the now-emerged northern flat part of the Caspian Sea and in its middle basin, and it stopped at ~13.8 cal kyr BP. The strong contribution from Volga river sources to the sediment is also indicated by pollen analyses (very low pollen concentrations with high occurrence of *Pinus* and reworked grains). Pollen assemblages detected then the Allerød and the Younger Dryas, and the dinocyst assemblages the subsequent Mangyshlak.

After the Chocolate Clays deposition and until 3.0 cal kyr BP, smectite became the dominant clay mineral in the sediment from the middle basin of the sea. Simultaneously, e_{Nd} values increased and stayed high during the Holocene indicating the major change of the sediment sources in this basin. Such values are comparable to those obtained for today's sediments deposited by Amu-Darya in the Aral Sea. The highest e_{Nd} values were recorded between 9 and 4 cal kyr BP and are similar to those obtained for today's sediments transported from Alborz Mountain by Sefidrud Rivers into the southern basin of the Caspian Sea.

¹Geological Institute, Russian Academy of Sciences, Moscow, Russian Federation. ²Paris-Sud University, Paris, France.

³Institute of Archeology, Russian Academy of Sciences, Moscow, Russian Federation

Abstract

The Northern Caspian region located far from the key areas with well-developed sequence and known types of global climate events. The main paleoclimate factors in the region are with sharply continental conditions, trade winds moves from Turkestan, Siberian glacial, Arctic and even Mediterranean. The local impact on paleoclimate events also affected by rapidly changes of the Caspian Sea level.

We studied paleoclimate events, reconstructed from paleo landscapes, and find a number of important features. These include a sharp change of vegetation landscapes, often without transitional stages, an unusual composition of plant communities for paleoclimate optima and minima, as well as unique latitudinal zonality of natural zones. Different types of hyperzonal landscapes predominance were the special feature of the local paleoclimate. Sometimes we fixed natural zonality, close to the meridional one, associated with radical change of the atmospheric air currents direction.

The dynamics of natural events are frequently correlate with extreme natural events of a catastrophic type. Some of them turn out to be concentrated in the form of unique episodes associated with natural events. Sand and dust storms are the main among natural disasters, as well as high-speed changes in the Caspian Sea level, and relief transformations, mud volcanism, gravity and seismic-gravity processes, powerful quick ground processes associated with extremely high pressures groundwater, and some hydrological disasters. The Late Glacial hydrological disasters in the Volga Valley, unlike other Eastern Europe river systems, destroyed almost all pre-Neolithic archaeological monuments. We also find some places with local extreme environmental events, with significant hydrogen sulfide gas emissions. This may cause partial mortality of large mammals.

What are the drivers of Caspian Sea level change during the Quaternary period?

Sifan A. Koriche¹, Joy S. Singarayer¹, Hannah L. Cloke^{1,2}, Paul Valdes³

¹Department of Meteorology, University of Reading, Reading, United Kingdom. ²Department of Geography and Environmental Science, University of Reading, Reading, United Kingdom. ³School of Geographical Sciences, University of Bristol, Bristol, United Kingdom

Abstract

The Caspian Sea, one of the world's largest lakes and located in a closed basin, experienced extreme water level changes ranging from tens to hundreds meters on various time-scales during the Quaternary period. Numerous studies have suggested that the water level variations of this region have depended on both geophysical processes, affecting the opening and closing gateways with the marine realm, and hydro-climatological processes, resulting in water balance changes. However, there are conflicting ideas concerning the relative importance of different potential drivers of past sea level variability, as well as the mechanisms/routes by which they impacted basin connectivity and sea level variation. In this study, firstly we focus on reviewing the potential drivers of sea level change and secondly we study the impacts of hydro-climatological processes and catchment dynamics on water level. Climate model simulations from a global coupled ocean-atmosphere-vegetation climate model, HadCM3, are used to drive a hydrological model to examine lake level change. We explore catchment water balance variability as well as changes in catchment size over the last 120 thousand years. Hypothetical scenarios of runoff source area are investigated to understand the impact of extinct river systems and pro-glacial melt water pulses on lake levels and connectivity. By this method we will explore and constrain the drivers and sources of runoff that control the sea level variations of Caspian Sea.

Keywords: Sea Level change, hydroclimate processes, hydrological modelling, catchment dynamics.

Abstract

The remnants of the palaeo-channels much larger than the modern ones are widespread in the floodplains of lowland rivers in the Black Sea basin on the East European and Pannonian plains. Palynological studies of palaeo-rivers alluvium make it possible to locate the climatic and hydrologic region-analogues of the landscapes at the time of their development, from 16 to 19 ka BP. These analogues allowed reconstruction of the former surface runoff of the large Late Glacial rivers, as well as the total volume of flow to the Black Sea from the East European and Pannonian plains, using the transform functions. The mean annual water yield from this territory for several thousand years was up to 700-800 km³ and reached 2800 km³ per year for a few decades during the extreme runoff stage. This huge river runoff was the main factor of the Black sea level rise in that period. The flow velocity calculations, lithological composition of deposits and morphology of the Bosphorus and Dardanelles straits shows that these canals were cleaned of loose sediments by this powerful flow, and the basement rocks were exposed. There is an uncertainty in the position of the highest rock sill, as the maximum rock surface altitude is similar in the Dardanelles and in the Bosphorus (about -75...-80 m). We assume that the rock sill in the Dardanelles was formerly higher than at present (about -70 m), and was lowered down to its modern position by the powerful flow through the canal. When the ocean level was lower than the rock sill in the Dardanelles, the level of the Black Sea was controlled by flow hydraulics on this sill. The spillway flow theory was used to calculate the water level on the rock sill using discharge, critical velocity of rock erosion initiation and cross-section geometry. At the stage of the maximum discharge (the "hydrocratic" transgression of the Black Sea), sea level was about -62...-64 m. Later on, with diminishing discharge it decreased to -66...-67 m. Since about 14 ka BP, when the ocean level rose above the altitude of the Dardanelles rock sill, the new stage of the "eustatic" transgression has begun. The level of the Black Sea was then controlled by the ocean level and remained close to it ever since.

This study was funded by Russian Federation program "The Evolution and Transformation of Erosion-Channel Systems under Changing Environment and Human impact."

MIS5 in the Marmara Sea: palynological reconstructions of climate and water parameters

Suzanne Leroy^{1,2}, Pierre Henry³, Christine Pailles³, Julia Kende³, Kazuyo Tachikawa³, Kürşad Kadir Eriş⁴, Fabienne Marret²

¹LAMPEA - AMU, Aix-en-Provence, France. ²Environm Sci, Uni Liverpool, Liverpool, United Kingdom. ³Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, Aix-en-Provence, France. ⁴Marine Geology and Geophysics, ITU, Istanbul, Turkey

Abstract

The Marmara Sea is the ultimate western connexion of the Pontocaspian to the Mediterranean Sea. It has had a complex history of connections both with the latter and with the Black Sea. During periods of isolation, it was fully Pontocaspian with a brackish environment. During periods of connexion to the Mediterranean Sea through the Dardanelles, the Sea of Marmara water body experienced a more or less pronounced stratification, as during the Holocene. Palynology has been studied in two sedimentary sequences with a special focus on sapropel intervals attributed to MIS5. At those times, the Marmara Sea was stratified, and the bottom water, presumably of higher salinity, experienced episodes of anoxia.

The dinocyst assemblages in the sapropels are dominated by *Pyxidinospis psilata* and *Spiniferites cruciformis* and clearly differentiate the sapropels from the truly marine phases. The terrestrial pollen shows a clear alternation of steppic landscape (*Artemisia*) and oak forests, corresponding to the substages of MIS5. This confirms the proposed age-depth model. Moreover, warmer periods, likely during MIS 5a and 5c, appear to coincide with peaks of organic carbon content in the sediment.

Late Quaternary climate and environment reconstruction of Lake Urmia basin (Iran)

Ting Kong¹, Alina Tudryn¹, Elisabeth Gibert-Brunet¹, Seyed-Hani Motavalli-Anbaran², Piotr Tucholka¹, Mohammad Lankarani³, Hesam Ahmady-Birgani⁴, Aurélie Noret¹, Marc Massault¹, Serge Miska¹

¹UMR 8148-GEOPS CNRS-UPS, Univ. Paris-Sud/Paris-Saclay, Orsay, France. ²Institute of Geophysics, University of Tehran, Tehran, Iran, Islamic Republic of. ³School of Geology, University of Tehran, Tehran, Iran, Islamic Republic of.

⁴Faculty of Natural Resources, Urmia University, Urmia, Iran, Islamic Republic of

Abstract

The ongoing changes affecting Lake Urmia are revealed by the lake water level decrease by more than 7 m in the last 15 years, desertification and formation of dust storms. This drop has been attributed to rainfall declining by ~10% and to anthropogenic causes mainly the construction of numerous dams on rivers feeding the lake and abusive groundwater pumping. Nevertheless, the exact roles of natural and anthropogenic factors that influence the state of the lake are still not identified. Indeed, the lack of the detailed record of environmental evolution in the past limits the understanding of actual and future processes and as a consequence, the capability to develop integrated management of this water resource.

The Franco-Iranian project initiated by bilateral Gundishapour program (2016/2017), aims to obtain a high temporal resolution records of past environmental and climate changes in the Lake Urmia area for the whole Holocene. Preliminary results integrating the interpretation of environmental data in the vicinity of our lacustrine cored sequences are done with reference to modern hydrogeochemical and geological systems in relation with the establishment of a reliable ¹⁴C time-scale indispensable for palaeoclimatic reconstructions using various proxies at a global scale (Tudryn et al., in prep.).

During the fieldworks, several sediment cores (5-14 m long) have been obtained from recently dried out part of the lake close to Urmia city and sampling of the lake, wells and river waters has been done. Preliminary analyses were done on part of sediments and waters at laboratory UMR 8148-GEOPS. Sediments are composed by an alternation of sands and finer-silty and clayish fractions. Analyses for total mineralogy, clays, carbonates, magnetic properties, organic carbon, either contents and isotopes ¹³C_{org} and microscopic observations show important changes of the biological activity, sources of detrital material and transport energy, conditions of lake water evaporation and during early diagenesis. All these parameters are in relation with both lake water level fluctuations and precipitation variations over the lake watershed at local to regional scales through time. Ongoing analyses for ¹⁴C AMS dating on rests of plants will allow the establishment of the accurate chronology for observed changes.

O-3210

Lake Burdur (Turkey) environmental changes during the Late Quaternary inferred from the lake deposits: preliminary results

Nevzat Özgür¹, Eda Aydemir¹, Piotr Tucholka², Alina Tudryn², Ümit Memiş¹, Alperen Şentürk¹, Mehmet Arıcı¹
¹Suleyman Demirel University, Isparta, Turkey. ²Paris Sud-11 University, Paris, France

Abstract

Lake Burdur is located in Isparta region (Anatolia, Turkey). As it is closed, sensitive to the rapid climate changes reservoir, it belongs to large Eurasian lakes that are good climatic archives. Moreover, its geographical position allows the studies of the pale climate variations not only at local scale, but also at regional scale that integrates Mediterranean-Marmara-Black-Caspian seas area. Lake Burdur occupies the lowest part of the Burdur basin that was formed during Tertiary extensive tectonic phase as a graben. During the last 40 years water level of the lake lowered significantly (~ 15 meters), as well as the groundwater table in the area. This was attributed to climatic variations, human activity and/or seismic activity; nevertheless, exact impacts of these on actual lake evolution were not yet established. Indeed, the lack of the detailed record of environmental evolution in the past, limits the understanding of actual and future processes in the lake area.

The recently initiated Franco-Turkish project aims to obtain high temporal resolution records of past environmental and climate changes in the Lake Burdur area for the Late Pleistocene (from Last Glacial Maximum) and the whole Holocene. The process will integrate hydrogeological, hydrological and lake sediments studies.

During the fieldworks realized in 2017/2018, two continuous sediment cores (~20 m long) have been obtained from recently dried out part of the lake close to the Burdur city. Preliminary analyses were done on sediments at Research and Application Laboratory for Geothermal Energy, Groundwater and Mineral Resources (Isparta, Turkey) and in laboratory UMR 8148 – GEOPS (Orsay, France). Sediments are mostly composed of silty and clayish fractions, some levels that are rich in brownish organic material indicate the low water level or even dried state of the lake with soil development. First analyses for total mineralogy, specific carbonates, clay and magnetic minerals, organic carbon and microscopic observations show changes in sources and transport energy of detrital material, biological activity in the lake and conditions during the early diagenesis in sediments. These results provide a comprehensive record of changes in water level of the lake related to water resources availability, conditions in the lake itself (salinity, biological productivity), but also of changes in the catchment basin indicating variation of vegetation cover and erosion intensity. Ongoing analyses for ¹⁴C AMS dating on rests of plants will allow the establishment of the accurate chronology for observed changes.

The International Science Council as the Global Voice for Science and the role for Quaternary Science

Geoffrey Boulton

University of Edinburgh, Edinburgh, United Kingdom. International Science Council, Paris, France

Abstract

Humanity has become a defining geological force that has re-configured the global ecology in ways that are inimical to many of the natural processes that have created and sustained the biosphere, atmosphere and hydrosphere, and that form the life support system for the planet's inhabitants. Science faces a major challenge to identify pathways to sustainability in this system that in a technical sense is complex, involving convergent, coupled issues of climate change, environmental degradation, poverty, social conflict, corruption and inequality.

However, the setting into which scientific understanding plays is also changing. Although society needs science more than ever, it is arguably less inclined to listen to its voice, partly because of deep socio-economic shifts and partly because the tools of the digital revolution have been disruptive in unanticipated ways. The worldwideweb for example, notwithstanding its democratic potential, has proved indifferent to falsehood and honesty, becoming a powerful enabler of "alternative facts." We have a threefold challenge: a scientific challenge in understanding the complexity of the Earth system, including its human inhabitants; a political challenge in articulating policy options for pathways to sustainability in ways that respect the needs of policymakers; and a social challenge in bringing scientists and non-scientists together as collaborating knowledge partners able to create actionable knowledge that has credibility, practical relevance and the socio-political legitimacy without which political action stymied.

It is largely in response to such issues, and the vital need to bring the natural and social sciences together in addressing them, that the International Science Council (ISC), of which INQUA is a member, has been created, with the mission to act as the global voice for science. ISC has inherited the role of the International Council for Science (ICSU) as the formal representative body for science in the UN system, and is acting boldly to ensure that the voice of science is heard in the international political arena. ISC has identified four major strategic challenges for its current planning period: *sustainability and the SDGs, the digital revolution, science in policy and public discourse, and changing science systems*. INQUA and Quaternary scientists have a significant role to play in all these domains: in creating high resolution temporal narratives about the nature and consequences of human intervention in the Earth system; in ensuring that Quaternary science data can be effectively integrated to explore related complex phenomena, particularly in specific sustainable development goals; in engaging in open transdisciplinary discourse; and in easing the path towards more efficient interdisciplinary science. The presentation will give specific examples where greater engagement from Quaternary science is needed.

Quaternary sciences document the reality, magnitude and threat levels of current planetary climate warming

George Stone

Wisconsin Clean Cities, Milwaukee, USA. Milwaukee Area Technical College, Milwaukee, WI, USA

Abstract

Evidence documenting anthropogenic climate warming comes in abundance from virtually every branch of the natural sciences. Were judgment rendered in a U.S. court of law, the standards of “beyond a reasonable doubt” (criminal case) and “preponderance of the evidence” (civil case) have clearly been met and dramatically surpassed. Significant contributions to our understanding of current climate change have been made by researchers in the atmospheric, oceanic and geological sciences.

The concept of uniformitarianism developed by James Hutton in the late eighteenth century asserts that the universality of fundamental principles and natural laws in space and time validate the application of current process explanations to processes of the past (the familiar “the present is the key to the past”). Similarly, results and relationships of the past serve to constrain and elucidate those of the present and future. Insights from the geological record have been invaluable in interpreting current data trends; paleoclimatic studies indicate that climate models are more likely to underestimate than to overestimate long-term change.

Of great concern to climate scientists are the accelerating rates of change of current climate change parameters and the processes they document. Equally concerning as the increasing severity and frequency of extreme climate-related events. The recent IPCC report (November, 2018) emphasized the urgency of immediate policy action to reduce greenhouse gas emissions as the most effective means of mitigating global warming. In the words of UN Secretary-General Antonio Guterres, “This report by the world’s leading climate scientists is an ear-splitting wake-up call to the world. It confirms that climate change is running faster than we are – and we are running out of time.”

As we Quaternary scientists and educators acknowledge the validity of the science and express concern for victims of the impacts, our obligation to warn and to support action becomes compelling. Because of our special knowledge and experience, we bear special responsibility. It is incumbent upon us to speak up and demand policy change!

Mapping Sea-Level Change in Time, Space, and Probability

Benjamin Horton¹, Robert Kopp², Andra Garner², Carling Hay³, Nicole Khan¹, Keven Roy¹, Tim Shaw¹

¹Nanyang Technological University, Singapore, Singapore. ²Rutgers, New Brunswick, USA. ³Boston College, Chestnut Hill, USA

Abstract

As recorded instrumentally and reconstructed from geological proxies, sea levels have risen and fallen throughout Earth's history, on timescales ranging from minutes to millions of years. Sea-level projections depend on establishing a robust relationship between sea level and climate forcing, but the vast majority of instrumental records contain less than 60 years of data, which are from the late twentieth and early twenty-first centuries (1–3). This brief instrumental period captures only a single climate mode of rising temperatures and sea level within a baseline state that is climatically mild by geological standards. Complementing the instrumental records, geological proxies provide valuable archives of the rates of sea-level response to past climate variability, including periods of more extreme global mean surface temperature

We review the current methodologies and data sources used to reconstruct the history of sea-level change over geological (Pliocene, Last Interglacial, and Holocene) and instrumental (tide-gauge and satellite altimetry) eras, and the tools used to project the future spatial and temporal evolution of sea level. We summarize the understanding of the future evolution of sea level over the near (through 2050), medium (2100), and long (post-2100) terms. Using case studies from Singapore and New Jersey, we illustrate the ways in which current methodologies and historical data sources can constrain future projections, and how accurate projections can motivate the development of new sea-level research questions across relevant timescales.

Wildfire risk at different elevations: contextualizing modern fire activity through a paleo-perspective

Vachel Carter¹, Mitchell Power², Zachary Lundeen², Jesse Morris², Kenneth Petersen², Andrea Brunelle², Scott Anderson³, Jacqueline Shinker⁴, Lovina Turney², Rebecca Koll⁵, Patrick Bartlein⁶

¹Charles University, Prague, Czech Republic. ²University of Utah, Salt Lake City, USA. ³Northern Arizona University, Flagstaff, USA. ⁴University of Wyoming, Laramie, USA. ⁵University of Florida, Gainesville, USA. ⁶University of Oregon, Eugene, USA

Abstract

Anthropogenic-induced climate change is progressively increasing drought severity across many regions of the northern hemisphere including western North America. Over the last 30 years, prolonged droughts coupled with declines in winter snowpack and/or earlier spring runoff have created hazardous wildfire conditions through mid- and high-elevations across the U.S. Rocky Mountains (Westerling, 2016). With projections suggesting a continued increasing trend in global temperatures, wildfire risk is also expected to increase. Examining long-term paleoecological records are important for investigating whether fire activity at mid- and high-elevations is unprecedented in time and space, as well as for investigating potential climatic drivers and ecosystem responses. Here, we investigate wildfire activity across the U.S. Rocky Mountains over the last 1,500 years to contextualize past fire activity across various elevations using 37 sedimentary charcoal records. Our results show that at present, more biomass burning has occurred at mid-elevations in the northern Rocky Mountains compared to the southern Rocky Mountains. However, prior-to the Medieval Climate Anomaly (MCA) ~1350 cal yr BP, wildfire activity occurred through both mid- and high-elevation throughout the U.S. Rocky Mountains. Because climatic conditions during the MCA were similar to those seen at present, this time period could serve as a potential analog for future wildfire activity (Carter et al., 2018). Thus, investigating ecosystem response prior-to the MCA could inform land managers potential responses to future climate change and subsequent changes in fire regimes. Thus, investigating ecosystem-level responses prior-to the MCA could provide a means for land managers to evaluate responses to future climate change and subsequent changes in fire regimes.

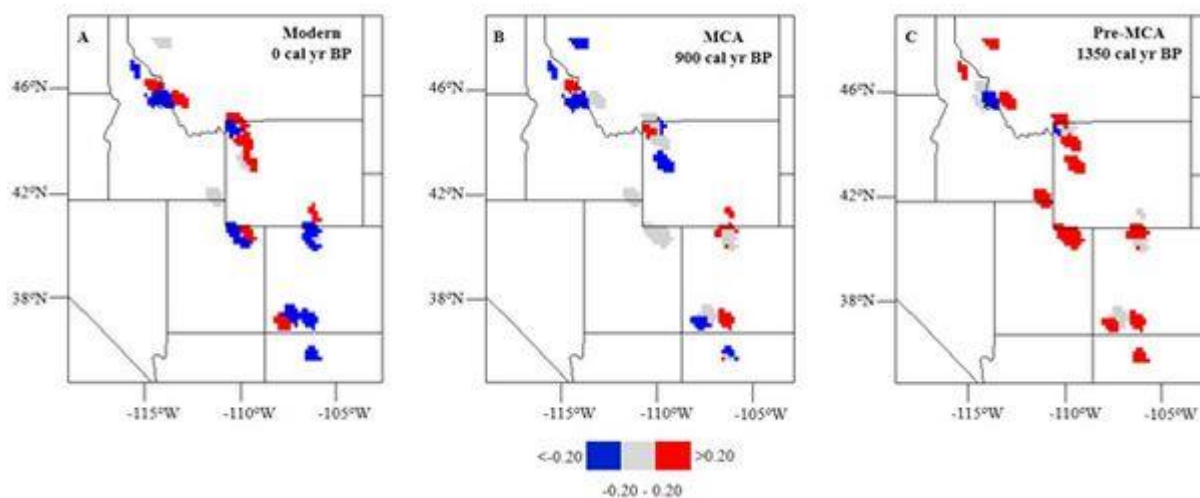

Figure 1. Trends in wildfire activity across the US Rocky Mountains during the A) the 20th century, B) 900 cal yr BP, and C) 1350 cal yr BP. Red indicates positive trends in burning; Gray indicates neutral trends; Blue indicates negative trends in burning.

Building resilient hydrologic systems for the future using lessons from past societies: from Ancient Rome to the Maya Lowlands

Sheryl Luzzadder-Beach, Timothy Beach
University of Texas at Austin, Austin, USA

Abstract

In 2018 the University of Texas at Austin launched an ambitious multi-disciplinary, multi-year project, Planet Texas 2050. The goal of this research is to build resilient human, environmental, and urban systems for Texas and beyond in the face of increasing environmental and health challenges, including climate change, drought, flooding, and severe weather scenarios. An important component of this research is studying past societies to provide both social and landscape analogues for the current Texas environment. Our research includes projects tracing ancient water management structures and strategies, ranging from Roman aqueducts to ancient Maya wetland agriculture. This paper presents the results from our 2018 and 2019 hydro-geoarchaeological field seasons in Italy and the Maya Lowlands of Central America. Results include documentation of little-known Roman aqueduct sections of the Aqua Traiana that still serve the broader City of Rome water system, and ancient Maya water management infrastructure in the Maya Lowlands.

O-3216

Recent advances in the palaeoflood hydrology of alluvial rivers

Samuel Munoz¹, Willem Toonen²

¹Northeastern University, Boston, USA. ²KU Leuven, Leuven, Belgium

Abstract

Riverine flooding is a widespread, commonly occurring, and costly hazard, with 2018 global economic losses to floods estimated to exceed \$10 billion. Conventional assessments of flood hazard (i.e., the probability that a flood of a given magnitude will occur) are based on statistical analyses of instrumental streamflow data, but these assessments assume geomorphic and climatic stability, and are prone to large uncertainties when estimating the probability of an extreme flood. Recent advances in palaeoflood hydrology now allow for the development of event-scale and quantitative reconstructions of past floods on alluvial rivers where populations and infrastructure are concentrated. Here, we present a series of recent and on-going projects from North America and Europe that use and apply palaeoflood records developed from floodplain lakes to reevaluate flood hazard with the long view provided by Quaternary science. We demonstrate how these palaeoflood records are developed, and how they can be integrated with statistical models, palaeoclimate data, and Earth system models to improve assessments of flood hazard. These examples form the basis for our argument that alluvial palaeoflood hydrology be more regularly incorporated into conventional assessments of flood hazard made by public and private entities.

O-3217

The application of Holocene alluvial stratigraphy to address streambank erosion and reservoir sedimentation in the Midwestern U.S.A.

Anthony Layzell, Rolfe Mandel
Kansas Geological Survey, Lawrence, USA

Abstract

Reservoir sedimentation is a significant problem in many parts of the world and has important implications for the sustainability of water supplies, flood protection, and aquatic habitats. In the Midwestern USA, streambanks have been identified as the primary contributor to total watershed sediment yield. In much of this region, deposits of fine-grained Holocene alluvium comprising streambanks have been assigned to a single lithostratigraphic unit, the DeForest Formation.

Stratigraphic relationships and the erodibility of the different members of the DeForest Formation were investigated in northeastern Kansas. Distinct differences in erodibility, measured in terms of critical shear stress by a submerged jet-test device, were observed between the different members. The most erodible member is the Camp Creek Member while the most resistant is the Gunder Member. Variability in erodibility between and within the different members is attributed to the magnitude of post-depositional soil-forming processes, including the presence of buried soils, as well as the inherent natural variability in the different parent materials. A weak positive correlation was found between percent clay and critical shear stress. Resistance to erosion by fluid flow was found to be significantly greater where clay contents exceed 28%.

Although the Camp Creek Member was the most erodible, it always occurs, stratigraphically, as the uppermost member. Bankfull stage indicators suggest that bankfull discharges rarely attain elevations sufficient to erode Camp Creek Member deposits. Therefore, other members of the DeForest Formation can exert some control on the rate of bank erosion by hydraulic flow. Furthermore, given the observed differences in lithology, soil development, and erodibility, the susceptibility to mass wasting processes also is likely to vary between the different members and is a focus of current research. Therefore, Holocene alluvial stratigraphic relationships have important implications for the nature of streambank erosion in the Midwestern USA as well as in other alluvial settings worldwide. These relationships can be used to locate areas more prone to streambank erosion that may serve as mitigation targets in order to reduce rates of reservoir sedimentation.

Paleo Dune Development on the Canary Islands: A Relationship to Atlantic Heinrich Stadials and Events?

Hartmut Heinrich¹, Christopher-Bastian Roettig²

¹10°E maritime consulting, Hamburg, Germany. ²Institut fuer Geographie, Dresden, Germany

Abstract

The internal structure and repetitive pattern of paleo dunes on the Canary Islands provide insight into the climatic dynamics of the North East Atlantic (NEA) during Heinrich Events (HE) and Heinrich Stadials (HS). Here we present an explanation of the dune development that could simultaneously solve the mystery of the jointly occurring HEs and HSs.

The paleo dunes show a systematic 3-phase sedimentary sequence starting with the deposition of marine biogenic sand and a certain amount of Sahara dust. The second phase shows a much higher dust content. Jointly appears a dense community of a few gastropod species and bee nests. The final phase is an indurated layer of maximum dust content that seals the sequence and, the cycle repeats. Optical stimulated luminescence (OSL) dating on some of the indurated layers reveals age ranges that match with the timeline of NEA HEs, suggesting that the Pleistocene ice-ocean-atmosphere dynamic in the NEA region played an essential role in the sequential development of the dune deposits.

I.e., the initial phase of the dune development needs a dry shelf area that makes biogenic sands susceptible to wind transport. This is when sea level drops as a consequence of growing Pleistocene ice shields. The climate of the NEA during this phase is relatively mild (in glacial terms) with little dust transport from the Sahara to the islands. The extension of the North Atlantic ice-sheets onto the shelves results in an increasing iceberg production which subsequently freshens and cools the NEA surface water including the overlying atmosphere. This enhances the temperature contrast between the polar and tropic region and thus, wind speeds. Consequently, transport of micaceous dust from the Sahara increases and, because the wetter westerly zone moves further south there is now sufficient precipitation allowing vegetation on the dunes which nourishes gastropods and bees. We suggest that this phase with cooler NEA surface waters and a cooler-wetter atmosphere is a HS.

Somewhere during this phase southern warmer sub surface waters advance towards the grounding lines of northern ice margins causing rapid melting that weakens the contacts between basal rocks and the ice. The ice sheets rather synchronously start collapsing, thus generating a HE. Consequently, even colder NEA surface water extends much further to the south, pushing the zone of westerly winds, too. The dust now contains elevated amounts of kaolinite from the desiccated subtropical-tropical regions of Africa. The HE ends when the interstadial oceanic circulation resumes. Then a new sequence starts. Thus, there seems to be no direct link between HEs and HSs but an indirect link to somewhere in the global south-north energy seesaw.

$\delta^{18}\text{O}$ record comparisons among Siberia stalagmite, Hulu Cave stalagmite, NGRIP2 and GISP2 ice cores during 33-60 Ka

Hong-Chun Li¹, Yi Shin Ye¹, Chuan-Chou Shen^{1,2}, Horng-Sheng Mii³, Tatiana Blyakharchuk⁴, Hsien-Chen Tsai¹

¹Department of Geosciences, National Taiwan University, Taipei, Taiwan. ²High-Precision Mass Spectrometry and Environment Change Laboratory (HISPEC), Department of Geosciences, National Taiwan University, Taipei, Taiwan.

³Department of Earth Sciences, National Taiwan Normal University, Taipei, Taiwan. ⁴Institute of monitoring of climatic and ecological systems of the Siberian branch of Russian Academy of science (IMCES SB RAS), Tomsk, Russian Federation

Abstract

A 23-cm long stalagmite (K6) from Kyok-Tash Cave (51°43'43" N, 85°39'23" E, 890 m a.s.l.) in south Altai Mountain of Siberia, Russia, was dated by ²³⁰Th/U method, spanning from 59.42 ka to 33.76 ka. Up to date, a total of 1404 samples were measured $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$. This high-resolution stalagmite $\delta^{18}\text{O}$ record has compared with the $\delta^{18}\text{O}$ records of GISP2 ice core (The Greenland Summit Ice Cores, 1997), NGRIP2 (North Greenland Ice Core Project members, 2004) and Hulu Cave stalagmite (Wang et al., 2001). The comparison shows that between 33 ka and 44 ka, all records have good comparisons, indicating heavier $\delta^{18}\text{O}$ peaks in stalagmites (drier climatic conditions) corresponding to cold episodes (lighter $\delta^{18}\text{O}$ peaks in ice core, e.g., H4); and vice versa. However, between 44 ka and 60 ka, K6 record compares well with GISP2 record, but not good with NGRIP2 and Hulu records. Since the Hulu record provided excellent chronology for age tuning of ice core records (the GRIP2001/ ss09sea timescale, Johnsen et al., 2001), the chronology of NGRIP2 record between 40 ka and 60 ka shifted 1-3 kyrs older than GISP2 record. This chronology tuning assumes that the forcing factor of Hulu $\delta^{18}\text{O}$ record should be single (i.e., amount effect or moisture source effect) and keep constant through time, and the climatic correlation between Asian summer monsoon and high latitude temperature (cold vs dry or weak summer monsoon) should remain unchanged. The K6 record shows multiple factors to influence stalagmite $\delta^{18}\text{O}$ in the south Altai region. For example, the K6 $\delta^{18}\text{O}$ record does not show strong enrichment during H5 event (no matter it was center at 45.5 ka or 48 ka), and strong depletion during DO14 event. We suspect that more winter precipitation with lighter $\delta^{18}\text{O}$ might obscure the amount effect (dry) during H5, whereas increased summer rain with heavier $\delta^{18}\text{O}$ balanced the wet effect during DO14. Between 60 ka and 44 ka the Siberian High might not be very strong, so the climatic discrepancies between south Altai and Asian monsoon regions were larger especially during interstadials. After 44 ka, the Siberian High became stronger, so that similarities of Hulu and K6 records were more. More ²³⁰Th/U dates will be obtained to refine the chronology of K6 record.

Dust and Flood Events during Heinrich Events - Evidence from a new annual resolution record from the maar lake of Auel

Frank Sirocko¹, Manfred Mudelsee², Gerald Haug³

¹Institute for Geoscience, Mainz, Germany. ²Climate Risk Analysis, Bad Gandersheim, Germany. ³MPIC, Mainz, Germany

Abstract

Two new overlapping sediment cores have been drilled from the infilled maar lake of Auel in the west Eifel volcanic field and document all stadials and interstadials of MIS2/3. The high sedimentation rate of 2 mm/a (caused by riverine input, dust deposition, and high biogenic productivity) allows annual resolution analysis with 0.5 mm μ XRF logging and 1.0 mm organic carbon logging. The two new 102 m long records are dated by a combination of ¹⁴C/tephrachronology/ice core tuning/varve counting. Average varve thickness has been determined for each stadial/interstadial and corroborates the tuned Bayesian age model.

High Corg, Si/Al and P characterize varved interstadials, which reveal an almost identical structure as the Greenland interstadial $\delta^{18}O$ record. Ti/Al documents fluvial runoff into the maar lake by erosion of Al-rich clay particles from the soils of the catchment during all stadials from GS17 to GS2. Eolian particles are best detected by Ca/K, which documents the abundance of limestone detrital grains in the dust fraction. Pollen complement the analysis and document the distinct vegetation of each stadial, interstadial and Heinrich event.

Heinrich 5 caused a massive deterioration of the early MIS3 trees of spruce and hornbeam and was characterized by highest Ti/Al values indicating intense stadial precipitation (rain or snow). It started with a time of strong lake level drop and reworking of older wood particles.

Heinrich 4 revealed strong precipitation only during its first phase, which occurred about 200 years hundred years after the Campanian Ignimbrite, which is visible in the Auel records as a 1 mm thick cryptotephra with agglutinated greyish glass shards. The centuries before the onset of GI8 had seen only some precipitation, but no Ca-rich dust. These centuries mark the time when grass pollen started to dominate the vegetation.

Heinrich 3 occurred immediately before GI4. It has seen the erosion of large amounts of clay into the lake (most probably as winter smelt), but also severe dust intensity. In this respect it is very different to the earlier Heinrich events.

Heinrich 2 is a short Ti/Al maximum in the section of continuously high glacial dust, which started at 26,000 and intensified at 23,400 yrs b2k. The clay rich layers of this time are characterized by Ranunculaceae pollen.

Heinrich 1 immediately before the 14,700 yr b2k warming reveals in contrast no clay and no pollen at all, but a pronounced Ca-rich dust maximum of about 500 year duration.

Accordingly, each Heinrich event had a unique climatic and environmental structure. H5 - H2 were associated with precipitation (probably winter snow fall), H3 - H1 with severe dust and thus aridity.

Abstract

Evidence of environmental changes triggered by Heinrich events (HE) are preserved in marine sediment archives around the world. Few studies, however, have determined the ultrastructure of each event or detailed its impact on freshwater ecosystems. Changes in abundances of fossil species assemblages are generally used as indirect information on the magnitude of climate and environmental impact. However, determining the magnitude and velocity of ecological change by applying multivariate methods on fossil counts, in both, aquatic and terrestrial ecosystems can provide a more accurate quantification of the impact.

Continental environmental information during Heinrich Stadials (HS) is limited in the northern Neotropics, because very few lakes in the region deposited sediment during the last glacial. One exception is Lake Petén Itzá, in the lowlands of northern Guatemala. The lake is deep (165 m) and large (100 km²), and its sediments contain information on the climate and environment of the past 400 ka. This closed-basin lake is especially sensitive to changes in the balance between evaporation and precipitation (E/P), and the sediment record can be used to infer past E/P and lake level. Extremely arid periods are marked by gypsum precipitation, and most layers deposited during HS.

Multiple biological (ostracodes, diatoms, pollen) and non-biological (geochemistry, mineralogy) sediment data from long cores PI-6 and PI-2 reveal different responses among HS 5a-1 as recorded by the aquatic ecosystem. For instance, HS5 and HS3 were characterized by prevailing dry conditions that subsequently became more humid; HS2 was predominantly humid, but became arid; HS4 and HS1 displayed fluctuating dry-humid conditions, and HS5a was mainly arid and displayed high lake conductivity. HS1 has been identified as the coldest and driest so far, where lake levels dropped 50-60 m. Presence of tropical ostracode species assemblages during HS indicates that water temperatures did not decline dramatically, and were only 1-3°C lower than modern lake temperatures. Geochemical and mineralogical analyses showed, however, that gypsum precipitation not only occurred during HS in lake Petén Itzá, but also during Greenland Stadials (GS) GS 4-8 and GS 14. HE are typically seen as episodes of rapid climate change that had profound, often negative effects on aquatic communities. Our record, however, shows that biodiversity during HE was higher than during other times. Significant changes in precipitation and lake level favored the establishment of numerous microhabitats and created greater environmental heterogeneity.

Our combination of biological and non-biological variables in sediments of Lake Petén Itzá revealed that northern neotropical lakes were sensitive to cold climate pulses originating from the North Atlantic (HE and GS), and the predominant climatic condition was dry and cold as a response of a more southern position of the ITCZ and a slowdown of the ocean's thermohaline circulation.

Abstract

The climate during the last glacial cycle was characterized by abrupt millennial-scale changes superimposed on long-term orbital control. The understanding of the terrestrial response in Europe to those abrupt events has increased during the last decade, but is still sparse. Previous studies on the Iberian Margin and in the Mediterranean Sea emphasize the sensitivity of this area to climate change in the North Atlantic realm. Unfortunately, speleothems and lacustrine sediments from southern Europe covering this time period are discontinuous and difficult to date, with the exception of few lacustrine sequences such as Lago Grande di Monticchio, anchored by tephra datings.

Here we present a stalagmite record from Ejulve cave, northeastern Iberia, covering the period between the end of Last Interglacial and Marine Isotope Stage (MIS 3) with an outstanding chronology based on U-Th dates. In contrast to many other speleothems from European caves which preferentially formed during warm/wet periods and commonly stopped growing when the climate turned cold/dry, this record is continuous and hence provides exceptional insights into the terrestrial mid-latitude response to forcing mechanisms across several climate transitions. Our results support previous studies showing a late demise of the Last Interglacial in southern Europe at 108.3 ± 0.3 kyr. During MIS 5, $\delta^{18}\text{O}$ is controlled by orbital pacing, with periods of low precession of boreal summer peaks characterized by wet conditions. In contrast, during MIS 4 and 3, $\delta^{18}\text{O}$ is decoupled from precession and co-varies with $\delta^{13}\text{C}$, suggesting a common control of both isotopes by enhanced degassing of drip waters during dry periods. $\delta^{13}\text{C}$ shows a positive correlation with Mg/Ca, reflecting water availability, vegetation productivity and soil microbial activity in the catchment of the cave's drip water. Rapid changes in the hydrology and the vegetation cover occurred during the Heinrich Stadials (HS) and the marine cold events C26 to C23, as well as Dansgaard-Oeschger (D-O) cycles.

Interestingly, two periods with a marked "W-shape" pattern are recognized as the response of the $\delta^{13}\text{C}$ to HS-6 and D-O 18 on the one hand, and to HS-5a and D-O 15 on the other hand and are interpreted as intra-Heinrich event variability alternating between cold/dry and mild/humid. The phases of cold/dry conditions are in concordance with a reinforcement of the northeasterly trade winds over the Iberian Margin and cold conditions in the subtropical Atlantic during HS-6 and HS-5a, while the mild/humid episodes occurred during the warm phases of D-O 18 and 15. These oscillations document the significant impact of rapid climate oscillations of last glacial cycle on the terrestrial environment on the Iberian Peninsula and provide new insights into the fine-scale climate variability (intra-Heinrich events) that will serve to better understand the mechanisms triggering these oscillations.

Abstract

On the Iberian Peninsula terrestrial archives that shed light on palaeoenvironmental conditions during the last glacial period are very rare. Due to the proximity of the North Atlantic a coupling between marine processes and terrestrial environments is suspected, but still difficult to verify.

Based on extensive stratigraphic work and abundant luminescence dating (OSL) the upper Tagus loess record proved to be a valuable environmental record for the late Pleistocene. Multiple phases have been identified that point to brief and vigorous loess deposition related to gusty winds under generally dry conditions. For the last 35 ka, we found a strong coincidence in time between phases of loess deposition in central Iberia and the occurrence of Heinrich Stadials (HS) that have been identified in marine records along the Iberian margin. The origin and genesis of the loess deposits indicate cold temperatures during HS-3, HS-2 and HS-1, while grain-size patterns suggest maximum wind strengths during HS-3, followed by HS-2 and HS-1. Moreover, based on $\delta^{13}\text{C}$ values of *n*-alkane compounds extracted from loess samples we can conclude that HS-3 was the driest period during the last glacial, while aridity was less pronounced during HS-2 coinciding with the so called last glacial maximum.

Our results are well compatible with the timing of palaeoglacier dynamics in central Iberian mountain ranges and allow to draw a picture of last glacial palaeoenvironmental and palaeohydrological conditions in the Iberian interior that appear to be strongly correlated with marine dynamics relating to the occurrence of Heinrich events respectively Heinrich stadials.

However, a still open question belongs to contrasting dynamics during the early to middle marine isotope stage 3, when loess deposition falls in between HS-5 and HS-4 and is absent during HS-4, which is, however, recorded most strongly in many marine records.

Abstract

Marine Isotopic Stage 3 (MIS 3, ca. 60-30 ka BP) is regarded as one of the most unstable period of the Late Pleistocene as far as climate is concerned, closely interwoven with the late human evolution history. During MIS 3, episodes of massive iceberg discharge into the North Atlantic (Heinrich events [HEs]) enhanced sea surface temperature (SST) cooling at mid- to low-latitudes (Darfeuille et al., 2016) inducing rapid vegetation changes in S-Europe and in the Mediterranean area (Fletcher et al., 2010).

To contribute to the discussion about the influence of HEs on European vegetation dynamics, we present a new high-resolution record from NE-Italy (Lake Fimon, southern Alpine foreland) covering the HE3-HE4 interval. This area is well-known as it provides both a Late Pleistocene palaeoecological record (Pini et al., 2010) and several Middle to Late Palaeolithic sites yielding evidence of Neandertal and AMHs occupation (Fumane cave and Broion shelter; Peresani et al, 2008, 2016; Peresani et al., in press).

The published paleoecological record from Lake Fimon, the resolution of which was too low to reconstruct in detail the history of terrestrial and aquatic ecosystems between 41 - 30 ka cal BP, was reconsidered. The core was resampled to achieve a resolution of ca. 1 sample/80 yrs between 41 - 36 ka cal BP and ca. 1 sample/120 yrs between 36 - 30 ka cal BP. Changes in pollen-algae-spores %, pollen-slide- and macrocharcoal concentrations, and geochemical proxies help to decipher the effects of climate variability on vegetation.

Despite the pollen record points to a general persistent afforestation, HE4 and HE3 intervals are identified by significant drops of the dominant tree taxon, *Pinus sylvestris/mugo*. Such variations are mirrored by upland herbs expansion, including xerophytes and Compositae Asteroideae, indicating phases of climate deterioration. A general low frequency and intensity fire regime, possibly influenced by moist conditions characterizing this geographical area, is punctuated by some fire episodes occurring during periods of possibly enhanced drier conditions related to HEs.

The evolution of the sedimentary basin in relation to HEs can be summarized as follow. A shallow lake persisted during HE4; afterwards, paleoecological and geochemical data indicate blooms of planktonic algae (*Pediastrum*, *Gloeotrichia*, *Scenedesmus*), expansion of submerged macrophytes (*Ceratophyllum demersum*) and detrital carbonates increase. These evidences suggest that the lake threshold rose before HE3, possibly due a clastic supply from an external fluvio-glacial river. The subsequent development of a Cyperaceae-dominated littoral belt suggests

reduced level excursions. According to calibrated radiocarbon ages, the mire development lasted ca 3000 years (31-27.5 ka cal BP), until the building of a subsequent fluvio-glacial dam at the LGM onset.

O-3225

The role of the marine ice cliff instability in past, present and future rapid ice sheet disintegration

Jeremy Bassis

University of Michigan, Ann Arbor, USA

Abstract

Ice sheets wax and wane in response to climate forcing. Climate forcing alone, however, is not sufficient to explain the rapid demise of ice sheets. For example, during the last glacial period the Laurentide Ice Sheet sporadically discharged vast armadas of icebergs through the Hudson Strait into the North Atlantic Ocean during so-called Heinrich Events. More recently, we have observed punctuated ice sheet decay during the unexpectedly catastrophic disintegration of ice shelves on the Antarctic Peninsula and during the retreat of marine terminating glaciers surrounding the Greenland Ice Sheet. Recent attempts to understand the interplay between ice flow, fracture and climate forcing at the root of rapid ice sheet demise have led to the hypothesis that ice sheets can rapidly collapse through a process called the 'marine ice cliff instability'. The marine ice cliff instability is based on the idea that the finite strength of ice places a limit on the maximum ice cliff height possible at the ice sheet calving front. When buttressing ice shelves are breached exposing a thick calving cliff, catastrophic ice sheet disintegration can occur. However, the marine ice cliff instability remains a new and untested hypothesis. Here, we examine modern and past evidence that informs the theoretical and observational basis for the marine ice cliff instability to show that the observations of Antarctica, Greenland, Svalbard and Alaskan glaciers are broadly consistent with the 'upper bound' on ice cliff height suggested by theory. We further show that invoking a maximum cliff height can help explain large-scale patterns of modern glacier advance and retreat and—subject to idealized forcing—Heinrich Events. In all of our simulations, ice sheets evolve to a state where they are vulnerable to small perturbations. Small perturbations associated with modest changes in ocean forcing (or other factors) at the calving front can then trigger sustained rapid retreat and drawdown. Surprisingly, however, applying the model to project the fate of Pine Island and Thwaites Glaciers, in the Amundsen Embayment section of modern West Antarctica, we find that rapid uplift associated with the low mantle viscosity inferred in the region has a strong stabilizing effect that can not only arrest ice sheet retreat, but also leads to subsequent re-advance. This suggests that regional solid Earth structure may play a larger role than previously recognized in century time scale projections of sea level rise and climate change.

Combining coupled ice sheet - sea level modelling and palaeo data to understand the mechanisms and timing of ice sheet change

Natalya Gomez¹, Mike Weber², David Pollard³

¹McGill University, Montreal, Canada. ²University of Bonn, Bonn, Germany. ³Pennsylvania State University, State College, USA

Abstract

Modeling paleo ice sheet and sea level changes has classically been approached by either (i) modeling the response of a single ice sheet to past climate changes with a dynamic ice flow model, or (ii) inferring ice cover history through inputting prescribed ice cover changes into a glacial isostatic adjustment model, predicting geographically variable global sea level changes, and comparing to palaeo sea level records. More recently, coupled ice sheet – sea level models have been developed that simultaneously predict dynamic ice sheet evolution in response to a changing climate and global sea level changes as well as considering the feedbacks that arise between these systems. These coupled models represents a new tool for self-consistently capturing regional ice sheets and their contributions to nearfield and farfield sea level changes globally, allowing for comparison to a wide range of ice age datasets. I will present the results of recent work combining coupled modeling and palaeo data to give insight into the timing, magnitude and mechanisms of past ice sheet evolution and associated sea level changes. I will also discuss the potential for inter-hemispheric teleconnections between ice sheets through sea level change. Specifically, results will highlight how, by combining coupled modeling with iceberg-rafted debris records and relative sea level data, we can assess the influence of sea level changes associated with Northern Hemisphere ice sheets on the evolution of the Antarctic Ice Sheet during the last glacial cycle.

Abstract

We present preliminary results of a project aiming to produce the first transient fully coupled climate/ice sheet simulation of the last deglaciation using the newly released Community Earth System Model 2.1 (CESM2.1). The main goal of the project is to investigate the role played by the different feedbacks and dynamical processes in controlling the deglaciation of the Northern Hemisphere ice sheets. The new model setup now includes interactive coupling between atmosphere, ocean, sea-ice and land components with a dynamic Ice Sheet Model (Community Ice Sheet Model 2.1, CISM2.1). Additionally, a one-way coupling between the ocean model (POP2) and CISM2.1 has been added in order to explicitly calculate ocean melting rates under the ice shelves.

Here, CESM-CISM2.1 is used to produce the first fully coupled 1° climate – 4 km ice sheets simulation of the Northern Hemisphere at the Last Glacial Maximum (LGM, 21 ka). The Earth System Model is forced according to the protocols of the Paleoclimate Modelling Intercomparison Project 4 (PMIP4), whereas the input paleobathymetry and ice sheet reconstruction are generated using a different global Glacial Isostatic Adjustment (GIA) model than in PMIP4. The recently updated empirically-constrained Eurasian Ice sheet reconstruction (developed as part of the BRITICE-CHRONO project) and the Greenland - North American ice sheets chronologies taken from Lecavalier et al., 2014 are combined and used as input for the GIA model.

A key feature of the CESM2.1 model setup is the bi-directional coupling between the land and ice sheet model, where the surface mass balance (SMB) and near-surface air temperature fields are computed at multiple elevations and then downscaled to the active ice sheet regions. Additionally, using the new one-way coupling from the ocean to the ice sheet model, the simulated depth-varying ocean temperature and salinity are used to force CISM2.1 during run-time. The simulated climate and ice sheets will be evaluated against a range of published empirical constraints. We encourage input from the community for further possibilities for model-data comparison and integration.

O-3228

Using Antarctic ice sheet palaeo-thinning rates to constrain numerical ice sheet model outputs.

David Small, Mark Pittard, Mike Bentley, Richard Jones, Pippa Whitehouse
Durham University, Durham, United Kingdom

Abstract

Geo-chronological data can constrain past configurations of ice sheets and act as empirical tests of modelled deglaciation scenarios. One technique that has been widely applied is cosmogenic exposure dating with the resulting ages conventionally used to define the timing of deglaciation for a particular site. Numerical model outputs can be compared to such data and scored accordingly. However, the spatial distribution and contiguity of geological data and model outputs are fundamentally different. This requires assumptions to be made about how well a point geological measurement represents larger scale ice-sheet configuration changes. Additionally, systematic uncertainties related to the dating technique add additional but unquantifiable uncertainty to each measurement meaning future refinements in the dating technique can affect existing model-data comparisons. The potential to compare ice sheet model output to *rates* of change has advantages over individual measurements. Rates reconstructed with a single nuclide (i.e. ^{10}Be) will be broadly insensitive to systematic uncertainties and rates can be reasoned on glaciological grounds to be representative of ice sheet change on scales similar to, and greater than, grid resolutions commonly used in modelling.

We present a collation of cosmogenic exposure ages from exposed nunataks in Antarctica that have been used, or have the potential to be used, to constrain rates of thinning of the Antarctic Ice Sheets since the Last Glacial Maximum. We present thinning rates, modelled by Monte Carlo linear regression analysis, from 23 sites across Antarctica. Palaeo-thinning rates are spatially variable with high rates appearing to correlate to areas of contemporary rapid changes. On centennial timescales past thinning rates are comparable to modern day observations implying that modern day thinning has the potential to persist for centuries in numerous parts of Antarctica. The thinning rate data set is the first Antarctic-wide collation of past ice sheet thinning rates and provides an empirical starting point for model-data comparisons. We outline our approach to utilising this data-set to score an ensemble of modelled Antarctic deglaciation scenarios to improve understanding of the evolution of the Antarctic Ice Sheet throughout the last glacial cycle which has important implications for understanding its present-day contribution to sea-level change.

Abstract

The flow of ice and basal conditions during past and future glacial advances in the Swiss lowlands are aspects to consider for assessing how glacial erosion may affect the long-term safety of proposed deep geological repositories for high-level radioactive wastes in Switzerland. We develop a high-resolution fully coupled thermo-mechanical three-dimensional transient ice flow model of the Swiss lowlands solving the Stokes and energy equations using Elmer/Ice for the period leading to the Last Glacial Maximum (LGM). A key difficulty to set up the model resides in the initialization which is difficult to constrain for the period just prior to the LGM (unknown ice extent, ice thickness and temperature). To overcome this difficulty, we run a sequence of two models of different complexities at different spatial and temporal scales. First, we run PISM (the Parallel Ice Sheet Model), a simplified shallow-ice shallow-shelf ice sheet model, over the entire western and central Alps from the last interglacial to the LGM. Then, we use the three dimensional full-Stokes ice flow model Elmer/Ice, initialized with ice thicknesses, temperatures, and ice extent obtained from PISM at a couple of thousand years before the LGM. The Elmer/Ice model is run forward in time up to the glacial maximum, giving a much more detailed and physical picture of the dynamics of the Rhine Glacier than the one given by PISM. We compare modeled ice extent at the LGM with moraine position, computed ice flow paths with evidence of striae and other ice flow indicators, basal conditions (temperate vs frozen bed) with features of past glacial erosion, and evidence of subglacial and ice-marginal meltwater channels with subglacial water flow paths computed from hydraulic potentials. Of particular interest are the basal conditions over the proposed deep geological repositories. We compute the duration of ice cover and the sliding distance (a first order estimate of glacial erosion) over these areas and develop criteria for estimating the potential for glacial erosion there.

Abstract

The BRITICE-CHRONO consortium of researchers has been a six-year project to constrain the timing of retreat of the last British-Irish Ice Sheet (BIIS) by a systematic dating programme focused on the marine-to-terrestrial transition. From two research cruises (18,000 km of geophysical data and 377 vibro- and piston cores), along with numerous investigations of stratigraphic sections on land we collected samples for dating from 914 sites from which 639 new geochronometric ages have been derived (336 radiocarbon, 156 luminescence and 157 cosmogenic). Organised into eight key transects from the shelf break to tens of kilometers onshore the pattern and pace of retreat has been compiled into an ice sheet wide reconstruction of ice extent at one thousand year times steps. We then forced ice sheet numerical models to comply with these ice extents, yielding simulations of ice sheet change which incorporate known ice sheet physics pertaining to grounding lines, ice shelves, ice streams, and glacio isostatic adjustment and sea level. This empirically-constrained simulation of the last British-Irish Ice Sheet will be presented and used to address the following hypotheses. 1) that the marine-influenced sectors collapsed rapidly (<1000 years) and that once onshore the ice sheet stabilised and retreated more slowly; 2) that the main ice catchments draining the BIIS retreated synchronously in response to external climatic and sea-level controls.

Fig 1. Summary of the BRITICE-CHRONO sample locations (n=914) used for deriving material for dating ice advance and retreat.

Modelling the generation, evolution, and pattern of ice stream flow over Britain and Ireland with the BISICLES ice sheet model

Niall Gandy¹, Lauren Gregoire¹, Jeremy Ely², Stephen Cornford³, Christopher Clark², David Hodgson¹, Richard Hindmarsh⁴

¹University of Leeds, Leeds, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom. ³Swansea University, Swansea, United Kingdom. ⁴British Antarctic Survey, Cambridge, United Kingdom

Abstract

Ice stream evolution is a major uncertainty in projections of the future of the Greenland and Antarctic Ice sheets. Basal processes and properties, like bed strength and meltwater availability, determine how ice streams flow. These are most commonly estimated in ice sheet models from inversions of surface velocity observations. However, basal properties evolve over a variety of timescales. Such feedback processes are not represented when basal sliding parameters are inverted, making them unsuitable for modelling ice streams over centennial and millennial timescales. An alternative is to incorporate these basal sliding feedbacks into a state-of-the-art ice sheet model, and to test the model on palaeo ice sheets. The palaeo-record provides snapshots of ice stream evolution, with a particularly well constrained ice sheet being the British-Irish Ice Sheet (BIIS).

We implement a new basal sliding scheme coupled with thermomechanics to BISICLES, a higher-order ice sheet model, to simulate the evolution of the ice streams of the BIIS. We find that the simulated location and spacing of ice streams matches well with the empirical reconstruction of ice stream flow (figure 1). Locations of troughs and calving margins are found to be a major control on the ice streams of the BIIS, whilst geothermal heat flux distribution was found to be a significant control offshore of western Ireland. We show that the empirical palaeo record is an essential test of the skill of ice sheet models, particularly when simulating the location, spacing, and migration of ice streams through centuries and millennia, since the extensive empirical record of the BIIS has allowed for the calibration of model parameters. We also demonstrate how model simulations can inform empirical evidence, with our model results stimulating further evaluation of the empirical record, including mapping offshore subglacial bedforms in regions of simulated ice streaming.

Figure 1: Simulated ice streams of the British-Irish Ice Sheet using a new basal sliding scheme in the BISICLES ice sheet model. Black arrows show locations of key empirically reconstructed ice streams.

¹University of Exeter, Exeter, United Kingdom. ²University of West Indies, Kingstown, Jamaica. ³Council for British Research in the Levant, Amman, Oman. ⁴Universidade Federal do Para, Belem, Brazil

Abstract

The highly modified soils generally located along the bluffs of the Amazon River and its major tributaries, known as Amazonian Dark Earths (ADEs), are arguably the most compelling evidence of human transformation of tropical environments in the Americas. Although soil scientists have made major progress in the understanding of the genesis of these archaeological sites, very little was known until recently about the land use practices carried out on these soils in pre-Columbian times. This presentation summarises and presents new combined archaeological, archaeobotanical, palaeoecological (lake and terrestrial) and climate data on land use on ADEs across Amazonia resulting from the University of Exeter's PAST project from Santarem (Lower Amazon), the Middle-Purus Madeira River (Central Amazonia) and Versalles (Bolivian Amazon). We provide new insight on agricultural practices, fire regimes, land cover and vulnerability to climate change of these past systems. We briefly discuss, their legacy and its implications for management and conservation efforts on Amazonian sustainable futures under current threat from climate change and development.

Widespread mid-Holocene population decline in South America: identifying thresholds and impacts

Philip Riris, Manuel Arroyo-Kalin
UCL Institute of Archaeology, London, United Kingdom

Abstract

Quantifying the impacts of climate change on prehistoric societies is crucial for understanding the adaptive pathways taken by humans in response to stress. While archaeologists in South America have identified periods of regional abandonment during the mid-Holocene (8200 to 4200 calendar years before present), the extent to which local patterns and 'archaeological silences' can be generalised and linked to large-scale trends has remained unclear. We present and integrate archaeological and palaeoclimatic data to show that multiple, sustained phases of population collapse occurred coeval with the mid-Holocene transition at the scale of the entire South American continent.

Employing a large and spatially extensive database of radiocarbon dates for the interval 12000 – 2000 cal BP as a proxy for relative prehistoric population levels, we are able to show to multiple demographic contractions dating to the mid-Holocene. Placing summed probability distributions of calibrated radiocarbon dates within a robust statistical framework, we are able to model the duration and relative severity of demographic decline. Outlier analysis of a selection of precipitation proxies with full latitudinal coverage of South America suggests that the frequency of anomalous climatic events may be a better predictor of Neotropical demographic downturns than the absolute magnitude of climate change (i.e. aridification). We note the increasing visibility of domesticated and managed plant resources starting in the early Holocene, and adds to the body of evidence that their importance was amplified after 8200 cal BP, possibly in response to flux in wild resource bases.

Together, these data allow us to place our findings in the context of previous work on the 'Archaic Gap' and 'archaeological silences' of the Middle Holocene in South America and greatly enhance archaeological knowledge on this topic. Variation in the distribution and configuration of complex social formations, diversified resource bases, and large-scale anthropic modifications to the environment in South America by European Contact may ultimately be rooted in conditions established and propagated following the mid-Holocene population bottleneck. More broadly, our results shed light on the limits of forager adaptive resilience in the face of abrupt climate change, and raise questions about what thresholds may constitute "sufficient" climatic or environmental variability, and the time frame over which it must occur, to trigger responses from human societies.

Abstract

The modern sciences of economics, human demography, and population dynamics started with Malthus, who suggested that populations grow geometrically as food resources expand at an arithmetic rate. Concerned for the unprecedented human population growth after the Industrial Revolution, demographers and population ecologists - 200 years after the publication of Malthus's book- have found a common conceptual framework for unfolding the feedback relationship between human demography, global climate and natural resources sustainability. Now it is well-documented that past hunter-gatherer and complex agrarian societies experienced demographic boom and bust cycles, or even collapsed. Despite of some recent studies on the collapse of human societies, the problem still remains poorly understood. So, to make strong cases for collapses in pre-historic societies, we combine the principles and elements of Population Dynamic theory and procedures to evaluate the impacts of climate variability and/or internal societal variables on the resources supply, and how these effects propagated into the demography. **In particular, we are interested in comparing the population dynamic patterns of boom and bust cycles between simple hunter-gathered and complex agrarian societies that have inhabited the Americas over the last 8,000 years.** Hence, this study pretends to provide a detailed comparison for history of pre-Hispanic collapses through the recompilation and analysis of paleodemographic data. In addition, to delineate a comparative analysis of population dynamics for detecting converges and divergences in the collapsing process among pre-Hispanic agrarian societies that differ either in socio-political complexity or environmental settings.

Abstract

Shell middens are human refuse mounds left behind by coastal dwellers and are found throughout coastal northern Chile, where they span more than 9000 years. Early to mid-Holocene shell middens accumulated from the discarded remains of terrestrial plants and shellfish discarded by local coastal hunter-gatherer cultures known as the Chinchorro. These shell middens can accumulate very quickly with one midden accumulating 3 m in 500 years. By radiocarbon dating samples of marine and terrestrial origin along a given stratigraphic horizon, shell middens can be used to estimate local (or regional) marine reservoir departures from the global marine ¹⁴C calibration curve (ΔR). These departures are due to shifts in upwelling as different water masses have different apparent ¹⁴C ages. Our well-replicated ΔR chronology is based on 102 ¹⁴C AMS dates and spans more than 9,000 years. The record was developed from several different shell middens located along 100 km of coastline in northern Chile. ΔR records were remarkably stable during the early to mid-Holocene and averaged ~ 270 yrs implying very stable upwelling and highly productive marine ecosystems which coincided with an exponential increase in coastal populations as reconstructed from a regional Summed Probability Distribution (SPD) of archaeological ¹⁴C-dates. ΔR values are highly variable between 6.5 – 6.3 ka and 5.4 – 4.7 ka, with oscillations in ΔR exceeding 1000 yrs. This implies strong environmental fluctuations associated with variable upwelling conditions possibly tied to changes in the long-term behavior of El Niño-Southern Oscillation (ENSO) and the South Pacific High (SPH). These variations were coeval with one of the largest coastal population collapses in northern Chile during the mid-Holocene. Conditions stabilized after 4.7 ka until 2.4 - 2.0 ka when large excursions again occur in our regional ΔR record and coincide with the near extinction of coastal hunter-gatherers and increased interactions with agricultural societies along coastal northern Chile. Such changes were likely driven by large-scale climate change (such as regional ENSO or SPH variability) and may be one of the key factors behind most large-scale demographic changes and coastal resource use seen in the remarkable coastal hunter-gatherer societies that inhabited northern Chile.

Contributions of IRSL and ^{14}C geochronology and sediment geochemistry to the issue of initial settlement in the New World

¹Université du Québec à Montréal, Montréal, Canada. ²Texas A&M University, College Station, USA

Abstract

Early archaeological sites from central Alaska (USA) have been dated using Optically Stimulated Luminescence (OSL) in order to document the arrival, adaptation and dispersal of early human groups in America. Eolian sediment samples (loess) from stratigraphic profiles in several localities have been systematically dated using this method and compared to the radiocarbon ages for the different human occupations. The interpreted geochronology suggests a human occupation of the area at the end of the Upper Pleistocene, which is in good agreement with the regional archaeological framework.

A relation can be made between the sedimentation rates and the territorial occupability patterns of the early human groups present in central Alaska. This relationship is implicitly related to paleo-environments as well as climate changes, since the accumulation rates of eolian sediments can be directly correlated with the glacial context of the region, and thus with the environmental processes of the past.

Geochemical analyses have been conducted on material sampled from the chronostratigraphic profiles in order to characterize the evolution of paleo-environment through the end of the Pleistocene and the Holocene periods.

A measurement protocol for the luminescence dating method with infrared stimulation (IRSL) has been developed to obtain accurate and reliable results for the minerals extracted from these late glacial loess sediments. The low temperature LPH-IRSL (Low preheat IRSL) protocol thus allows in this case the establishment of a detailed geochronological framework for the Central Alaska region, contributing to better refine the initial settlement in the New World.

Abstract

Soils have a substantial role in the environment as they give back several ecosystem services as food supply and carbon storage. But agricultural practices can modify soil properties and soil evolution processes, threatening these services. These modifications are poorly studied and resilience/adaptation times of soils to disruptions are unknown on pedogenesis time scale.

Lake sediment sequences can be used as continuous archives of long soil evolution. The study of four lake-catchment systems from the western North Alps inquires both soil evolution and the development of human activities throughout the Holocene.

The compared multiproxy analysis of sedimentary sequences of Lake La Thuile (875 m, Bauges), Lake Bénit (1450 m, Barge), Lake Gers (1540 m, Giffre), Lake Verney (2088 m, Italy, Petit Saint-Bernard Pass) and the soils of their catchment, allowed to decipher the interactions between agro-pastoral system, erosion and soils. Our main objective is to determine whether human became, over the Holocene, the overriding factor of the pedogenesis and what are the ecosystem responses to disruptions, in terms of resilience and sustainability.

The comparison of paleoenvironmental reconstructions, derived from lacustrine archives evidenced a progressive development of soils during the first part of the Holocene, associated with substrate decarbonation, acidification then podzolization of soils in the Holocene Climate Optimum. The second part of the Holocene is characterized by regressive pedogenesis, in response to agro-pastoral activities development, mainly around the Roman and Medieval periods, along with erosion increases. Environmental disruptions triggered colluviation movements and a regression of soil weathering, leading to a multiplication of (non-linear) soil evolution trajectories and a higher soil diversity in the Anthropocene.

The soils developed until first human settlements present a higher capacity of resistance to erosion than soils developing thereafter. Resilience processes appear to be dominated by the establishment of new agroecosystem equilibrium states and attest of the deep modifications performed on mountain environments for several millennia. These modifications are recorded by the soils and triggered the expression of aftereffects on current land use. Interactions within the critical zone form a dynamic whole linked together by human who appears as the main pedogenetic factors in the Anthropocene.

Cyanobacteria secondary metabolites: New proxies for past environmental change

Lynda Petherick¹, Rudi Marquez², Karyne Rogers³

¹Victoria University of Wellington, Wellington, New Zealand. ²University of Canterbury, Christchurch, New Zealand.

³GNS Science, Lower Hutt, New Zealand

Abstract

We present a new proxy for past climatic and environmental variability: cyanobacteria secondary metabolites (CSMs). Cyanobacteria are ubiquitous, tolerating climatic (e.g. temperature) and environmental (e.g. nutrient) variability more successfully than other organisms. This adaptability has made cyanobacteria one of the longest existing life-forms, with geologic evidence showing their existence since the Archaean (~3.5 billion yr. BP). Freshwater cyanobacteria produce a number of unique CSMs (e.g. microcystin, nodularins, moturporin). These species-specific secondary metabolites are easily identifiable and clearly distinguishable from those produced by other organisms.

CSMs archived in lake sediment cores reflect varying diversity in populations of freshwater cyanobacteria through time. A 2000 year old sediment core has been extracted from the dairy-surrounded Lake Kopureherehere, lower North Island, New Zealand. The record encompasses pre-human New Zealand, Polynesian arrival (ca. 800 yr BP), Māori settlement, European arrival (ca. 200 yr BP) and modern land-use intensification. Samples from the core have been analysed for CSMs by MALDI, gas chromatography mass spectrometry and high-performance liquid chromatography mass spectrometry. The mass spectrometry results are compared with our database of CSM molecular weights, and are used to identify the corresponding cyanobacteria species.

Human-driven changes in land-use are characterised by pollen, charcoal and stable isotopes ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values). These proxies show significant changes in vegetation through time, corresponding with human activity on the landscape. Results indicate that cyanobacteria respond to human-driven changes in landcover (e.g. vegetation) during the late Holocene. Our findings suggest that our new method for reconstructing past lake health is successful.

Abstract

During the last glacial period, the Greenland ice core records show a succession of rapid, millennial-scale warmings, called Dansgaard-Oeschger (DO) events. Their widespread environmental impact is documented in proxy records throughout the Northern Hemisphere. A range of different mechanisms have been proposed that can produce similar warming in model experiments, however the progression and ultimate trigger of the events still remains elusive. Especially the spatio-temporal progression of environmental changes at the onset of the warm events can yield valuable insight into possible trigger mechanisms. However, because of their fast nature, this progression is challenging to reconstruct from paleoclimate data due to the limited temporal resolution achievable in many archives and cross-dating uncertainties between records.

In the presented study we present new high-resolution multi-proxy records of sea-salt (derived from sea spray and sea ice over the North Atlantic) and mineral dust (derived from the Central Asian deserts) aerosol concentrations over the period 10–60ka from the Greenland NGRIP and NEEM ice cores. We use these records in conjunction with local precipitation and temperature proxies from one of the cores to investigate the progression of environmental changes at the onset of the warming events at annual to multi-annual resolution.

Our results show on average a small lead of the changes in both local precipitation and terrestrial dust aerosol concentrations over the change in sea-salt aerosol concentrations and local temperature of approximately one decade. This suggests that, connected to the reinvigoration of the Atlantic Meridional Overturning Circulation and the warming in the North Atlantic, both synoptic and hemispheric atmospheric circulation changed at the onset of the DO warmings, affecting both the moisture transport to Greenland and the Asian monsoon systems. Taken at face value, this suggests that a collapse of the sea-ice cover was not the initial trigger for the DO events.

Abstract

Speleothems are a key tool for improving our understanding of the global expression and timing of abrupt climate changes during the last glacial period. Precise and accurate uranium-thorium dating enables high-resolution and precisely constrained chronologies of the events to be assembled. The wide geographic distribution of speleothems permits the expression of the events in various climate regions to be examined. Numerous speleothem records have been published, yet until now, the incidence, timing or expression of stadial-interstadial changes in these records has not been rigorously compared.

Here we compile 64 published speleothem records to assess the degree of global synchrony in the timing of the onset of interstadials. All records were standardised by recalculating the uranium-thorium ages using the latest decay constants and performing an optimal correction for detrital thorium. Depth-age relationships were then remodelled using a Bayesian Monte Carlo based age-modelling technique to produce a revised chronology for each record from which the onset of interstadial conditions were identified. Statistical methods were then employed to compare the timing of events between records.

We show that climate changes associated with abrupt high-latitude warming were synchronous to within a few decades to a century across the Europe-Mediterranean, Asian monsoon and South American monsoon regions, indicating that high-latitude climate changes were rapidly transmitted to the tropics. Strong evidence for such synchrony permits us to combine the speleothem event timings to produce exceptionally precise estimates for the onset of interstadials. We compare the combined speleothem event timings to the timing of interstadials in the GICC05 chronology. We do not detect any systematic ice-core-to-speleothem age difference that could be linked to either background climate state, or interstadial duration, amplitude and rate of warming, although there is a tendency for GICC05modelext to be slightly older between 75-70 kyr BP and slightly younger between 111-104 kyr BP. These comparisons strongly support the accuracy of the GICC05 (including GICC05modelext) chronology, but suggest that the quoted uncertainties are too conservative. Our study provides unprecedented chronological information on the timing of climate changes during stadial-interstadial transitions, with important ramifications for understanding regional synchrony, and for refining the ice-core chronology.

Abstract

Gibraltar, located at the gateway between the Atlantic and the Mediterranean marks a climatologically important position at the southern limit of Atlantic storm tracks. We present a near-continuous multi-proxy speleothem record spanning the modern day to 200 ka. The record is anchored to a chronology based on over 200 high precision U-Th ages and the stable oxygen and carbon isotope records sampled by micromilling provide decadal to sub-decadal time resolution. Eight years of cave environmental monitoring precede this study and provide critical evidence for the main meteorological and environmental controls on proxy variability and speleothem capture of western Mediterranean terrestrial climate.

Records from the recent past and cave monitoring clearly show that $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ in modern speleothem calcite are controlled by seasonal within-cave processes dependent on external temperature and water balance. The older Gibraltar record shows variations in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ on timescales from multi-decadal to multi-millennial which we compare with independently dated records including long marine core sequences and the Greenland ice core record. The radiometrically dated Gibraltar speleothem chronology provides a precise reference record to correlate with other proxy records, and we can demonstrate remarkable correspondence with the timing of change in Greenland temperature for much of the last glacial period. However, we note that periods in which the rates of change of Gibraltar water isotopes and Greenland temperature are more complex and provide evidence of other regional climatic influences. Trace elements provide evidence for other aspects of environmental change such as aridity, vegetation activity, and colloidal transport processes from the soil into the cave system.

The Gibraltar speleothem record provides a new precisely dated reference record for comparison with previously published datasets and for mapping isotope gradients across the Mediterranean and Europe over glacial-interglacial intervals.

Abstract

Shandong peninsula is climatically dictated by East Asian monsoons and bordered by the Bohai Sea and Yellow Sea in East Asia, two marginal seas with less than 100 meters water depth at present time. As continental ice sheets built up and sea level fell down, the coastline shifted southeast, and likely shifted 800-1000 km during the last glacial maximum when sea level was ~120m lower than at present time. This tremendous shift of coastline could have substantial impacts on the climate at Shandong peninsula. Here, we present a high-resolution and precisely dated speleothem isotope record from the Shangxiaofeng Cave and reconstruct the history of precipitation $\delta^{18}\text{O}$ spanning the penultimate deglaciation in Shandong peninsula, northern China.

The results of the $\delta^{18}\text{O}$ analysis reveal two outstanding features. Firstly, our $\delta^{18}\text{O}$ record magnitude of the glacial-interglacial change (~0.7‰) is significantly smaller compared to those (1.4-2.4‰) of the $\delta^{18}\text{O}$ record from Southern China (Dongge, Sanbao and Yangkou caves). Assuming that all $\delta^{18}\text{O}$ records mainly reflect precipitation isotope composition changes above the caves, the glacial-interglacial $\delta^{18}\text{O}$ difference between the various Chinese caves could be related to changes in atmospheric circulations, changing effect of altitude between the various caves and climate mean states, and particularly large-scale changes in regional land-sea coverage due to sea level changes. The latter leads to disappearance and expansion of Bohai and Yellow seas during glacial and interglacial episodes, respectively, and likely affect the isotope composition of precipitation.

Secondly, the SD1 $\delta^{18}\text{O}$ record of the penultimate deglaciation documents the instabilities which show the abrupt shifts center at ca.134.5ka, 132.8ka and 131ka BP, coincident with so called "H11 complex" identified from marine sediments. We also identified a brief excursion with enriched $\delta^{18}\text{O}$ centered at 128.3 ka BP and last ca. 400 years, implying a Younger-Dryas-type event during the penultimate deglaciation.

Taken together, our study highlights that hydroclimate imprints of the East Asian Monsoon changes during the penultimate glacial-interglacial cycle were spatially heterogeneous and centennial-scale monsoonal hydroclimate instabilities are inherent features of deglacial climate transition.

³Landcare Research, Lincoln, New Zealand

Abstract

The terrestrial southern mid latitudes are underrepresented in palaeoclimate research, which causes a gap in our understanding of regional complexities of global past climate compilations. We present a new pollen record and associated mean annual air temperature (MAT) reconstruction from Orakei Basin, northern New Zealand that can help fill this gap. The crater contains ~85 m of lacustrine sediments and peat, which accumulated between the Last Interglacial and the Early Holocene, when the crater rim was breached by the ocean. The age-depth model for the core is based on tephrostratigraphy, radiocarbon dating, luminescence dating on feldspars, paleomagnetic variation and Beryllium-10 variation.

We compare the Orakei Basin record to the numerous fragmentary terrestrial records from New Zealand, to the Okarito Pakihi pollen record in southern New Zealand (Newnham et al., 2007), to speleothem, glacial geomorphic and marine records from the region (Williams et al., 2015), the LR04 marine stack (Lisiecki and Raymo, 2015), and to ice core records from Greenland and Antarctica. Paleomagnetic excursions, such as the Laschamp event (~41 ka), and volcanic ash layers such as the Kawakawa/Oruanui tephra (~25.4 ka), can act as anchor points in these comparisons.

The Orakei Basin record shows five distinct phases comparable to Marine Isotope Stages (MIS) 5 to 1. The broad similarity of the Orakei MAT trend to the MIS and other records from New Zealand implies all were driven by northern high-latitude summer insolation, consistent with the Milankovitch orbital forcing hypothesis. Several patterns superimposed on the general trend stand out: firstly, MIS 4 is a brief cool period, which is different from the observation that glaciers were more extensive in New Zealand's Southern Alps during MIS 4 compared to MIS 2, possibly due to the seasonal distribution of energy from solar insolation. Secondly, MIS 3 displays an earlier warm phase followed by a progressive cooling trend which might be correlated to decreasing local summer insolation intensity. Thirdly, glacial conditions of MIS 2 appear consistent with the early onset of the Last Glacial Maximum in the southern mid latitudes, which was likely driven by regional insolation intensity. Together, these results point out the importance of considering regional-to-local drivers of climate changes superimposed on global reconstructions.

Future planned work on this core includes increasing the resolution so abrupt climate change events (such as Dansgaard-Oeschger cycles or Antarctic Isotope Maxima) can be identified, and developing a chironomid record, from which summer air temperatures can be reconstructed, allowing a look into past seasonality.

Evaluating existing discrete-depth ^{14}C dating practices in deep-sea sediment archives.

Bryan Lougheed¹, Philippa Ascough², Andrew Dolman³, Ludvig Löwemark⁴, Brett Metcalfe⁵

¹Uppsala University, Uppsala, Sweden. ²Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom. ³Alfred Wegener Institute, Potsdam, Germany. ⁴National Taiwan University, Taipei, Taiwan. ⁵Vrije Universiteit, Amsterdam, Netherlands

Abstract

For a number of decades, radiocarbon (^{14}C) dating has been readily applied to deep-sea sediment archives. The material that is typically ^{14}C analysed from these archives is the calcareous tests of foraminifera. The ^{14}C method, however, has traditionally required at least 1 mg of carbonate material, meaning that researchers have typically had to pick tens to hundreds of individual specimens from a single discrete core interval (typically 1 cm of core depth) and pool these into a single subsample for analysis. Such pooled samples are not heterogeneous in ^{14}C age, and ^{14}C measurements of pooled samples only report the mean ^{14}C activity and machine measurement error, thus concealing the true intra-sample ^{14}C age heterogeneity (i.e., the full analytical error). Failure to consider the effects of ^{14}C age heterogeneity of pooled samples can lead to downcore ^{14}C age artefacts caused by the interplay between post-depositional vertical mixing of foraminifera (bioturbation), the dynamic $\Delta^{14}\text{C}$ history of planet Earth, and the fact that ^{14}C is a radioisotope (i.e., younger foraminifera specimens within a pooled sample contribute exponentially more to the mean ^{14}C activity of a pooled sample).

Here, a newly developed model (the **sediment accumulation simulator** - SEAMUS) is used to evaluate the baseline accuracy of ^{14}C dating in deep sea sediment cores, by simulating the deposition and bioturbation history of single foraminifera within the deep sea sediment archive, using established understanding of $\Delta^{14}\text{C}$ history and bioturbation processes. To represent such a baseline scenario, we consider 'best case scenarios' involving constant sediment accumulation rate, constant bioturbation depth, constant foraminiferal species abundance and constant ^{14}C reservoir age. The simulation results indicate that even such 'best case scenarios' can exhibit large ^{14}C age artefacts (> 100 ^{14}C yr) in pooled samples, particularly during periods of dynamic $\Delta^{14}\text{C}$ history (such as the Younger Dryas and the Laschamp event) and in the case of lower sediment accumulation rates (< 10 cm/ka). Furthermore, such ^{14}C age artefacts are greatly amplified during the ^{14}C calibration process, producing large calendar age artefacts (> 200 calendar years), even in the case of higher sediment accumulation rates (> 40 cm/ka).

These findings highlight the pressing need to develop an improved ^{14}C calibration algorithm for deep sea sediment cores, whereby a bioturbation *a priori* is implemented. Furthermore, these findings also highlight the importance of single foraminifera ^{14}C analysis for furthering our understanding of the palaeoclimate signal in deep sea sediment cores.

Abstract

The sections of Greenland and Antarctic ice cores covering last glacial period have previously been synchronized primarily by their common records of gas concentrations and cosmogenic isotopes. Here, we apply annual layer counting and matching of volcanic peak patterns to synchronize the onsets and terminations of Greenland Interstadials (GI) in Marine Isotope Stage 3 (MIS3, 25-60 ka). Based on the identification of more than 50 significant bipolar volcanic events throughout MIS3, most abrupt climate events can be synchronized between the two Hemispheres at decadal precision. Layer counting has been performed in the Greenland NGRIP and the Antarctic EDML ice cores using high-resolution records of chemical impurities, dust, and visual grey scale intensity. The time scales obtained from layer counting are not always in agreement with existing ice core chronologies. Volcanic peak patterns have been identified in all available acidity records from the Greenland GRIP, GISP2, NGRIP, and NEEM and the Antarctic EDML (Atlantic sector), EDC (East Antarctic plateau), and WDC (West Antarctica) ice cores. The obtained volcanic synchronizations within Greenland and within Antarctica are in agreement with existing volcanic synchronizations. The bipolar volcanic synchronization is supported by cosmogenic record patterns at several of the major GI onsets and it is in accord with the cosmogenic synchronization at around the geomagnetic Laschamp event (41 ka). The bipolar volcanic synchronization is offset from the NGRIP-WDC methane synchronization by up to 150 years, generally pushing the Antarctic record towards older ages at the GI onsets. The general Antarctic response to a GI onset is a direct warming at the EDC and WDC sites that peaks within a century and a less significant cooling at the EDML site, possibly attributed to a northward shift of the southern hemisphere westerly winds. This pattern is, however, not consistent among all GI onsets and in particular the weaker GI events show deviating Antarctic response patterns. Several of the sharp Greenland climate transitions in MIS3 are associated with periods of strong volcanism suggesting that volcanism may work as a trigger of abrupt climate change. Other abrupt transitions are not associated with volcanism and many strong volcanic events do not show a response in the climate records. Overall, the bipolar volcanic synchronization gives strong support for the suggested bipolar seesaw mechanism.

Reconstructing palaeoenvironments in South Africa's Cape Floristic Region: a palynological approach

Lynne Quick¹, Brian Chase², Michael Meadows³, Alastair Potts¹, Richard Cowling¹

¹African Centre for Coastal Palaeoscience, Nelson Mandela University, Port Elizabeth, South Africa. ²Institut des Sciences de l'Evolution de Montpellier, Centre National de Recherche Scientifique, Montpellier, France. ³Department of Environmental and Geographical Science, University of Cape Town, Cape Town, South Africa

Abstract

The Cape Floristic Region (CFR) is a key focus area within southern Africa due to its botanical importance in terms of high levels of biodiversity as well as its rich cultural and archaeological heritage. The area is highly sensitive to cycles of regional and global environmental change, and records obtained from the region may provide valuable information regarding past climate variability. Prior to the last decade, few high resolution palaeoenvironmental records were recovered from the region, and therefore its environmental history was previously poorly understood. This presentation summarises some of the most important findings that have emanated from several pollen records generated over the last few years and outlines current and future directions for palynological research in this region.

The records presented are derived from unique natural archives found within the CFR and include pollen results from rock hyrax middens and coastal lowland wetland deposits that cover various portions of the Holocene, the last glacial and, in the case of one record, the last interglacial. These records document the nature and timing of past vegetation shifts and can be used to infer distinct changes in rainfall amounts and seasonality. They have improved our understanding of how different subregions (e.g. interior vs. coast) of the CFR have responded to past climate changes. Assessed in conjunction with other proxy evidence, the variability within the records suggest that the underlying drivers of climate change in this important region of southern Africa are associated with high latitude Southern Hemisphere climate dynamics (e.g. the position of the Subtropical Front and the westerlies storm track). However, more crucially, they also indicate that there is a larger degree of complexity than previously thought and highlight a series of avenues for future research.

O-4016

Changing vegetation patterns in Border Cave, KwaZulu-Natal, South Africa, ~ 250 000 to ~ 43 000 years ago

Sandra Lennox

Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa

Abstract

The location of this study is the Border Cave environment near the Maputaland centre of endemism in northern KwaZulu-Natal. The topic is to investigate vegetation change through time (from approximately 250 000 years (ka) ago to 43 ka and the possibility that Miombo Woodland existed before approximately 150 ka when micromammals from the palaeofaunal record included taxa that prefer a drier environment than today. Relicts of Miombo woodland still exist in northern South Africa, for example in the Soutpansberg. The method used is anthracology, which is recording anatomical features of charcoal by means of reflected light microscopy and digital photography while using the IAWA code, the InsideWood online database and modern wood charcoal reference collections. The materials studied are archaeological charcoal pieces recently excavated through the long sequence of Brown Sand (BS) and White Ash (WA) Members numbered from 6BS to 1WA. In these Members lithic technology changed from early to late Middle Stone Age, then Early Later Stone Age. The charcoal identifications show that the woody taxa represent a vegetation profile within the modern day range. There are some differences in the presence of taxa between Members 3BS (~64ka) deciduous vegetation is more strongly represented than evergreen in contrast to 2BS (~49ka) where evergreen vegetation is more strongly represented than deciduous vegetation, with seemingly little difference in eight Members. Bushveld genera are more strongly represented than forest in the Members except for Member 4WA (~115ka) and 2BS (~49ka). The vegetation profile over a long period does not suggest much change through time, that is, Lebombo Bushveld and Summit Sourveld probably persisted throughout the sequence. A comparison may be made between other archaeological sites in KwaZulu-Natal, for example, Sibudu where a mosaic of vegetation communities included evergreen forest and patches of open savanna.

Tropical-extratropical rainfall systems interaction in the Southern Atacama Desert since 17ka

Maria Eugenia de Porras¹, Antonio Maldonado Castro^{2,3}, Isabel Cartajena⁴

¹IANIGLA, Mendoza, Argentina. ²CEAZA, La Serena, Chile. ³Universidad de La Serena, La Serena, Chile. ⁴Universidad de Chile, Santiago de Chile, Chile

Abstract

The southernmost part of the Atacama Desert (24-27°S; SAD) lies in the transitional area between the tropical and extra-tropical rainfall systems linked to the South America Summer Monsoon (SASM) and the Southern Westerlies Wind Belt (SWWB), respectively, providing a unique chance to trace their interactions in the past.

It has been largely hypothesized about the source of the rainfall associated to the different wet phases recorded in the SAD since 17ka, mainly based on the temporal and spatial patterns recorded in the different kind of archives and/or proxies. This led to some inconsistencies attributed to the different temporal and spatial scales in which palaeoclimatic archives/proxies capture the past climate variability. Furthermore, the geographic complexity of the regional climate such as variation in the sources and/or mechanisms delivering the precipitation in space over the entire SAD, made the picture in time even more complicated.

In order to trace the past palaeoclimatic dynamics at the southern Atacama Desert and then, the interaction of tropical/extra-tropical interaction of the rainfall systems since the Late Pleistocene, this paper analyzed the changes in the fossil midden pollen assemblages (same archive/proxy) in time and space aided by a modern regional vegetation-pollen-climate calibration set.

Rodent midden pollen series at 24.5°S show extremely humid conditions during the Late Pleistocene (14-10.8ka) coinciding with the Central Atacama Pluvial Event II (CAPE II) which gradually turned into extremely dry at 8.5ka which lasted until 2ka. Then, a climatic amelioration towards slightly wetter conditions occurred up to the present interrupted by a dry phase between 1.4-1.0ka. At 26-27°S, pollen assemblages preserved in fossil rodent middens reflect humid conditions between 17-13ka which gradually turned into extremely dry ones around 10ka peaking up to 9ka. During the Mid-Holocene and up to 3.3ka drier than present conditions prevailed followed by a wet phase up to 2.2ka and a dry period between 1.0-0.6ka. At 0.6ka, an increase in humidity was recorded followed by a trend to drier conditions similar to the present.

Extremely humid conditions during the Late Pleistocene and early Holocene followed by severely arid phases prevailed both at 24.5°S and 26-27°S suggesting the intensification and posterior weakening of both, tropical and extra-tropical rainfall systems. Amelioration of dry conditions occurred into the Late Holocene which was characterized by alternating dry and wet phases at the centennial scale. The increase of humidity and occurrence of wet phases at 26-27°S indicate that the extra-tropical rainfall system intensified during the Late Holocene, particularly after 3.3ka and ca. 0.6ka whereas the tropical rainfall system behaved similar to the present.

⁵Ludwig-Maximilians-Universität, München, Germany. ⁶Forschungszentrum Jülich GmbH, Jülich, Germany

Abstract

Multiproxy climate reconstructions are scarce for southern South America but urgently needed to improve our understanding of spatio-temporal patterns of past and future climate conditions. The presented radiocarbon-dated lacustrine sediment record from Laguna Azul (52°05' S, 69°35' W, 100 m a.s.l.) provides high-resolution data of hydroclimatic variability for southern-most South America. The investigated crater lake is located 25 km north of the Magellan Strait and was formed by volcanic activities in the Quaternary Pali-Aike Volcanic Field during the Late-Glacial. Prevalence of Southern Hemispheric Westerlies (SHW) controls the regional climate in the rain shadow of the Andes. This determining factor results in cool-temperate (6–7 °C mean annual temperature), semiarid (200–300 mm annual rainfall), windy and highly evaporative conditions with Magellanic steppe as the resulting biome. The catchment area (0.24 km²) of Laguna Azul is restricted to the inner crater walls and small in relation to the lake's water surface (0.15 km²). Today, the water body is stratified (dimictic, holomictic) with a well-developed metalimnion during southern summers and classifies as mesotrophic to eutrophic. The obtained multiproxy-sediment record documents a millennial-scale Holocene variability of SHW overprinted by centennial-scale variations between warm/dry and cool/wet phases during the Meghalayan. These climatic fluctuations influenced water-column stratification as well as lake levels with feedbacks on lakeshore erosion, algal communities, trophic conditions, bottom-water oxygenation and authigenic mineral formation. The lacustrine history started with cool/wet climatic conditions at the onset of the Greenlandian (11,600–10,100 cal BP) followed by an extended dry period (10,100–8300 cal BP) related to intensified SHW with development of a shallow lake, ectogenic meromixis, strong anoxia, methanogenesis and high salinity. During the Northgrippian (8300–4000 cal BP) the influence of SHW weakened resulting in less arid conditions and development of a deep freshwater lake. For the Meghalayan (4000 cal BP until present-day), regional temperature decreased in accordance with the onset of the Neoglacial and was accompanied by intensified SHW reaching full strength after 3000 cal BP. Superimposed on the multi-millennial SHW variability, Laguna Azul experienced century-long warm/dry spells contemporaneous with La Niña-like ENSO conditions around 2200 and 1000 cal BP as well as during the 20th century. Less arid and colder conditions occurred between these warm/dry periods. The most pronounced of these episodes are synchronous with the northern hemispheric "Dark Age Cold Period" and the "Little Ice Age". While centennial climatic fluctuations appear at the same time for Southern and Northern Hemispheres, millennial-scale variability is linked to SHW dynamics provoking distinct climatic differences between luv- and lee-sides of the Andes.

Patagonian glacier-climate changes during the Holocene based on ^{10}Be (and ^{14}C) dating

Michael Kaplan¹, Schaefer Joerg¹, Reynhout Scott², Sagredo Esteban³, Strelin Jorge^{4,5}, Juan Carlos Aravena⁶, Mateo Martini⁵, Patricio Moreno², Rodrigo Villa Martinez⁶, Carly Peltier¹, Rodrigo Soteres³, Juan Luis Garcia³
¹LDEO, Palisades, USA. ²Universidad de Chile, Sanitago, Chile. ³Pontificia Universidad Católica de Chile, Sanitago, Chile. ⁴Instituto Antártico Argentino, Buenos Aires, Argentina. ⁵Universidad Nacional de Córdoba, Cordoba, Argentina. ⁶Universidad de Magallanes, Punta Arenas, Chile

Abstract

Mountain glaciers respond sensitively to changes in Earth's atmosphere such that records of their history serve as a useful proxy for past climates. The record of glacier behavior around Patagonia reflects former climates that affected the cryosphere at the middle to high latitudes of the Southern Hemisphere. Recently, in situ ^{10}Be cosmogenic nuclide dating, combined with detailed geomorphic mapping, has been applied to Holocene-age moraines in southern and central Patagonia. We summarize at least three areas where we are focusing: there are in the drainage areas of Lago Argentino and Lago Viedma, and around the San Lorenzo massif. On the one hand, the findings indicate, in general, an early Holocene warm period with reduced glacier extents. This finding is strongly supported by other proxies, which collectively indicate a swath of warmth from the middle to high latitudes. On the other hand, observations so far indicate that smaller glaciers do register relatively brief cool periods that punctuated the generally warm early Holocene interval. By 8,000-6,000 years ago, climatic conditions favored cooling and recurrent glacier expansions for much of the remaining Holocene. At least one temporal exception of limited glacier expansion occurred from 4,000 to 2,500 years ago, which agrees with other proxy records for a relatively warm dry period. Several advances occurred during the Little Ice Age interval in Europe; however, in all areas we have worked in Patagonia – these are generally not the largest expansions of the Holocene.

We compare ^{10}Be (and ^{14}C) glacier chronologies with recent reconstructions of SAM-like conditions since Late Glacial time, based on other proxy types including of past vegetation changes. Positive and negative SAM-like conditions are associated with warm/dry and cool/wet climates in central/southern Patagonia, which are favorable for reduced and expansive glaciers, respectively. We conclude that millennial and centennial intervals of generally reduced ice – from the middle to high latitudes – occur when positive Southern Annular Mode (SAM)-like conditions are persistent. We infer these intervals are times of weakening and/or poleward expansion of the Southern Hemisphere westerlies, and they are associated with reduced sea ice. Conversely, persistent negative SAM-like conditions, increased sea ice, and perhaps equator-ward focus of the westerlies are favorable for glacier expansions in Patagonia.

Abstract

The thermal bipolar seesaw [Stocker and Johnsen, 2003] is the leading hypothesis to explain the millennial-scale temperature changes of the last glacial termination, which are of opposing sign between the polar ice cores. However, the spatial extent and temporal structure of these events outside of the high latitudes and thus, the climatic mechanisms responsible, remain poorly constrained. Here we address this shortcoming with quantitative constraints on the timing and magnitude of atmospheric and sea-surface temperature changes during the Antarctic Cold Reversal from the New Zealand region. Our new glacier-based air temperature reconstructions and foram-derived sea surface temperature record exhibit coldest temperatures within centuries of the onset of this millennial-scale event, followed by gradual warming prior to 13 ka. Placed in the context of Antarctic ice cores and the thermal bipolar seesaw hypothesis, our evidence for centennial-scale response at this far-field, southern mid-latitude location challenges the Stocker and Johnsen [2003] hypothesis by suggesting a teleconnection to the North Atlantic that is not modulated by their proposed Southern Ocean heat reservoir. Coupled atmosphere-ocean mechanisms operating north of the Antarctic Circumpolar Current, as indicated by recent climate modelling, provide a physical framework that may reconcile the different climate response times of the southern mid- and high-latitudes during the Antarctic Cold Reversal.

Tracking the last glacial termination in the Southern Alps of New Zealand

David Barrell¹, George Denton², Aaron Putnam²

¹GNS Science, Dunedin, New Zealand. ²School of Earth and Climate Sciences, University of Maine, Orono, USA

Abstract

In the Southern Alps, application of surface-exposure dating using in-situ produced terrestrial cosmogenic nuclides (SED) over the past decade or so has produced comprehensive chronologies for moraine sequences in several major east-draining mountain valleys (Darvill et al. 2016 - Quaternary Science Reviews (QSR) 149: 200-214). A regional-scale glacial geomorphologic map published for the central sector of the Southern Alps (Barrell et al. 2011; GNS Science Monograph 27), together with well-resolved SED moraine chronologies, provide an invaluable framework for reconstructing past glacier extents and deriving paleoclimate estimates via glaciological modelling. Spanning from Marine Isotope Stage 4 through to Termination 1 (~18 ka), the moraine sequence geomorphology and SED chronology of the Pukaki and Ohau valleys (Putnam et al. 2013a – QSR 62: 114-141; Kelley et al. 2014 - Earth and Planetary Science Letters (EPSL) 405: 194-206; Schaefer et al. 2015 – QSR 114: 52-60; Doughty et al. 2015 - Geology 43: 407-410) afford substantive evidence for at least 8 major episodes of terminal and/or lateral moraine formation at or near full-glacial ice extent. Shulmeister et al. 2019 (QSR 206: 1-20) recognise an additional episode of glacier expansion from luminescence-dated glaciogenic sediments, making a total of at least 9 major cold-climate episodes during the last glaciation.

In the Pukaki and Ohau valleys, as well as in the Rakaia valley (Putnam et al. 2013b – EPSL 382: 98-110), terminal moraines were formed at ~18 ka, followed by rapid ice recession that, by ~17 ka, had seen each glacier trunk downwaste by at least several hundred metres, with implied terminal recession of as much as 40% of the overall glacier length. Similar recession is also indicated by SED ages from the Rangitata valley, where glacier downwasting of at least 300 m was in progress at ~17.7 ka (Barrell et al. 2019 – QSR 203: 141-150). The glacial moraine record implies an atmospheric warming of several degrees during the ~18 to ~17 ka interval. The paleoenvironmental impacts of this change are reflected to varying degrees of resolution in other New Zealand (NZ) terrestrial paleoclimate proxies (Barrell et al. 2013 – QSR 74: 4-20) and registered most crisply at a lowland pollen record site (Vandergoes et al. 2013 – QSR 74: 215-229) where subalpine shrub and grass taxa were replaced by full lowland temperate rainforest over that ~1 kyr interval. At about the same time, the Subtropical Frontal Zone shifted poleward to the south of NZ (Bostock et al. 2015 - Paleoceanography 30: 824-844), while substantial glacier recession and resurgence of temperate forest vegetation occurred in western Patagonia (Moreno et al. 2015 – QSR 122: 233-249). These findings highlight that the last glacial termination in the austral mid-latitudes was rapid, sustained and of at least pan-Pacific extent.

Gone to seed? Organic residue analysis shows the earliest prehistoric Saharan pottery was used for plant processing

Julie Dunne¹, Katie Manning², Nick Drake², Paul Breeze², Richard Evershed¹

¹University of Bristol, Bristol, United Kingdom. ²King's College, London, London, United Kingdom

Abstract

North Africa is one of the earliest known centres for pottery production across the world. These earliest African ceramics, technologically advanced and extremely well made, were found at Ounjougou, Mali (c. 9400 cal BC) and at other sites in the mountains of the Central Sahara (Algeria, Libya, Chad and Niger), the Eastern Sahara (Sudan) and the Nile Valley (Egypt).

Despite the late domestication of plants in Africa, archaeological and archaeobotanical evidence from early and middle Holocene sites across north Africa revealed considerable assemblages of exceptionally well-preserved plant and vegetal macro-remains. Together with the adoption of appropriate technology, such as pottery and grinding stones, this suggests sustained and systematic exploitation of significant varieties of wild plants by the hunter-gathering groups living in the region.

Here, we use a combined archaeological, molecular and isotopic approach to identify extensive processing of plant material within ceramic vessels from early Holocene sites across north Africa. Biomarkers such as *n*-alkane distributions and sequences of long-chain fatty acid distributions demonstrate that different species of plants, such as wild grasses and aquatic plants, were processed in the vessels. The high P/S ratios of some of the residues, and comparison to archaeological propagules, also confirm that oil was likely processed in the vessels, perhaps from boiling of seeds within the pots to extract the oil. These data confirm that the gathering and processing of a wide variety of plants, including grains/seeds, leafy and aquatic plants, played a significant role in the diets and subsistence practices of Holocene prehistoric groups.

The ceramic technology practiced at Dolni Vestonice, ca. 26,000 B.P., compared to some others in Eurasia

Pamela Vandiver

Dept. of Materials Science and Engrg., University of Arizona, Tucson, USA

Abstract

The archaeological site of Dolni Věstonice I, dated by radiocarbon and stratigraphy to 26,000 B.P., lies along the northeast side of the Pavlov Hills near the Dyje River in the Moravian basin, now in the Czech Republic. Dolni Věstonice I is known for ceramic figurines of animals and humans and for small slabs, spherical balls and pellets of fired clay that number about 5760. Together with the nearby sites of Dolni Věstonice II, Pavlov I and II, Předmosti and Petřkovice, dated between 28,000 and 24,000 B.P., the ceramic inventory totals over 10,000. A domed and banked hearth, with 2300 ceramic fragments in and near it, was excavated in 1979. It was used to fire at least some of the figurines and other ceramics. A second horseshoe-shaped kiln, excavated in 1951-1952 was found in a hut upslope from the habitation site. It was made in layers of the same Aeolian loess as the figurines. Some other large fired-loess fragments that we have called structural ceramics, may have been used as a small, elevated working space or support platform, possibly placed near a hearth.

This paper aims at reporting the raw materials and production technologies, and the implied knowledge of ceramic materials, processing and properties, that developed at Dolni Věstonice to produce ceramics, and at making comparisons to the ceramic and pigment technologies at other Pavlovian sites in Moravia. Other comparisons are made to sites to the east; such as, Kostenki I-1 (ca. 22,000 B.P.) on the Don River and Maina (ca. 15,000 B.P.) in the Yenesei River basin, Russia, and Zazaragi (ca. 18,000 B.P.) near Sendai, Japan. Each of these sites has clay resources with dissimilar properties. Another comparison is made to the ceramic balls from Mas d'Azil (ca. 14,000), French Pyrenées. This inhabited and decorated cave is above a river that connects two valleys.

At each site, humans developed ceramic technology to make figurines and/or ceramic balls and pellets using clay and water processed using knowledge of forming, drying and firing. Some of these clays also were suitable for use as pigments, and some we have documented were used as both pigments and ceramics. The inhabitants at each site could have used the readily available plastic clays to make pots, as I have done at Dolni Věstonice, Kostenki, Maina and Mas d'Azil to demonstrate that it can be done. Although the inhabitants had the know-how or craft practice, they did not have a need for moveable ceramic pots, the idea of a pot, or a natural model upon which to base such an innovation. The closest archaeological features are the stationary skin-lined pits or depressions near hearths used for cooking with preheated, so-called "boiling stones."

O-4024

The emergence of ceramics in Southwest Asia

Kevin Gibbs

University of California, Berkeley, Berkeley, USA

Abstract

In Southwest Asia, early ceramics are generally associated with sedentary farming communities. This is unlike many other parts of Asia, where ceramics were first manufactured by hunter-gatherers. Radiocarbon evidence indicates that sustained production of ceramic containers—pottery—began at several sites in Anatolia, Upper Mesopotamia and the northern Levant around 7000 BC or slightly later, although there are indications that very small-scale production of pottery sometimes occurred at even earlier dates. In other regions (e.g. the southern Levant, Cyprus) pottery does not become common until centuries later. This paper examines regional variability in Southwest Asian ceramic production in terms of its timing, technology, use and contexts. It considers the reasons for the early adoption of pottery in some parts of the broader region and why, in other areas, adoption was delayed despite probable knowledge of the materials and methods needed to make pottery. It also considers the legacy of early archaeological studies of southwest Asian pottery for our general understanding of the emergence of ceramics. For example, Gordon Childe's concept of a 'Neolithic package' promoted a close association between the emergence of farming and pottery, which can no longer be supported for many parts of Asia.

Ceramics in the desert: Mongolian pottery in context

Lisa Janz^{1,2}, Bukhchuluun Dashzeveg³, Arlene M. Rosen⁴, Cheryl Makarewicz⁵, Odsuren Davaakhuu⁶

¹Trent University, Peterborough, Canada. ²University of Arizona, Tucson, USA. ³Yale University, New Haven, USA.

⁴University of Texas Austin, Austin, USA. ⁵University of Kiel, Kiel, Germany. ⁶Mongolian Academy of Science, Ulaanbaatar, Mongolia

Abstract

The regular use of pottery technology in Mongolian archaeological sites is largely coincidental with major shifts in land-use and the adoption of other food processing technologies such as grinding stones. Decorative styles show strong connections with contiguous regions of northern China, suggesting cultural connections across the arid belt of Mongolia and north China, with similar technologies but various approaches to land-use. Radiocarbon dating, site distribution, and statistically significant trends in raw material reduction strategies between environmental settings all show that these technological changes are coincidental with a decline in residential mobility and a wetland-centric mode of land use. This shift corresponds to a middle Holocene Climatic Optimum and the “greening” of the Gobi Desert. Similar shifts in land-use, relative to their environmental contexts, occurred across northern China and Mongolia at the same time and may have been instrumental to the rise of agricultural economies in less arid parts of China. In the Gobi Desert, this period represents a prolonged phase of a wetland-centric hunting and gathering-based economy. Based on recent excavation and geoarchaeological research in eastern Mongolia, it is probable that wetland use was closely tied to wet phases and that individual wetlands were abandoned, or there were overall changes in land-use, as a result of aridification. Despite the emphasis on wetlands and the fact that residue analysis of pottery from other regions of Northeast Asia demonstrates their importance in processing aquatic foods, faunal analysis of archaeological sites and preliminary organic residue analysis on vessels from the Gobi Desert suggest an overwhelmingly terrestrial focus. This presentation will summarize previous findings on chronology and site distribution, as well as present new data, including chronometric dates, stratigraphic sequences, fauna, and organic residue analysis, all of which reveal the context of pottery use in the Gobi Desert.

O-4026

Environmental conditions of early ceramics appearance in the Late Pleistocene – Early Holocene (the Transbaikal region, South Siberia)

Natalia Tsydenova¹, Dai Kunikita², Hiroyuki Sato², Shizuo Onuki³, Daigo Natsuki²

¹The Institute of Mongolian, Buddhist and Tibetan studies of SB RAS, Ulan-Ude, Russian Federation. ²Graduate School of Humanities and Sociology, The University of Tokyo, Tokyo, Japan. ³The Kokugakuin University, Tokyo, Japan

Abstract

Early ceramic assemblages of the Transbaikal region were dated by AMS and OSL (Konstantinov, 1994; Razgildeeva et al, 2013; Hommel et al., 2017; Tsydenova et al., 2017). The obtained results demonstrated their Late Pleistocene – Early Holocene ages. New AMS dating of the early ceramic layer from the Krasnaya Gorka site also gave reasons to define the age of assemblage as the Late Pleistocene - Early Holocene. There is another opinion, that regional ceramic could not appear as early due to the cold climatic conditions. Hence, the Studenoe 1 (layers 8–9) and Ust'-Menza 1 (layers 5–8) age estimations were regarded as incorrect and Atlantic period of Holocene has been supposed (Konstantinov, 2016). However, the most recent paleoenvironmental data indicates the colder conditions, than expected earlier and does not propose the Atlantic age (Razgildeeva et al., 2011). In addition, the results of pollen analyses indicate that the climatic changes in the Late Pleistocene - Early Holocene of the Baikal region correspond to the general climatic scale [Bezrukova et al., 2011; Bezrukova, 2012]. The regional climate becomes more humid and mild around 14.5–12.5 cal. kyr BP, what is corresponding to the European Allerød interstadial. The warmest paleoenvironmental conditions have been recorded around 13.5 cal. kyr BP [Bezrukova, 2012; Reshetova, Bezrukova, 2016]. The most recent dates from the early ceramic sites correspond to this period.

Starch grain evidence reveals early pottery function cooking plant foods in North China

Xiaoyan Yang¹, Zhikun Ma², Tao Wang³, Linda Perry⁴

¹Chinese Academy of Sciences, Beijing, China. ²Northwest University, Xi'an, China. ³Capital Normal University, Beijing, China. ⁴The Foundation for Archaeobotanical Research in Microfossils, Fairfax, USA

Abstract

Early pottery sherds excavated in northern China date back to more than 11,000 cal a BP, and are presumed to have been used as cooking vessels. Pottery invention in different geographic areas is believed to have been driven by different factors including, but not limited to, architecture, culinary use, resource intensification, and/or social/symbolic elaboration. Studies of the function of early pottery are fundamental in gaining an understanding of why ancient people began to use ceramic vessels. In both northern and southern China, the presence of scorch and soot marks on the exterior surfaces of ancient sherds has led to the hypothesis that pottery was used for cooking food. Other functions may have included the extraction of bone marrow and grease, raw food preparation and storage, the brewing of alcoholic beverages, and use in social roles such as feasting. Notably, these functions have remained hypothetical due to the lack of residue analyses of the early pottery from these regions. Here we report ancient starch grains recovered from carbonized residues adhering to the bases of flat-bottomed vessels excavated from the Zhuannian site dating more than 10,000 cal a BP in the North China Plain. This evidence demonstrates that early pottery was being used to cook cereal grains, particularly millets, and acorns in terms of using the dichotomous key we set up. Because millets were in the process of domestication at this time, we propose that pottery invention in northern China may have been related to early farming activities.

O-4028

Watershed Event or Piecemeal Process: Exploring Behavioural Adaptations Surrounding Early Pottery Use in Northeast Asia

Karisa Terry¹, Ian Buvit²

¹Central Washington University, Ellensburg, USA. ²Oregon State University, Corvallis, USA

Abstract

Inquiries focusing on addition of ceramic production within the behavioural and technological systems of hunting-gathering-fishing societies of Late Pleistocene Northeast Asia are only recently developing. We compare the timing of ceramic adoption as well as its role in behavioral adaptations to changing environments roughly 14,000-10,000 ¹⁴C BP (Bølling-Allerød-Younger Dryas) from sites in Transbaikal Russia, Russian Far East, northeastern China, and Hokkaido. Our analysis revolves around identifying reorganization of behavioural adaptations in terms of settlement patterns, sedentism and storage, subsistence, extractive technology, and human reciprocity that overlay both environmental destabilization from 14,000 to 10,000 ¹⁴C BP and timing of ceramic vessel adoption. Specifically, we will compare site locations and features, fauna exploited, stone and organic tools, symbolic representations, and ceramic construction and styles. As adoption of pottery is not uniform across time or geographic locations within the region, we will elucidate some factors that prompted foraging people to use pottery under some circumstances but not others.

Investigating the mid-Holocene tectonic geomorphology of northern Crete and Late Bronze Age Santorini tsunamite candidate based on a multiproxy approach

Vera Werner¹, Kalliopi Baika², Anastasia Tzigounaki³, Klaus Reicherter⁴, Ioannis Papanikolaou⁵, Kurt Emde¹, Peter Fischer¹, Lea Obrocki¹, Andreas Vött¹

¹Institute for Geography, Johannes Gutenberg-Universität Mainz, Mainz, Germany. ²Centre Camille Jullian, Aix-Marseille Université, Aix-en-Provence, France. ³Ephorate of Antiquities of Rethymnon, Rethymnon, Greece. ⁴Institute of Geoscience, Neotectonics and Natural Hazards, Aachen, Germany. ⁵Institute of General and Environmental Geology, Agricultural University of Athens, Athens, Greece

Abstract

The Late Bronze Age (LBA) tsunami and the A.D. 365 tsunami are supposed to have affected the northern coasts of Crete. However, near-coast sedimentary archives have been rarely investigated in this area, and sedimentary archives including palaeotsunami fingerprints are still unknown. The main objective of our research was to search for appropriate tsunami sediment traps in order to gain detailed insights into the Holocene palaeotsunami history of northern Crete. We found an excellent fine sediment archive near Pírgos, located to the west of Rethymnon. Based on a multi-electrode geoelectrical survey and an 11-m-deep sediment core, we analysed the eventgeochronostratigraphical

record by means of sedimentological, geochemical, geochronological, geomorphological, and microfossil investigations. The Pírgos record revealed a thick unit of homogeneous mud of a lagoonal environment starting ~6000 years ago. The lagoon was affected by five high-energy events, leaving layers of allochthonous sand. Microfossil analyses of these layers revealed a mixed foraminiferal assemblage including species from brackish habitats but also displaced and transported species from open marine and deep-water environments. Considering sedimentary characteristics, the local wave climate of the Cretan Sea, and the overall geomorphological setting, we interpret these layers as related to extreme wave events (EWE). Based on a local radiocarbon age-depth-model, we identified one EWE layer as a reliable candidate for the LBA Santorini tsunami. Another EWE layer is most probably associated with the A.D. 365 tsunami. This EWE ended abruptly the lagoonal conditions at Pírgos because of the 1.64 m coseismic uplift at the site. The Pírgos lagoon existed between the first half of the 6th mill. B.C. and (at least) the end of the 2nd mill. B.C. We found that the area around Pírgos has continuously subsided over 3000 or so years, reflecting constant tectonogeomorphological conditions dominated by the nearby subduction zone between the Aegean and African plates

O-4030

The identification and characterisation of the Storegga Slide Tsunami in the southern North Sea using a multiproxy approach

Vince Gaffney¹, Robin Allaby², Simon Fitch¹, Rosie Ware², Becky Cribdon², Benjamin Gearey³, Kevin Kearney³, Thomas Hill⁴, Rosie Everett², Richard Bates⁵, Martin Bates⁶, David Smith⁷, Tim Kinnaird⁵

¹University of Bradford, Bradford, United Kingdom. ²University of Warwick, Warwick, United Kingdom. ³University College Cork, Cork, Ireland. ⁴Natural History Museum, Warwick, United Kingdom. ⁵University of St Andrews, St Andrews, United Kingdom. ⁶University of Wales Trinity St Davids, Lampeter, United Kingdom. ⁷University of Birmingham, Birmingham, United Kingdom

Abstract

Doggerland is a landmass occupying the area currently beneath the North Sea, which was inundated during the early Holocene, separating the British landmass from the rest of Europe. The Storegga slide was a major submarine landslide, which triggered a Tsunami that has been identified in sediments in the northern North Sea, northeast coastlines of the British Isles and across the north Atlantic. The extent and impact of this tsunami and its role in the final inundation of Doggerland is unknown as to date no direct evidence for this event has been recovered from the southern North Sea. In this paper, we present multi-proxy palaeoenvironmental (diatom, pollen and mollusc) and sedimentary ancient DNA (sedaDNA) data from a core recovered from an off-shore palaeo-river system identified using seismic survey and dated using Optically Stimulated Luminescence. The character and chronology of a distinct lithostratigraphic unit within the core, indicates the impact of the Storegga Tsunami. Seismic tracking of this unit across the palaeo-river system implies that the effects of the Tsunami reached the southern North Sea, but effects were probably localized and possibly limited by the dominant woodland vegetation and topography. We hypothesise that clear physical evidence of the Tsunami event are thus likely to be restricted to specific contexts, such as incised river valley systems.

Wadden Sea Geoarchaeology- Reconstructing a drowned coastal landscape around the medieval trading centre Rungholt (North Frisia, Germany) by multi-proxy analyses

Hanna Hadler¹, Andreas Vött¹, Dennis Wilken², Michaela Schwardt², Timo Willesrhäuser¹, Vera Werner¹, Annika Fediuk², Peter Fischer¹, Wolfgang Rabbel², Tina Wunderliche²

¹Johannes Gutenberg-Universität Mainz, Mainz, Germany. ²Christian-Albrechts-Universität zu Kiel, Kiel, Germany

Abstract

In the 12th to 14th cent. AD, the Wadden Sea of North Frisia (Schleswig-Holstein, Germany) - today protected as UNESCO World Heritage - represented an extensively cultivated landscape, where natural coastal marsh- and fenlands were widely embanked, drained and cultivated by Frisian settlers. At that time, the tidal flats around the marsh island Hallig Südfall belonged to the historical Edomsharde district and its main settlement Rungholt. During medieval and early modern times, vast areas of this settled marshland were drowned by extreme storm surges like the 1. Grote Mandrenke in 1362 AD. Within days, hundreds of square kilometres of cultivated marshland were turned into tidal flats and permanently lost to the sea.

In the present-day Wadden Sea, remnants of the medieval coastal landscape are still preserved beneath younger sediments. Where currents or waves erode the sediment cover, relics of marshland become exposed and remains of dikes, drainage ditches, terps and even plough marks emerge from the tidal flats. However, due to the tides, hard accessibility of many areas and unfavourable weather conditions archaeological investigations in the tidal flats are still a rather difficult task. So, until today, rather little is known about the appearance coastal North Frisian in late medieval times.

For the first time in North Frisia, a broad research approach based on geoarchaeological, geophysical and geomorphological investigations now aims at (i) reconstructing the historical landscape around sunken Rungholt, (ii) evaluating the impact of storm surges on the medieval marshland by identifying traces of such events in the Wadden Sea and (iii) deciphering the complex interactions between man and environment.

So far, geophysical investigations by means of magnetic, seismic and electrical resistivity prospection, revealed distinct evidence of former settlements including remains of dykes and dwelling mounds. Geomorphological investigations based on vibracoring, direct push (DP) sensing and a detailed multi-proxy analysis of sediment cores, retrieved from the tidal flat zone around Hallig Südfall and from the Hallig itself, allowed to elucidate major environmental changes that considerably altered the coastal landscape since medieval times. By combining results from detailed sedimentological, micropalaeontological, geochemical analyses with geophysical and geochronological data, we were able to identify remains of a late medieval palaeosol associated with the medieval marshland and differentiate between settled and unsettled areas. For the first time for North Frisia, we also provide geological evidence of marshland destruction by the Grote Mandrenke in 1362 AD. Altogether, the Wadden Sea turned out to be a promising archive for geoarchaeological prospection.

Late Holocene coastal change in northwest Ireland

Helene Burningham¹, Jasper Knight², James Madoc-Jones¹

¹UCL, London, United Kingdom. ²University of the Witwatersrand, Johannesburg, South Africa

Abstract

Coastal sediments in northwest Ireland have the potential to explain much about climate and sea-level changes in the last few millennia, but accommodation space for preserved depositional sequences is limited and at times, compromised. Previous efforts to establish relative sea-level contexts and characterise late-Holocene coastal evolution here have necessarily focused on intertidal freshwater peats (i.e. evidence of lower than present sea-level) and raised beaches (i.e. evidence for high stands). It is clear that the far north (e.g. Malin Head) experienced a distinct high-stand c. 6000 yr BP, but evidence of this farther south/west, suggested in glacioisostatic modelling has yet to be forthcoming.

North of Burtonport (County Donegal, northwest Ireland), bedrock headlands and an archipelago of small offshore islands have provided accommodation space pockets where sediment sequences formed during the mid- to late-Holocene, some of which have been preserved. Here, a weathered granite bedrock surface just below the level of mean high water neaps is overlain by beach gravels topped by an organic-rich peat containing in situ *Pinus* stumps (at about mean high water). Above this is a 2 m thick exposure of peaty sediment bounded by undulating erosional unconformities, topped by a palaeosol (20 cm thick) and 60 cm of recent dune sand. The central portion of peaty sediment comprises distinct packages (20-80 cm thick) where organic-rich sediments are interbedded with laterally continuous sandy layers (<1 cm thick) that generally increase in thickness upwards at the expense of the organic layers.

Following a multi-faceted approach including magnetic susceptibility, particle size analysis, geochemistry and microfossil assemblages (diatoms), the sequence is explored for evidence of marine forcing and environmental. Five samples were also removed for AMS ¹⁴C dating, which firmly place the entire sequence in the late Holocene. Results point to a complex sequence of changes in coastal physiography and depositional context during a period of higher than present sea level. Marine influence, evidenced by the increased presence of multiple species of brackish diatoms and distinct cyclicity in organo- to minerogenic accretion, appears to have peaked at 2.7 m OD, >1.5m above the contemporary mean high water springs, but notably within the maximum surge level of recent years. The sequence places some control on late-Holocene sea-level change, but importantly provides clear indication of coastal response within a complicated setting to marine forcing over a 3000 year period.

³University of Aberdeen, Aberdeen, United Kingdom. ⁴National University Galway, Galway, United Kingdom.

⁵University of Glasgow, Glasgow, United Kingdom. ⁶Manchester Metropolitan University, Manchester, United Kingdom

Abstract

Tidewater glaciers (TWGs) exert a major control on the short- and long-term mass balance of the Greenland Ice Sheet (GIS) and have experienced widespread retreat over the last century. However, in many cases inferences on their dynamics, prior to this, are poorly constrained due to a lack of observations and paucity of mapped or mappable deglacial geomorphology. Especially lacking is evidence associated with TWG *advance* during the Little Ice Age (LIA, AD c. 1300 to 1850). Such data are crucial for numerical model calibration and validation in order to more confidently forward model ice sheet dynamics and projection future sea-level rise. Therefore, empirical data constraints from the palaeo-record, that span such timescales (decadal to millennial), are essential.

To address this, we present a unique reconstruction of advance and retreat at a major Greenlandic tidewater spanning the last millennium utilising a multi-proxy approach (geomorphological, sedimentological and archaeological evidence). We demonstrate the rapid advance of Kangiata Nunaata Sermia (KNS) by 15 km ($\sim 113 \text{ m a}^{-1}$) from AD 1076 ± 84 to 1230 ± 44 , approaching to within 5 km of its Little Ice Age maximum (LIA_{max}). This provides the first evidence that sustained rates of tidewater glacier advance are similar to the dramatic rates of retreat observed across Greenland over the last century (Kjeldsen et al., 2015). The advance occurs during a period of atmospheric cooling indicated by independent climate proxies (Vinther et al., 2010; Von Gunten et al., 2012). New evidence confirming the contemporaneous occupation of a Norse farmstead, proximal to the advancing calving front, also suggests that iceberg production rates during advance were lower compared to the retreat dominated behaviour of KNS over the last c.200 years (Lea et al., 2014a; 2014b). Sedimentary and geomorphological evidence reveals that KNS was subsequently stable near to its LIA_{max} configuration for approximately 500 years despite significant climate variability. For the first time, these findings provide key context for how climate can impact calving behaviour, driving both rapid advance and of tidewater glaciers over centennial timescales during the Norse era.

UAV photogrammetry and 3D scan data for topographic mapping and monitoring of coastal areas

Kieran Craven, James Barry, Sean Cullen, Ronan O'Toole
Geological Survey Ireland, Dublin, Ireland

Abstract

Coastal areas experience change via marine processes and other natural and anthropogenic causes. These changes to coastal geomorphology must be assessed on a range of temporal and spatial scales to understand the evolution of these environments, particularly in the context of projected climate change yielding increased sea-levels and storm frequency. Commercial survey grade unmanned aerial vehicle (UAV) and 3D scan equipment, data processing and analysis tools are available to coastal managers, engineers and researchers.

This study, undertaken as part of the CHERISH project, analyses the use of photogrammetry via UAVs and 3D scan data from scanning total stations in Irish coastal locations to produce orthoimage mosaics and digital surface models. These products extend and complement acoustic bathymetric data from the Irish national seabed mapping programme (INFOMAR) in mapping coastal regions. Preliminary results indicate that combining relevant techniques to produce seamless onshore-offshore maps can provide high-resolution information about emergent and submergent coastal geomorphology on a range of scales for use in coastal mapping, monitoring and management.

O-4035

Do Higher 20th Century Cliff-top Retreat Rates Necessarily Imply Recent Acceleration in Sea-cliff Erosion?

Amit Mushkin^{1,2}, Oded Katz¹

¹Geological Survey of Israel, Jerusalem, Israel. ²University of Washington, Seattle, WA, USA

Abstract

Inland retreat of sea cliffs in response to post LGM (last glacial maximum) sea-level rise is an ongoing process that affects coastal environments and communities worldwide. Here, we examine a globally recurring pattern where reported sea-cliff retreat rates since the 20th century often appear to exceed longer-term millennial-scale ('background') rates, which rarely exceed ~0.1 m/yr. Focusing on Israel's 30-km-long Mediterranean 'Sharon' sea-cliff as a case study we demonstrate that such apparent increase in rates may also reflect a widely acknowledged sampling bias in geologic rate estimates inferred from observation time windows (T_{obs}) shorter than process episodicity. We show that this possible bias leads to an ambiguity in conventional rate estimates obtained by averaging observed retreat distances over T_{obs} , and that as a result despite ubiquitous and robust observations of cliff retreat since the 20th century (e.g., aerial photographs) recent/current retreat rates for many of the world's episodically retreating sea cliffs remain effectively unknown. To address this limitation in our current ability to detect and quantify recent changes in sea-cliff retreat rates we use a sediment-budget approach that builds on repeat LiDAR surveys to measure the continuous wave-driven volumetric erosion of collapsed material from the cliff base as an effective upper-bound constraint for the m/yr rate of episodic retreat of the cliff itself. We find that while conventional m/yr rate estimates for retreat of the Sharon sea-cliff since the 20th reach values of up to several m/yr the LiDAR-constrained retreat rates for the same period are comparable to the cliff's background retreat rate of 0.03-0.07 m/yr since the mid Holocene and thus indicate no recent acceleration in retreat. This new ability to unambiguously constrain sea-cliff retreat rates through annual-decadal scale measurements of the coastal sediment budget directly impacts the global-scale push to quantify, better understand and ultimately predict the response of sea cliff erosion and retreat to recent/projected changes in environmental conditions such as sea-level, climate, near-shore ocean dynamics and anthropogenic influences.

Sea-cliff retreat rates inferred from annual-decadal observations of cliff-top retreat are artefactually high because retreat episodicity has a time-scale of several hundred years. Instead, we use repeat airborne LiDAR to measure the continuous wave scouring of talus material from the cliff-base

as a rate limiting process for episodic retreat of the cliff itself above. LiDAR measurements demonstrate that current/recent sea cliff erosion continues at background rates while rates inferred from conventional measurements of recent cliff-top retreat may erroneously suggest otherwise.

OSL and ESR thermochronometry of the Hida Range, northern Japanese Alps

Georgina King¹, Shigeru Sueoka², Sumiko Tsukamoto³, Frédéric Herman¹, Floriane Ahadi⁴, Cécile Gautheron⁴, Guillaume Delpech⁴, Takahiro Tagami⁵

¹Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland. ²Japan Atomic Energy Agency, Kyoto, Japan. ³Leibniz Institute of Applied Geophysics, Hanover, Germany. ⁴Université de Paris Sud, Paris, France. ⁵Kyoto University, Kyoto, Japan

Abstract

Optically stimulated luminescence (OSL) and electron spin resonance (ESR) thermochronometry are recently developed techniques that can constrain erosion histories at sub-Quaternary timescales. OSL and ESR thermochronometry determine the timing and rate at which electrons are trapped and thermally released in minerals, in response to in-situ radiation and rock cooling. Erosion histories can be inferred by translating rock cooling rates into an erosion rate using knowledge of the Earth's thermal field. In contrast to OSL which can only be applied over timescales of up to ~400 ka, ESR may be applicable over the whole Quaternary period, significantly extending the applicability of trapped-charge dating based thermochronometric methods. In this presentation, the basis of ESR and OSL thermochronometry will be outlined, before consideration of a recent application of these methods to the Hida Range, northern Japanese Alps.

Japan is one of the most tectonically active locations on Earth, situated adjacent to two triple junctions between four tectonic plates. Within this convergent zone, the Hida range is thought to have been uplifted within the last 1 to 3 Myr. OSL and ESR thermochronometry were applied to a suite of 19 bedrock samples collected from the Hida range to constrain its Quaternary evolution. Initial results show that the ESR and OSL data yield similar cooling histories, indicating rapid erosion of the Hida range over the past 100 ka. Inverting the data for erosion rates, assuming a geothermal gradient of 60 °C/km reveals a reduction in rates from ~10 mm a⁻¹ throughout MIS4, during which the most intense glaciation of the Japanese Alps occurred, to ~1-3 mm a⁻¹ over the past 20 ka. Our preliminary data indicate that erosion rates within the Hida range were higher under a cooler and wetter climate.

Advancing U-Th geochronology via distribution of gravimetric standards and matrix-free synthetic age solutions

David Richards¹, Noah McClean², Dan Condon³, Diana Sahy³, Stephen Noble³, Gideon Henderson⁴, Andrew Mason⁴, Morten Andersen⁵, Tao Li¹, Joseph Stewart¹, Laura Robinson¹

¹University of Bristol, Bristol, United Kingdom. ²University of Kansas, Lawrence, USA. ³British Geological Survey, Keyworth, United Kingdom. ⁴University of Oxford, Oxford, United Kingdom. ⁵Cardiff University, Cardiff, United Kingdom

Abstract

U-Th methods have the potential to provide the most precise and accurate age constraints for past climate, oceanographic, archaeological, geophysical change in the Quaternary. Over the past two decades, analytical precision of U-series isotope measurements has improved dramatically, largely due to the steadily increasing sensitivity of multiple-collector inductively coupled plasma mass spectrometry (MC-ICP-MS). Analytical uncertainties in U-Th dates now approach or are better than 0.1% (2σ), for instance ± 100 years for a speleothem or coral that is 130 kyr old (Cheng et al., 2013). However, the accuracy of U-series dates also depends on the accuracy of tracer calibrations, reference solutions and data reduction protocols, which has not kept pace in many laboratories. This means that dates measured in different labs, while impressively precise, may not be directly comparable. Many laboratories thoroughly report detailed methodologies and full documentation of their results for U isotope or U-Th secular-equilibrium standards, but the traceability is not optimal. Confidence in derived U-Th ages for all laboratories is undermined to varying degrees by the lack of ideal reference materials and common data reductions tools.

To address issues of inter-laboratory bias and improve the accuracy and inter-comparability of U-Th dates, we instigated NERC-funded work to provide the community with two types of solutions: (1) synthetic matrix-free U-Th age solutions, mixed from high-purity mono-isotopic solutions to mimic the isotopic composition of commonly-analyzed materials (a coral from the last interglacial, with $(^{230}\text{Th}/^{238}\text{U}) \approx 0.75$ and $\delta^{234}\text{U} \approx 100$; speleothem material from the last interglacial, with $(^{230}\text{Th}/^{238}\text{U}) \approx 1$ and $\delta^{234}\text{U} \approx 500$; a young coral, with $(^{230}\text{Th}/^{238}\text{U}) < 0.05$ and $\delta^{234}\text{U} \approx 146$). These age solutions will form the basis for a major inter-laboratory comparison and serve as international reference materials for assessing long-term reproducibility. (2) Several U-Th gravimetric standards, produced using high purity material (NBL CRM 112a U metal, Ames Th crystal bar or e-beam melted Ames Th), which can be used to calibrate the mixed U-Th tracers used in the community without having to rely on materials assumed to be in secular equilibrium. Tracers calibrated against these solutions, and therefore U-Th dates measured with these tracers, will be fully metrologically traceable.

We are pleased to report that the proposed U-Th synthetic solutions and standards are now available for distribution. We report on some of the challenges thus far and lessons learned from preliminary calibration and inter-comparison efforts. We make suggestions for the next phase of comparison, eventual dissemination of results and, most importantly, we politely request community guidance and support for widespread adoption of the solutions.

O-4038

Surface exposure dating precision: limitations and prospects

Derek Fabel, Richard Shanks

Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom

Abstract

Contradictory empirical studies have inferred that the Younger Dryas (YD) ice cap in Scotland was at its maximum extent late in the YD and conversely that Scotland was entirely deglaciated. Understanding how the abrupt YD temperature change influenced ice retreat rates relies on precise constraints on deglaciation rates. Currently the only technique for determining deglaciation ages directly from landforms left behind by retreating ice is surface exposure dating using accelerator mass spectrometry (AMS), but AMS suffers from *metrological limitations*. For ^{10}Be , the most commonly used cosmogenic nuclide, precision of 1% has been claimed in some publications but this is usually based on individual sample measurement statistics rather than the repeatability of YD equivalent 'age' standards, which usually perform at 2-3% during AMS experiments. This introduces relative uncertainties of 200-300 years which prevents resolution of chronological inconsistencies.

AMS measurement precision can be improved with operational changes but there will always be limitations associated with sputter ion sources. Here we present a state-of-the-art new technology, invented at SUERC, which has been demonstrated to be able to measure the rare radionuclides ^{14}C and ^{26}Al using positive ion mass spectrometry (PIMS). PIMS represents a step change in rare isotope metrology equivalent to the change from ^{14}C decay counting to ^{14}C -AMS. PIMS addresses current limitations of sputter ion sources in sample to sample scatter and counting statistics by using a plasma ion source to extract a large, stable positive ion beam from the sample. A patent pending process removes interferences to the measurement from the beam by simultaneously destroying molecules and converting the beam from positive to negative charge. The treated beam is free from any interferences because the isobaric interference to both ^{14}C and ^{26}Al (which are ^{14}N and ^{26}Mg) do not form negative ions. Other advantages to using Al-PIMS over Be-AMS include lower backgrounds (there is no meteoric contamination for ^{26}Al) and aluminium samples usually do not need to have carrier added, plus simpler and safer (no toxic BeO) sample preparation chemistry. A customised system has been built and used to demonstrate that the technique can surpass conventional AMS for ^{14}C measurements. This process is now being extended to ^{26}Al .

O-4039

Accuracy of U-Th age determinations on suboptimal speleothem material

John Hellstrom

The University of Melbourne, Melbourne, Australia

Abstract

U-Th dating provides precise and typically accurate timescales which now underpin much of late Quaternary geochronology. This is especially true of speleothems, which provide many important paleoenvironmental records in their own right and also increasingly allow the transfer of absolute radiometric chronology to otherwise better-understood ice and marine core records. Given this increasing importance of U-Th geochronology it is important to be able to anticipate and identify those times where it does not provide accurate results.

U-Th age determinations can be inaccurate by four means: post depositional mobility of uranium, inclusion of significant thorium at time zero, inclusion of isotopically heterogeneous thorium at time zero, or through analytical error. Despite the considerable difficulty of U-Th isotopic analyses required for dating there is very little evidence of analytical inaccuracy in the thousands of age determinations now published each year and this can be largely disregarded as a source of error. The most common source of age error is inclusion of ^{230}Th at time of sample formation which can usually be accurately corrected for using ^{232}Th as an index, at the expense of increased age uncertainty - there are several existing methods of estimating the necessary initial $^{230}\text{Th}/^{232}\text{Th}$ ratio and its uncertainty.

Recent studies have highlighted the impact of post-depositional uranium mobility in speleothems, and the difficulty of detecting it in all cases. Correction techniques have been proposed (but not well accepted) for other materials including bone and coral, but its strongly heterogeneous impact in speleothem means that affected (and suspected) samples must be discarded as no correction is possible. Strongly variable initial $^{230}\text{Th}/^{232}\text{Th}$ arises through mixing of initial Th from two or more isotopically discrete sources and is not currently (and may never be) possible to accurately correct for except by assigning sometimes prohibitively large uncertainty to the correction.

Detection of U-Th age inaccuracy if present is usually straightforward where dating density is high. This high density might take the form of closely spaced ages along a growth axis where inaccurate samples will be clearly out of sequence with their neighbours; or alternatively a single time horizon might be dated multiple times in which case most sources of inaccuracy will cause a failure of ages to replicate with respect to uncertainty. Where inaccuracy is caused by elevated but (relatively) isotopically homogeneous initial Thorium it is typically straightforward to correct for.

The effects of Uranium mobility and isotopically variable initial Th can be very similar yet must be understood in assessing the accuracy of an affected chronology. Strategies for detection and decision making regarding correction or rejection of age determinations will be presented, informed by the study of synthetic data and records from the literature.

O-4040

How far back can we date using luminescence ?

Mayank Jain¹, Jan-Pieter Buylaert^{1,2}, Marine Frouin³, Andrew Murray²

¹Center for Nuclear Technologies, Technical University of Denmark, Risø Campus, Roskilde, Denmark. ²Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, DTU Risø Campus, Roskilde, Denmark. ³Research Laboratory for Archaeology and the History of Art, School of Archaeology, University of Oxford 1-2 South Parks Road, Oxford, United Kingdom

Abstract

Luminescence dosimetry techniques are widely used for dating Quaternary deposits in a variety of geomorphological, sedimentological and archaeological contexts. Optically stimulated luminescence (OSL) from quartz has been the most commonly employed method; unfortunately the signal response to burial time saturates at around 100-150 ka (depending on the environmental dose rate), thus setting this upper age limit of the OSL technique. There is a great interest in pushing back the upper age range of the luminescence dating technique to understand sedimentary archives from the penultimate and even earlier Quaternary glacial cycles.

The last decade or so has seen several exciting new developments in this regard. New signals have been discovered in quartz which show the potential for extending the dose measurement range to greater than a kilo Gray (unit Gy = J.Kg⁻¹). These methods include thermally-transferred OSL (TT-OSL), violet stimulated luminescence (VSL) and isothermal thermoluminescence (ITL) which suggest the potential to date as far back as 1 million years. Similarly, new methods have been developed for feldspar, the other widely used chronometer, to accurately determine dose in a kGy region using different variants of signals obtained using infrared (IR) stimulation (e.g. IR stimulated luminescence and IR photoluminescence) and IR emission (e.g. IR radiofluorescence). Although, issues remain it appears that it is possible, in a great majority of circumstances, to date deposits at least as old as middle Pleistocene using feldspar, and possibly even older deposits.

In this presentation, we will report on the performance of the most promising signals and summarise the state of the art and the potential of the luminescence dating technique with regards to dating beyond the last 100 ka.

Results of AMS dating of flow cytometry-sorted pollen from two lakes in California's Sierra Nevada

Irene Tunno¹, Susan Zimmerman¹, Tom Brown¹, Christiane Hassel²

¹Lawrence Livermore National Laboratory, Livermore, USA. ²University of Indiana, Bloomington, USA

Abstract

High-resolution chronologies are crucial in paleoenvironmental studies. AMS dating is still the most used method for dating macrofossils in sediment cores. When terrestrial macrofossils are not available, pollen grains may represent the most valuable source to obtain a chronology. As previous studies demonstrated, pollen grains can be dated by AMS, but this process presents some difficulties in isolating pollen from other organic matter and obtaining enough carbon to produce a useful age. We present an improved method for extracting and isolating pollen through chemical digestion and flow cytometry sorting for AMS measurements. The cytometric sorting allows the nearly complete separation of pollen grains from other particles that cannot be eliminated during the pollen extraction and represent a potential source of contamination, such as microcharcoal. The results of AMS measurements of pollen concentrates from Mono Lake and Fallen Leaf Lake are presented. Both of the lakes are located on the eastern side of the Sierra Nevada and have pollen assemblages dominated by pine, but they have very different sediments: Fallen Leaf Lake contains homogeneous, organic- and pollen-rich sediment, while Mono Lake presents very heterogeneous sediments with volcanic ashes and calcareous-rich layers with variable pollen concentration. In addition to fossil samples, the results from modern specimens, collected along surface transects from the shore of Mono Lake to the Sierra Nevada, were used to test the possibility that pollen could be aged on the land surface. The pollen extraction followed a protocol modified from that used for palynological analysis, and the different sediment types required adjustments during the chemical treatment and showed different final pollen concentrations. At least 50,000 pollen grains were sorted and dated when possible, but this amount of pollen was not always available in the sediments starting from a standard sample of 1-2 cc of sediment. The smallest sample dated with reliable results contained ~16,000 grains and 0.042 mg C. The comparison of the results between two very different lakes contributes to understanding if and where pollen concentrates can be used to build a high-resolution chronology when terrestrial macrofossils are rare or completely absent in sediment cores.

O-4042

Tree ring dating using oxygen isotopes: a master chronology for central England

N.J. Loader¹, D. McCarroll¹, D. Miles², G.H.F. Young¹, D. Davies¹, C Ramsey²

¹Prifysgol Abertawe/Swansea University, Swansea, United Kingdom. ²Oxford University, Oxford, United Kingdom

Abstract

Traditional dendrochronology, based on matching patterns of ring width variability, works best when trees are growing under significant environmental (climatic) stress. In the UK, and elsewhere in the temperate mid-latitudes, trees generally experience less stress, so dating is more difficult and often fails. Oxygen isotopes in tree rings passively record changes in the isotopic ratios of summer precipitation, so they carry a strong common signal, which offers potential for cross-dating.

A master chronology covering the period 1200-2000CE was constructed using the oxygen isotope ratios of the latewood cellulose of oak samples from central England and the method evaluated by dating timbers of known age and historic timbers that could not be dated by conventional dendrochronology. The agreement between samples and the master chronology is exceptionally strong, allowing the dating of timbers with far fewer rings than is normally the case for conventional dendrochronology.

The isotope dating method has the potential to revolutionise dendrochronology, allowing the dating of short and invariant ring sequences from young, fast-grown trees which are commonplace throughout the historic building record and which were, until now, considered almost impossible to date.

O-4043

Applications of geomorphic features produced by extreme storm events: unraveling the seismic slip and creep components of fault slip

Thomas Rockwell, Chelsea Blanton, Allen Gontz
San Diego State University, San Diego, USA

Abstract

The southern-most San Andreas Fault in California last experienced an earthquake resulting in surface rupture in ca 1726 CE. Palaeoseismic and neotectonic studies have revealed that this section of the fault has a long-term slip rate of approximately 20 mm/yr. Creep meter, InSAR and historical data in the area suggest that this section is creeping at about 3 mm/yr. Differentiating creep and coseismic slip rates are critical in understanding palaeoseismic records and developing estimates of future slip per event. In addition, landforms such as rills and channels that are offset by creep can be used to assess mechanisms of formation of rills as their ages can be estimated by the amount of creep offset

The southern San Andreas Fault (SAF) traverses the Coachella and Imperial valleys of California. This area of California is arid and receives less than 70 mm/yr of rainfall. Major precipitation events are rare and generally relate to hurricanes or subtropical depressions that are tied to El Nino periods. Significant 1-day rainfall events in this arid region of >180 mm have been recorded. These events are capable of reactivating the landscape, developing rills and creating new channels. Two such storms, 1939 San Pedro Tropical Depression and 1858 Hurricane, have been recorded in the area. The 1939 storm, known as the Lash of St Francis, was downgraded from a category 1 storm to a depression just prior to landfall in San Pedro, CA and resulted in 180 mm of rain in 3 hours in the Coachella Valley. This was in addition to 355 mm from a series of tropical depressions earlier in the month. The 1858 Hurricane was recorded as a category 1 at landfall. No rainfall records from the Coachella Valley are available from this time period.

A Phantom 4 Pro was used to acquire high-resolution, low altitude aerial imagery of sites along the southern SAF. The < 25 m altitude resulted in sub-cm resolution imagery and was used to generate point clouds and orthophoto mosaics, which were converted into digital terrain models, hillshades and slope maps. Analysis of the imagery products resulted in the identification of two clusters of rill offset distances: 24+3 cm and 50+4 cm. Using the 3 mm/yr creep rate results in ~80 and 167 years since creation of the rills, or ca. 1939 and 1852 and almost certainly correlate to the 1939 San Pedro storm and the 1858 Hurricane.

If rill formation only occurs primarily during extreme rainfall events associated with strong El Nino conditions, then combining paleoseismic data on the timing of past earthquakes with past climate data may provide a much finer resolution to the longer-term slip history of the southern San Andreas fault.

Abstract

The December 26, 2018, Mw 4.9, Fleri earthquake, is among the largest shallow ($H=1$ km; INGV) seismic event instrumentally recorded on Mt. Etna volcano. On Dec 26 morning we started mapping surface faulting and other coseismic ground effects along the NNW-trending, right-lateral Fiandaca Fault. Heavy damage affected the localities of Fleri (Zafferana Etnea), Mazzasette, Pennisi, Fiandaca, and Santa Maria La Stella, located along the fault trace. Very shallow focal depths are typical for the damaging tectonic earthquakes on the eastern flank of Mt. Etna volcano; in particular, the Fiandaca Fault generated similar events on 07/01/1875, 8/08/1894, 07/12/1907, 07/05/1914, 03/08/1931, 19/06/1984, 19/10/1984, 25/10/1984, 11/11/1997. Surface fault slip has been also observed along at least other 4 known capable faults (Fig.1).

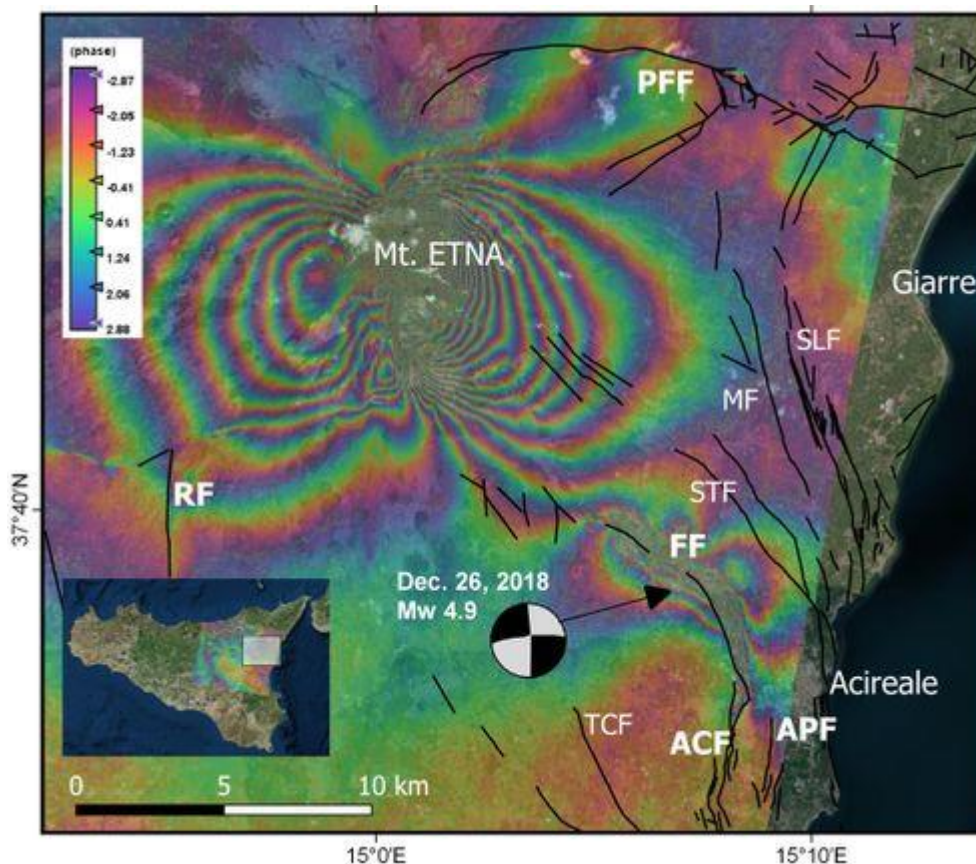

Figure 1: Surface rupture and fault creep following the Dec. 26, 2018, earthquake along the FF Fiandaca , ACF AciCatena, APF AciPlatani, RF Ragalna, PF Pernicana Faults;interferogram made with SNAP, Sentinel-1 scenes, descending, VV polarization, taken on 22 and 28/12/2018 (<http://step.esa.int/main/toolboxes/snap/>)

Along the Fiandaca Fault, we mapped continuous surface faulting throughout the entire epicentral area, for a length of about 5 km (Fig.2). We measured a belt of complex rupture segments, trending N - S, NNW - SSE, and NW – SE. In the southern section, between SantaMaria LaStella, Fiandaca, Pennisi and Mazzasette, across strike rupture width ranges between 20 and 100 m, including 3 to 8 en-echelon NNW-trending open fissures, up to 1.50 m wide and more than 3 m deep (I ESI 07 = IX). We assessed vertical displacement of 10 - 30 cm and right-lateral displacement of 2-15 cm. The northern section is affected by cracks of the same orientation but smaller opening of 3-5 cm; at SanGiovannello (Fleri), they show vertical displacement of 10-15 cm with small right-lateral components. At Monte Illice small landslides were detected too.

Figure 2: Coseismic surface rupture along the Fiandaca Fault (Domenico Bella, 26/12/2008 morning).

In the afternoon of 26/12/2018 in AciPlatani, around 14PM, we observed the inception of fault creep along the trace of the AciPlatani fault, for a length of about 700 m; creep was still in progress at the moment of writing, on 09.01.2019, with an overall normal displacement of few cm. Creep events on the AciPlatani fault are a recurring phenomenon, reported in the past for instance in 1879, 1886 and 1899.

Fault creep has been recorded also on the Fiandaca fault, especially in the southern section that affects the territory of AciCatena.

The ongoing detailed investigations will be compared with the environmental effects of the August 21, 2017, Casamicciola (Ischia Island) earthquake, providing unprecedented data for a more effective assessment of the seismic hazard in volcanic areas in Italy and abroad.

The Timing and Extent of the Last Surface Rupture Event on the Himalayan Frontal Thrust in Central Nepal around Butwal

Koji Okumura¹, Prakash Pokhrel², Soma Nath Sapkota², Hisao Kondo³, Takuya Furuhashi⁴

¹Hiroshima University, Higashihiroshima, Japan. ²Department of Mines and Geology, Kathmandu, Nepal. ³Geological Survey of Japan, AIST, Tsukuba, Japan. ⁴Taiheiyo Cement Corporation, Kochi, Japan

Abstract

The 2015 Gorkha earthquake ruptured only the deeper northern part of the thrust during the Mw 7.8 earthquake, but did not rupture the surface and shallow portion of the Himalayan Frontal Thrust (HFT) in south. Since then, the evaluation of the potential of the future surface rupture event on the HFT in central Nepal in south of 2015 rupture became an important task for paleoseismology. Mishra et al. (2016), Bollinger et al. (2016), and Wesnousky et al. (2017) proposed respective 1100 CE, 1344 CE and/or 1408 CE, and 1221 CE to 1262 CE (possibly 1255 CE) for the timing of the last surface-rupture event. Each report eliminates the timing of earthquake proposed by the other authors. Therefore, it is necessary to think over the possibility of multiple events in short (less than 100 km) segments or of misleading radiocarbon dates. Also, the existence and the east termination of 1505 CE Indian central seismic gap event (Malik et al., 2017) are not certain yet. In order to solve the rupture history and rupture extents in central and western Nepal, we excavated two trenches across the HFT around the city of Butwal. One is at 12 km west of Butwal at Sorauli (27.70°N 83.36°E) and another is at 60 km ESE of Butwal at Susto (27.48°N 83.86°E). Around the Sorauli trench site there is no clear continuous scarp along the Siwalik hill front, but ~100 m wide zone of alluvial surface adjacent to the foot of the hills tilt toward south and juxtaposed to flat alluvial surface. The boundary between the tilted surface and the flat plain is continuous and looks like the active front of a flexure scarp. The trench across a small scarp on the tilted surface did not expose any fault, but a fine sand layer was tilted towards the boundary. A Bayesian model of radiocarbon dates indicates the timing of tilting is between 1405 CE and 1467 CE. This period coincides with the 1344 CE earthquake (Bollinger et al., 2016). The Susto trench in the east of Butwal was dug into the foot of ~20 m high fault/flexure scarp below an uplifted terrace surface. In this trench also, 13° south-dipping fine sand layers appeared but the fault was below the water table and not exposed. The timing of the tilt in Susuto trench as well as results from investigation in further west in the boundary area between 1344 CE and 1505 CE event will be reported. The results will be critical to evaluate the seismic risks along HFT in central and western Nepal.

Calibration of lacustrine paleoseismological records in the Eastern Alps with historical earthquake data: potential and challenges

Christoph Daxer¹, Christa Hammerl², Maria del Puy Papi-Isaba², Michael Strasser¹, Jasper Moernaut¹

¹Institute of Geology, University of Innsbruck, Innsbruck, Austria. ²ZAMG – Central Institute for Meteorology and Geodynamics, Vienna, Austria

Abstract

In intraplate settings with moderate seismicity, recurrence intervals of strong earthquakes ($M_w > 6$) typically exceed the short time span of instrumental and historical data. In order to assess the seismic hazard in such regions, lake sediments can be used as earthquake archives: they can record strong seismic shaking as mass transport deposits (MTDs), turbidites or sediment deformations and can reach back several thousands of years. To provide information on paleo-earthquake size, however, the sedimentary imprints need to be thoroughly calibrated with independent information on seismic shaking strength.

In Carinthia (Eastern Alps, Austria), numerous lakes have experienced several devastating historical earthquakes with local intensities ranging from V-XI (EMS-98 scale), although located in an intraplate environment. Due to these events well-spaced in time (AD1348, AD1511, AD1690, AD1857 and AD1976), exceptional historical documentation and shakemaps based on a local intensity prediction equation, we can examine the relationship between seismic intensity and the type and size of sedimentary imprint in the lakes.

Eight lakes – differing in size, morphology, catchment lithology and sediment composition – were investigated by a dense grid of reflection seismic profiles (~460 km overall), numerous sediment cores (~100, up to 14 meters long) and multibeam bathymetry. Mapping of MTDs, their scarps and associated turbidites as well as accurate dating (radiocarbon and varve counting on sediment thin sections) showed that the AD1348 earthquake ($M_w \sim 7$) led to extensive slope failures in the bigger lakes. The AD1511 ($M_w \sim 6.9$) and AD1690 ($M_w \sim 6.5$) events, although reportedly exhibiting intensities comparable to those of AD1348, however, are only recorded as minor MTDs and turbidites in some of the lakes. This could be due to different reasons: 1) The recurrence interval of earthquakes with high local intensities is too short to critically recharge the slopes with sediment. 2) The real intensities at the lake sites were different than what we can reconstruct from historical records. 3) The individual events differed in frequency content, shaking duration and/or directivity.

We try to overcome these problems by comparing the traces of a single event in the different lakes and by integrating our vast lake data and historical intensity data points into a probabilistic model, narrowing down possible earthquake scenarios. In the smaller lakes, even the biggest earthquakes are only recorded as thin event deposits or lack entirely, indicating lower sensitivity to seismic shaking.

Our study shows that studying one lake, let alone one sediment core, is insufficient to reconstruct a region's seismic history. Due to the exceptional setting of Carinthia, however, we can constrain the intensity pattern and localise the most likely epicentral region and fault source of past earthquakes. In an ongoing study, we use this calibration to construct long calibrated lacustrine records for the last 14 ka.

Resolving the paradox of geomorphic and paleoseismic rupture histories on the Teton fault, Wyoming, USA

Glenn Thackray¹, Mark Zellman², Joseph Licciardi³, Darren Larsen⁴

¹Idaho State University, Pocatello, USA. ²BGC Engineering, Golden, USA. ³University of New Hampshire, Durham, USA. ⁴Occidental College, Los Angeles, USA

Abstract

Geomorphic and paleoseismic analyses produce complementary records of fault rupture history and slip rates. The two approaches yield integrated and event-specific slip rates, respectively, while providing insight into both seismic hazards and landscape evolution. These methods are ideally suited for settings such as the dramatic normal-faulted mountain front of the Teton Range in the northeastern Basin and Range Province of western North America. Moraines, outwash terraces, and alluvial fans of varying geomorphic ages comprise much of the range-front landscape and, where cut by the 70 km long Teton fault, provide opportunities to estimate the slip rate of the fault.

Fault scarps on surfaces covered by the most recent ice advances during the late Pleistocene Pinedale glaciation (terminating ~15 ka) have an average vertical separation of ~11 m, representing an average slip rate of 0.8 m/ka. Fault scarps on surfaces and features outside those latest Pleistocene ice limits, such as fan deposits and prominent high lateral moraine crests, have vertical separation up to 35 m. These large scarps suggest that the landforms are substantially older, or that they experienced higher slip rates prior to deglaciation. Because of sparse age constraints, the slip rate estimates for these features are highly uncertain.

Likewise, until recently the entire surface faulting history of the Teton fault has been characterized by a single trench, located on the southern portion of the fault. Two Holocene events, a penultimate event at ~7.9 ka and a most recent event between 4.8 to 7.0 ka, were used to estimate a Holocene offset rate that is lower (0.3–1.1 mm/yr) than the average offset rate between deglaciation (~15 ka) and 7.9 ka (1.3–2.4 mm/yr).

To address major uncertainties such as the late Pleistocene to early Holocene slip rate and paleoseismic event history we have excavated six new paleoseismic trenches, cored range front lake sediments, and performed new cosmogenic radionuclide exposure dating on previously undated surfaces, including the higher lateral moraines. The new trenches reveal evidence of multiple Holocene rupture events. Event horizons in range-front lakes suggest more frequent seismic shaking events than are revealed through trenching, suggesting that the lakes may record strong shaking events that are not associated with surface rupture or may be triggered by distal events. Together, the geomorphic, trench, and lake sediment records provide an integrated record of fault slip spanning the past 15-25 ka and details of specific event timing and slip magnitudes.

Active tectonics of the Dinarides in Slovenia - new insights from palaeoseismology

Christoph Gruetzner¹, Simone Aschenbrenner², Petra Jamšek Rupnik³, Alexander Krämer², Nour Saifelislam², Kamil Ustaszewski¹, Blaž Vičič⁴, Andrea Viscolani², Marko Vrabc⁵, Julian Welte¹, Klaus Reicherter²

¹Friedrich-Schiller-University Jena, Jena, Germany. ²RWTH Aachen University, Aachen, Germany. ³Geological Survey of Slovenia, Ljubljana, Slovenia. ⁴ICTP, Trieste, Italy. ⁵University of Ljubljana, Ljubljana, Slovenia

Abstract

The highest seismicity in the Adria-Alpine collision zone occurs at the transition between the eastern Southern Alps and the Dinarides in north-eastern Italy and western Slovenia. Thrusting on E-W striking faults prevails along the Alpine front in Italy. In Slovenia, right-lateral strike-slip faulting occurs on NW-SE trending structures. Instrumental and historical earthquakes exceeded magnitude M6 here. However, strong earthquakes are relatively rare and for most events it is not clear which fault moved. No surface ruptures are known from Slovenia. Also, little is known about the recurrence intervals of strong earthquakes on individual faults and about their relative activity. In order to better understand the active tectonics of the Alpine-Dinarides collision zone, we analyse high-resolution digital elevation models that allow detecting morphological hints for recent surface-rupturing earthquakes, and we use palaeoseismological trenching studies to reveal strong past earthquakes on the main faults in Slovenia. In this study we present first results from the Predjama and Idrija Faults, the latter of which is a possible source for the destructive 1511 Idrija Earthquake. According to macroseismic sources, the 1511 earthquake reached intensity IX MCS. Magnitude estimates range between 6.3 and ~7.0. It is still debated which fault(s) ruptured in this quake. We opened a palaeoseismological trench in the central part of the Idrija Fault. We found coarse fluvial sediments and fine-grained channel fills, which show deformation features such as vertically aligned pebbles and terminated layers. A fissure filled with material from overlying layers penetrates the channel fill sediments. We interpret these structures as evidence for recent surface faulting in a strong earthquake. At the north-western part of Predjama Fault, we encountered a small uphill-facing scarp very close to the mapped fault trace. We interpret this morphology as possibly caused by a surface rupturing earthquake and trenched across this feature. Offset Palaeogene sandstones show a vertical component of motion, but the age of this deformation is not necessarily related to young tectonics. However, changes in thickness of the youngest soil horizons may indicate Late Quaternary surface faulting at this location as well. Our study shows that surface rupturing earthquakes occurred in the recent past in Slovenia, although no evidence for surface ruptures was hitherto known from historical sources. Combined with existing data, our results indicate that a number of faults are active in a wide deformation zone in Slovenia, and that each fault has the potential to rupture in large earthquakes. However, the overall deformation in the study area is rather slow and each individual fault has a low slip-rate. Therefore, recurrence intervals of large earthquakes tend to be long. Our project is part of SPP 2017 'Mountain building processes in 4D', financed by the German Science Foundation (DFG).

Cosmogenic ^{10}Be dating in a bedrock fault scarp at the Middle Kedrovaya paleoseismic rupture zone (Baikal Mountains, Russia)

OKSANA LUNINA¹, Dewen Li², Yanwu Lyv², Youpeng Wang², Ming Li², Gao Yu², Andrei Gladkov¹, Ivan Denisenko¹, Anton Gladkov¹

¹Institute of the Earth's Crust, Siberian Branch of Russian Academy of Sciences, Irkutsk, Russian Federation. ²Key laboratory of Crustal Dynamics, Institute of Crustal Dynamics, China Earthquake Administration, Beijing, China

Abstract

The 30-km-long Middle Kedrovaya (MK) paleoseismic rupture zone, on the northwestern flank of Lake Baikal, is one of most impressive late Quaternary fault scarps in the Baikal rift. It is expressed by downhill- and uphill-facing scarps and associated troughs that are developed mainly in very coarse talus deposits composed of large blocks (*kurum* in Russian). In places, clearly seismogenic ruptures are cutting bedrock and offer some opportunities to examine the faulting history.

Using cosmogenic ^{10}Be exposure dating, we first measured the exposure ages of one of the MK scarps located at site with coordinates 54.44630° N, 108.51524° E and elevation 985 m. This ~12-m-high fault scarp is consisting of cataclasites in early Proterozoic granitoids of the Irel complex. We analyzed 12 from 18 collected samples, every 0.5 m, from 0.45 m above the bottom of the scarp dipping 55° (samples 1–6) and 45° (samples 7–12). However, only samples 1 (2.24 ± 0.56 ka), 2 (1.53 ± 0.56 ka), 3 (0.81 ± 0.57 ka), 5 (1.44 ± 0.56 ka), 6 (2.12 ± 0.64 ka), 8 (1.46 ± 0.49 ka) and 9 (1.41 ± 0.53 ka) gave results with relatively large errors, resulting from the large uncertainties of AMS measurements of Be isotopic ratios. Nevertheless, based on the oldest-age model, the relationship between the calculated ages and the relative sampling height along the scarp suggests that a recent rupture event with a vertical normal fault throw of at least 2.05 m (dip-slip is at least 2.5 m) occurred on the cliff ~2.18 ka ago (samples 1 and 6). If we take into account distance between bottom of sampled outcrop and first sample #SK28-1 the normal fault throw will be at least 2.419 m and dip-slip is at least 2.95 m.

A more concentrated age mode of about 1.46 ka (samples 2, 5, 8 and 9), which is in incorrect stratigraphic order in reference to the older ages, implies that a gravitational event happened on the studied fault surface. It is possible a younger earthquake without a significant displacement followed there or occurred on other faults in the northern part of Lake Baikal and adjacent area. The only age of 0.81 ka can be random due to denudation or lesser shocks from distal seismic events.

This work is partly supported by the National Natural Science Foundation of China (grant No. 41471002) and Russian Scientific Foundation (grant No. 19-17-00015).

Using Optically Stimulated Luminescence dating to refine the history of Late Holocene alluviation and land-use in the Severn Catchment, UK

Ben Pears¹, Tony Brown^{2,1}, Richard Jones³, Phillip Toms⁴

¹University of Southampton, Southampton, United Kingdom. ²Tromso Museum, UiT, Tromso, Norway. ³University of Leicester, Leicester, United Kingdom. ⁴University of Gloucestershire, Gloucester, United Kingdom

Abstract

The development and refinement of Optically Stimulated Luminescence (OSL) dating techniques now enables high-resolution chronostratigraphic modelling of alluvial deposits lacking organic content. The Severn catchment has historically been the focus of extensive fluvial geomorphological and archaeological research, with radiocarbon dating of organics in former river channels, and chemostratigraphy in mining areas. As a result, numerous alluvial sedimentary sequences remain only partially dated or totally undated, and overbank chronologies rarely extend into the later historic period.

This paper showcases the success, and ultimately the extended potential, of OSL dating within floodplains of the Severn Catchment, and how this technique can extend our understanding of historical land-use in such landscapes. Dated sedimentary sequences are presented from sites on the Severn, Wye, Teme and Warwickshire Avon. These were sampled in locations where local place-names indicate specific water behaviours in the past, providing a crucial link to settlement and land-use in the early to later medieval period, which is largely under-represented in the archaeological record.

The results of this research demonstrate that widespread alluviation occurred in the Severn Catchment in the Late Holocene. Overbank sedimentation occurred at all the sampled sites from the Iron Age to the present day, with both climatic and land-use variations playing key roles in the extent and typology of sediments. Age-depth modelling has also enabled a better understanding of catchment responses to changing population levels, land-use and tenure from the post-Roman to post-medieval periods.

Crucially, the results also demonstrate the importance of the interaction between high-resolution dated sequences and environmental information within place-names which, in combination, inform on the dynamics of both fluvial and archaeological landscapes at a number of scales from individual sites, to wider reaches and whole catchments.

A 6000-year record of mass-wasting and flooding reconstructed from sediments in the distal-glacier fed Lake Sandvinvatnet, southwest Norway.

Fanny Ekblom Johansson^{1,2}, Jostein Bakke^{1,2}, Eivind Wilhelm Nagel Støren^{1,2}

¹University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, Bergen, Norway

Abstract

The communities around and down the valley from the lake Sandvinvatnet experience increasing threat of various natural hazards as the climate of western Norway has become warmer and wetter. Both flood- and mass movements are common as well as occasionally outburst floods from the glacier Folgefonna. The last rain/snow melting flood event (October 2014), classified as a 200 years flood, led to vast erosion and destruction of property along the river Opo through the city of Odda. In total, five houses and one bridge were destroyed. The rebuilding of the riverbanks and the infrastructure did cost close to 20 mill. EUR. In addition, a smaller rockslide blocked off a road during the winter of 2017.

The aim of our study is to explore lake sediments deposited in Lake Sandvinvatnet in order to gain a long-term understanding of hazardous events during the last 6000 years. We want to answer the following questions; what was the past frequency of various natural hazards? What was the average magnitude of these past events? Further, we explore the influence of the glacier Folgefonna on the catchment processes. Of special interest in a future warmer climate is to see if the frequency and magnitude of past floods are connected to the presence of the glacier and its size in the catchment.

Lake Sandvinvatnet is a huge sediment sink for all types of sediments produced by different earth surface processes in the catchment. Our aim is to unravel these sediments and link them to various process. We have retrieved cores from the central part of the basin at 127 meters water depth during two field seasons (2016 and 2017). The main sediment core is an 8-meter long piston core. Additionally, we have retrieved several gravity cores including one taken at the same position as the main core. By correlating the uppermost sediments and its sediment properties to recent historical events, we will fingerprint the sediments and use these to identify similar events down core. This will base upon a multi-proxy approach using X-ray fluorescence (XRF), magnetic susceptibility (MS) and computed tomography (CT). The age model is mainly constructed from carbon-14 dates and lead-210 of the most recent sediments. The current bottom sample is dated to 6203 calibrated years before present.

The piston core shows large variability in sediment properties throughout most of the core. Both thick to thin and clay- to sand-sized layers are identified in addition to a lot of organic material in several of the layers. This suggests different types of hazardous events occurring with increasing frequency during the late Holocene. By using the past as a reference, we want to gain insight into future frequency and magnitude of natural hazards in the area.

O-4052

Geomorphologic and geochronological reconstruction of Holocene jökulhlaups along the Hvítá River and Gullfoss waterfall, Iceland

Greta Wells, Sheryl Luzzadder-Beach, Timothy Beach
University of Texas at Austin, Austin, USA

Abstract

Gullfoss is one of Iceland's most visited sites, a two-tiered waterfall where the Hvítá River plunges 32 meters into the 70-meter-deep Hvítárgljúfur canyon. This system is one of the most prominent lines of evidence for catastrophic glacial outburst floods that surged across southwestern Iceland in the early Holocene. As the Icelandic Ice Sheet retreated, meltwater pooled at ice margins and drained in glacial lake outburst floods (GLOFs), also known as jökulhlaups. Some of the most catastrophic floods drained from Glacial Lake Kjölur, surging south from the interior highlands to the Atlantic Ocean. These floods left behind extensive geomorphologic evidence along the modern-day course of the Hvítá, including strath terraces, cataract systems, scoured bedrock, and boulder deposits (Figure 1). The largest events reached an estimated maximum peak discharge of $300,000 \text{ m}^3 \text{ s}^{-1}$, ranking them among the largest known floods in Iceland and on Earth (Tómasson, 1993).

Yet, all our evidence for the Kjölur jökulhlaups comes from only one publication to date (Tómasson, 1993). My research employs new methods to better constrain flood timing, routing, magnitude, and recurrence interval at this underexplored site. This presentation has three main goals: 1) present new and synthesized geomorphologic field evidence; 2) outline a sampling strategy for geochronological analysis, namely cosmogenic nuclide exposure dating and sedimentological and tephrochronological analyses; and 3) discuss future flood reconstruction efforts such as hydraulic modeling.

Reconstructing flood timing and dynamics will situate the Kjölur floods within late Pleistocene and early Holocene deglaciation chronology in Iceland. These events may also serve as an analogue to contemporary GLOFs from ice-dammed lakes, which pose an increasing geohazard in Arctic and alpine regions worldwide due to rapid climate-driven glacial lake expansion. Moreover, reconstructing the Kjölur jökulhlaups will help answer the perennial geomorphologic question of the role of high-magnitude, low-frequency events in Earth surface change.

Citation: Tómasson, H., 1993. Jökulstífluð vötn á Kili og hamfarahlaup í Hvítá í Árnessýslu. Náttúrufræðingurinn 62, 77-98.

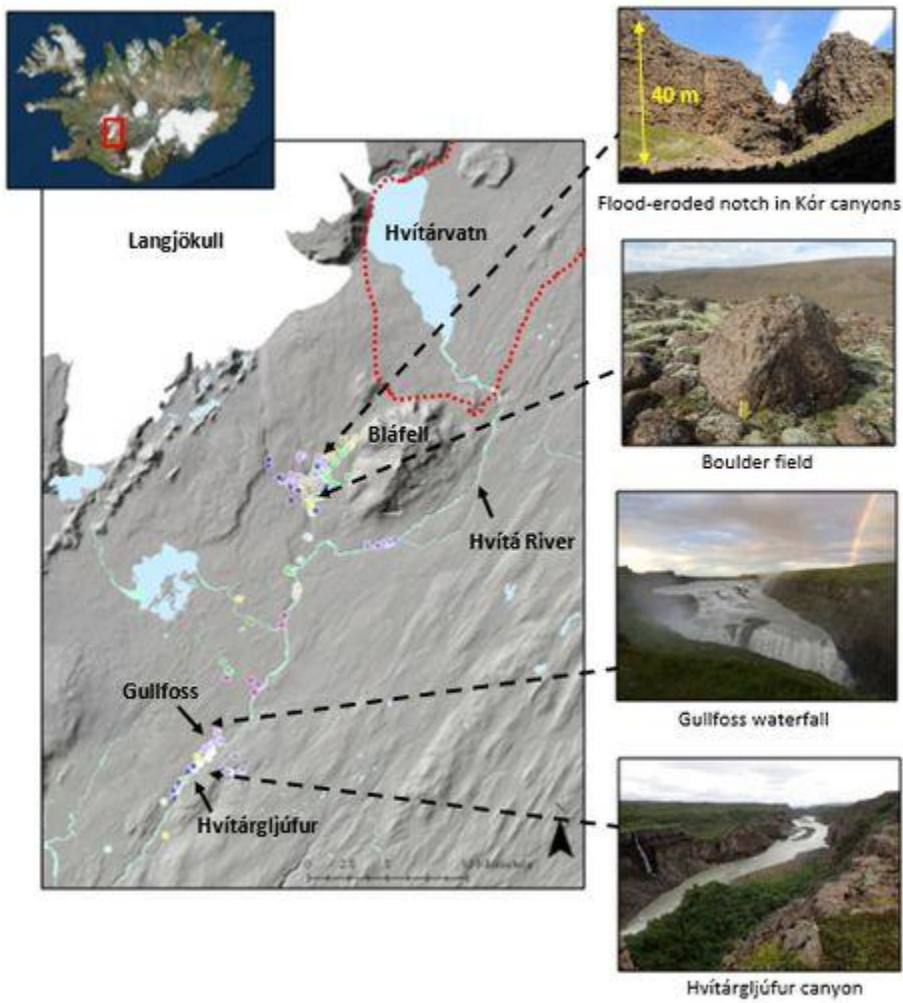

Figure 1. Study area (Arctic DEM basemap), with photos of selected Kjölur jökulhlaup geomorphologic features. Multicolored dots denote GPS points marking Kjölur jökulhlaup evidence. Red dotted line traces approximate extent of Glacial Lake Kjölur (as estimated by Tómasson, 1993).

Paleofloods records from Ladakh Himalaya

Pradeep Srivastava¹, Anil Kumar¹, Choudhurimayum Pankaj Sharma Sharma¹, Poonam Chahal², Saurabh Singhal¹, YP Sundriyal², Rajesh Agnihotri³, Robert J Wasson⁴, Alan Ziegler⁵

¹Wadia Institute of Himalayan Geology, Dehradun, India. ²HNB Garhwal University, Garhwal Srinagar, India. ³Birbal Sahnii Institute of Palaeosciences, Lucknow, India. ⁴Australian National University, Canberra, Australia. ⁵National University of Singapore, Singapore, Singapore

Abstract

The rivers draining the Himalaya support ~15% of the global population and the agricultural based economy of their catchment region largely depends on the hydrological consistency of these rivers systems. The normal monsoon floods in the Himalayan rivers act as conduit between mountain and the foreland bringing fine grained nutrient rich sediments to arable floodplains. However, the extreme floods resulting due to the excessive rainfall events, glacial and landslide dammed lake outbursts such the floods of June 2013 in Garhwal Himalaya and of August 2010 in Ladakh Himalaya destroy the economy and life that was built over the years. Whether such flood events are the result of natural climatic ramp or are the result of anthropogenic impact would only be understood if we have the longer records of past floods. Available historical and instrumental records are not sufficient to understand the trends and possible future intensity of such events, hence paleoflood archives to understand the variability is explored.

The upper Indus River flowing through the SW edge of Tibet in Ladakh and Indus Suture Zone is a part of the largest river catchment in the Himalaya. Geologically, the Indus valley is bounded by Ladakh batholith in the northeast and highly folded and thrust Indus Molasse in the southwest. Zaskar River, one of the major tributary of the Indus, increases the discharge and sediment flux of the Indus in multiple scale. Climatically, the Ladakh Himalaya is classified as cold desert, where the average annual precipitation is ~ 100 mm (at Leh) which at present is shared equally by westerlies (~ 50%). However, excess of contribution from the Indian Summer Monsoon (ISM) in the past often leads to extreme rainfall event and floods in the region e.g. August 2010, 2015 floods in Leh valley.

This study reconstructs the Late Pleistocene-Holocene history of extreme flood events in Ladakh using slack water deposits sequences comprised of sand-silt-clay couplet along the Indus and Zaskar river system. Chronology based on twelve ¹⁴C AMS and thirty optically stimulated luminescence dating of charcoal and sand samples, respectively, suggest four major clusters of flood events occurring between ~16-4 ka that override the phases of strengthened monsoon. U-Pb chronology of Zircons used for provenance fingerprinting indicated that the flood of Indus and Zaskar rivers originated in the deglaciated regions of the catchment. This suggested the potential role of glacial lake outbursts and/or landslide lake outbursts in compounding flood magnitudes. Further, the flood sequences were noticed comprising burnt layers (hearth) and dung cake at places indicating the flood occurrences vis-à-vis human migration into the Ladakh region.

O-4054

Are the kettle-holes of Piława–Płytnica sandur (NW Poland) of the glacier flood origin?

Joanna Ewa Szafraniec

University of Silesia in Katowice, Katowice, Poland

Abstract

Studies on the origin of the kettle-holes within Pomerania outwash plains mainly indicate their relationship with the melting of buried fragments of glacial ice during the deglaciation at the end of the Pleistocene: 1) they conserved the subglacial tunnels under fluvioglacial sediments, 2) they could have remained after the ice-core melting within the frontal moraine, 3) they could be fields of the stretched glacier tongue after the active phase of the glacier surge. The aim of the analysis was to investigate the hypothesis about the glacial flood origin of kettle-holes based on the morphometry of landforms. Selected morphometric indices were also compared to the landforms within Skeiðarársandur (S Iceland) created after the melting of ice blocks detached from the glacier front during jökulhlaup.

The research used data from the digitization of topographic maps (171 landforms) and ALS data (39 Pomeranian and 1792 Icelandic). Closed Depressions and Analytical Hillshading options (SAGA GIS 2.3.2), densed contour lines and hypsometric tints methods were used to isolate the kettle-holes. The volume, maximum and mean depth were calculated using the Surfer 12, the remaining parameters – in QGIS 2.18 and spreadsheet.

The Piława–Płytnica sandur in the roof layer (~2 m) consists of unstructured gravel-sand sediments with boulders forming two fans with a southern exposure of almost (0.1°–0.2°) flat surface varied by the remains of ‘washed out’ older frontal moraines. Kettle-holes within the distal part have an average area and an average mean depth more than twice smaller than the landforms in northern part of the study area – considered to be a marginal melting basin covered with fluvioglacial deposits. Depressions within fans show a greater degree of rounding; the compactness coefficient is 1.50 (similar to the Icelandic landforms), while those in the northern part – 2.05. The ratio of mean depth to diameter/width is on average 0.035, while in the northern part – 0.092, and so as in the case of subglacial valleys (0.090). The feature that connects the kettle-holes of Piława–Płytnica outwash plain and Skeiðarársandur (despite the size differences) is the volume model constituting a 1/5–1/4 volume of spheroid with axes corresponding to the maximum depth and the diameter. This model does not work for the northern landforms.

This morphometric analysis indicates the genetic diversity of the kettle-holes. Smaller ones within the Piława–Płytnica sandur can originate from the melting of ice blocks floated during the glacier flood. This is indicated by their morphometric similarity to the Icelandic landforms of flood origin and the unstructured deposits as well as the presence of ‘washed out’ fragments of frontal moraines. The settlement of this issue may be the dating of sediments, indicating the period of forming the depressions.

Imprint of recent Glacial Lake Outburst Floods (GLOFs) in Baker fjord sediments (Chile, 48 °S)

Elke Vandekerkhove¹, Sébastien Bertrand¹, Brian Reid², Krystyna M. Saunders³, Malin Kylander⁴, Silvio Pantoja⁵
¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium. ²Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Universidad Austral de Chile, Coyhaique, Chile. ³Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia. ⁴Department of Geological Sciences, Stockholm University, Stockholm, Sweden. ⁵Department of Oceanography and COPAS Sur-Austral, University of Concepción, Concepción, Chile

Abstract

Glacial Lake Outburst Floods (GLOFs) constitute a major threat in glacier-covered regions. These catastrophic events occur when a lake dammed by a glacier or moraine suddenly empties, resulting in abrupt flooding. This issue is particularly pronounced in the Baker region (47 – 48 °S) of Patagonia, where 21 GLOFs have been documented in the last decade. During such events, the Baker River, which drains most of the eastern side of the Northern Patagonian Icefield, triples in discharge and suspended sediment concentrations increase by more than one order of magnitude. The recent occurrence and the vast impact of these large-scale events on the Baker River raises the question of how these events are recorded in Baker fjord sediments. The goal of this project is therefore to understand how GLOFs are registered in Baker fjord sediments, in order to reconstruct their occurrence in the past, i.e., when river discharge was not monitored. To do so, the bathymetry of the prodelta region of Baker fjord was mapped at high resolution and a total of ten sediment cores were collected. The sediment cores were described, photographed, and scanned at 2 mm resolution on a Geotek MSCL for magnetic susceptibility, gamma density, and spectrophotometry. Additionally, XRF scanning was performed at 2 mm resolution. A core chronology was established on the most promising core using ²¹⁰Pb concentrations. Results show that the subaquatic delta in Baker fjord is deeply incised with well-developed sinuous channels (maximum depth of 26 m). The most prominent channel has an average width of 140 m and extends up to 8 km in Baker fjord. The morphology of the channels and the occurrence of sediment waves within the axial channels imply recent sediment transport by turbidity currents. The sediment cores, which display at least seven turbidites in a time span of 46 ± 7 years, confirm the occurrence of active turbidity currents. Although several potential triggering processes are plausible for the occurrence of dense underflows in Baker fjord and detailed monitoring of the subaquatic delta is required to pinpoint the exact triggering process(es), we believe that elevated river discharge during GLOFs is the main cause of the turbidite currents within the fjord. Although seasonal increases in river discharge due to snowmelt may trigger turbidity currents, it is more likely that the turbidites observed in the deepest sediment cores represent large-scale turbidity currents triggered by GLOFs. The lower number of turbidites in the sediment cores compared to the number of recent GLOF events however suggests that only the largest GLOFs are recorded as turbidites. This study demonstrates that GLOFs might be of key importance in shaping the fjord's morphology, and that their occurrence in the past may be reconstructed using turbidite stratigraphy.

Abstract

The lateral mobility of the Rhine River during the Holocene and its consequence on the distribution of settlements since the Neolithic period remained poorly understood in the Upper Rhine Plain at the French-German border. This interdisciplinary study, bringing together geoscientists and archaeologists from the Universities of Strasbourg and Freiburg-im-Breisgau, focuses on the Holocene floodplain reach comprised between Strasbourg and Lauterbourg (Drusenheim/Rheinmünster and Seltz/Rastatt). Within our study area, characterized by anastomosing and meandering channels before the Rhine was regulated in the 19th c., we investigate the Rhine River mobility on a long-term perspective and its consequence on the preservation of ancient settlements.

The reconstruction of the evolution of the Holocene alluvial landscape is based on (1) a synthesis of historical and archaeological data, (2) the analysis of high-resolution LiDAR data and ancient maps (18th and 19th c.), and (3) the study of 30 new sedimentary cores drilled across the Holocene alluvial plain. The analysis of the cores brings together geomorphologists, palaeoenvironmentalists, geochronologists and archaeologists in order to (i) reconstruct lateral instability of the Rhine channels and changes of fluvial regime over time, (ii) to trace the changes in sediment origin and (iii) to produce a reliable chronological framework using different dating methods (IRSL-screening, OSL, ¹⁴C) as well as archaeological and historical data. Ultimately, this reconstruction of the evolution of the alluvial plain of the Rhine is integrated into a wider palaeoclimatic context and we establish an evolutionary model of the strategy of settlement location adopted by the riverine communities since the Neolithic.

How much did the Black Death affect regional scale vegetation composition in southern Sweden?

Anne Birgitte Nielsen

Department of Geology, Lund University, Lund, Sweden

Abstract

The plague pandemic known as the Black Death reached Sweden in AD 1350 and led to a large decline in the human population size. It has been shown in many local scale pollen studies from smaller sites, that this decline was followed by a decrease in land use, especially crop cultivation, and local reforestation. These changes have locally been seen to have an impact on lake catchment erosion and nutrient transport, and the land-use decline has even been suggested to have an impact on the nutrient input and oxygen levels in the Baltic Sea.

However, not all small sites show a strong land-use decline at this time, and upscaling from local studies to a wider regional scale is a challenge. In pollen diagrams from large lakes, the signals of land use change at this time are often rather subtle. In this study, the REVEALS model of the Landscape Reconstruction Algorithm is applied to new and pre-existing pollen assemblages from large lakes in southern Sweden from the medieval period, in order to quantify the regional scale vegetation changes across the period of the Black Death. By taking account of differences in pollen productivity and dispersal between species, we get a picture of a much more open landscape in most of Southern Sweden than implied by non-arboreal pollen percentages alone. However, the magnitude of this effect varies from site to site, and through time, underlining the importance of applying models to quantify land cover composition.

For smaller sites, the largest landscape changes often seem to occur in agriculturally marginal areas. Once vegetation and land use change has been quantified, the spatial patterns in the changes are analysed to see if this pattern also holds true at a larger spatial scale, and whether the responses are related to abiotic factors such as soil type and topography.

New land cover estimates for late-Quaternary interior Alaska: implications for early human settlement

Mary Edwards^{1,2}, Mary Edwards¹, Michelle Farrell³, Jane Bunting⁴, Thierry Fonville¹, Marie-Jose Gaillard-Lemdah⁵, Shinya Sugita⁶

¹School of Geography and Environmental Science, University of Southampton, Southampton, United Kingdom. ²HS2 Limited, Birmingham, United Kingdom. ³Centre for Agroecology, Water and Resilience, University of Coventry, Coventry, United Kingdom. ⁴School of Environmental Sciences, University of Hull, Hull, United Kingdom. ⁵Department of Biology and Environmental Science, Linnaeus University, Kalmar, Sweden. ⁶School of Natural Sciences and Health, Tallinn University, Tallinn, Estonia

Abstract

Interior Alaska, a large region of northern boreal forest and alpine tundra, has some of the oldest early human localities in North America. The Yukon-Tanana drainage was an important corridor for eastward human migration and subsequent settlement in the late Pleistocene. The oldest archaeological sites date to 14 ka BP, which also marks the onset of major climate and vegetation change. The pollen record is well studied, but key plant taxa have greatly differing pollen productivity, which has not been quantified. Thus, views vary concerning the nature of the herbaceous vegetation mosaic that persisted under cool, dry conditions until ca 14 ka and the subsequent openness of the landscape when woody taxa increased in importance as the climate became warmer and moister. Previous studies have demonstrated regional variation in relative pollen productivity for key species across Europe. Alaska's flora has had a different Quaternary history from that of much of boreal North America, and this has probably led to genetic differentiation in many taxa. We therefore developed an independent set of pollen productivity estimates (PPEs) for Alaska prior to applying the landscape reconstruction algorithm (LRA-REVEALS) to sites in the interior. Our aim was to use a quantitative approach to evaluate the vegetation cover of the landscapes experienced by the early human inhabitants of the interior. We used vegetation surveys in the alpine zone (Denali Highway) and boreal forest (middle Tanana valley), together with pollen samples, to estimate PPEs. Notably, *Betula* PPEs obtained for tundra-shrub and forest-tree taxa differed markedly. We also obtained PPEs for *Populus* (two species, undifferentiated), a generally low pollen producer that characterizes early-Holocene pollen assemblages. In testing REVEALS on large lakes and a set of small lakes, we applied mostly tundra PPEs to samples dating to the late-Pleistocene and earliest-Holocene and mostly forest PPEs to samples dating from the establishment of *Picea*-dominated evergreen boreal forest (ca 10 ka BP and later). The main findings for the early (pre-evergreen) period were that i) *Salix* was as important, or more so, than *Betula* in the shrub component of vegetation cover, ii) grasses and sedges were as abundant as shrubs, and iii) *Populus* probably had high importance, at least locally, suggesting deciduous woodland was a significant component of the vegetation mosaic. In the later period, *Betula* was less important than its pollen values might suggest, while the reverse is the case for *Picea*, *Salix*, *Poaceae*, *Populus* and *Ericales* (Figure 1). These findings suggest that concepts of the vegetation mosaic and availability of key taxa should be revised when considering resources available to early human populations.

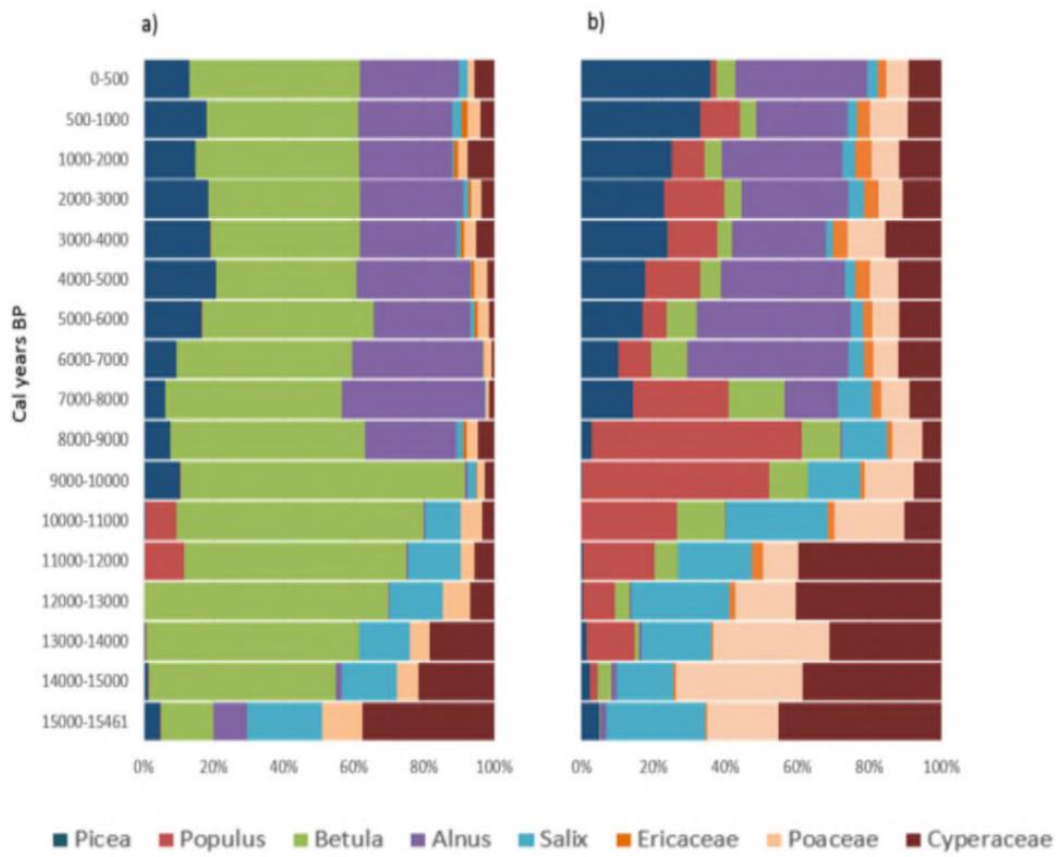

Figure 1. a) unmodified composite pollen values, interior Alaska; b) REVEALS estimates of vegetation cover using Alaska PPEs .

Abstract

Understanding the long-term dynamics of high Andean steppe and upper tree-line communities in Patagonia is a key step in designing effective conservation and management strategies for these ecosystems in the face of expected climate changes. Pollen records covering the last 1200 years, which spans several ecologically significant climate changes in the region, are available, but applying landcover reconstruction methods to pollen records from Patagonia is still a challenge because these models are not yet parameterized for these habitats. Past work has shown that there are stable pollen-vegetation cover relationships for the main plants of interest (e.g. Burry et al., 2001; Sottile et al., 2016).

This paper reports on the calibration of pollen dispersal and deposition models for the main plant types in this region, and their implications for the reconstruction of patch-scale dynamics at the upper tree line over the last 1200 years in response to known climatic drivers. A dataset of paired modern pollen surface samples and field and remote sensing vegetation data collected at multiple distance increments using a design which incorporates the wind regime of southern South America are analysed. Multivariate analysis of the pollen assemblages from the moss polster samples showed that the pollen types *Nothofagus*, Poaceae, Asteraceae subf. Asteroideae, *Empetrum*, *Gaultheria*, Apiaceae, *Azorella*, *Mulinum* and *Nassauvia* were the most important variables for separating forest and non-forest communities, and therefore for reconstructing past forest patch dynamics. Extended R-Value analysis is then used to estimate the Relative Pollen Productivity of these pollen types, using fall speed estimates based on measurement of at least 30 locally collected grains of each pollen type. Relevant Source Areas of Pollen are then explored for both moss polsters and for potential pollen record sources using both empirical and simulation approaches in order to estimate the spatial resolution possible for land cover reconstruction at this critical ecotone.

Once the appropriate dispersal model is identified and calibrated, it can be applied both in simulation to explore the sensitivity of the pollen record to patch dynamics in this landscape and directly to the reconstruction of past land cover in this sensitive and biogeographically valuable region.

⁶University of Birmingham, Birmingham, United Kingdom

Abstract

Archaeological records show that humans have long been attracted to the range of resources available in wetland ecosystems, and that a wide range of settlement and economic activities occur around the wetland-dryland interface. Wetland-dryland mosaics are highly dynamic landscapes, with the position and nature of the boundaries between different elements changing in space and time throughout the Holocene, in response to both internal dynamics (e.g. growth of raised mires) and external forcing factors (e.g. changing relative sea level). Better understanding of the natural structure and functioning of lowland wetland complexes in western Europe offers a valuable contribution to planning natural flood management against current sea level rise, to conservation of remaining wetlands across major river systems, and to the reconstruction of palaeogeographies which can help locate, interpret, and protect the archaeological record of wetland use by human societies.

Lowland wetland complexes preserve records of their evolution in complex sequences of sediments from fluvial, estuarine and terrestrial peatland ecosystems. Existing pollen data from sedimentary records can be collated and past land cover reconstructed at meso-scales using pollen dispersal and deposition models through the Multiple Scenario Approach (Bunting et al. 2018). In this presentation we will explore how MSA reconstructions can provide valuable context for analysis of archaeological data of past patterns and economics of human settlement and for exploring the ecology of past and possibly future lowland wetland landscapes.

Our case study is the Humberhead Levels (eastern England), which occupy the southern basin of a former pro-glacial lake and extend over an area of about 30x35km. Today the land cover is mostly intensive agriculture, with some protected areas centred on the remnants of heavily exploited lowland ombrotrophic mires. Historical maps and sediments underlying the fields tell a different story, showing a landscape of wetlands, marshes, water meadows, fen, wet woodland and mire, and human settlement and activity clustered on islands of higher ground. Using existing pollen records, sediment logs and other palaeoenvironmental data, the Wildscapes project is seeking to trace the dynamic history of the wetland complexes across this landscape, from their formation as rising sea level increased base levels in the Humber River around 7000 years ago, to the extensive draining and “reclaiming” works of agricultural improvement in the last centuries.

We will present reconstructions of land cover for five Holocene time windows, the late Mesolithic, mid-Neolithic, early Bronze Age, early Iron Age and Anglo-Saxon and consider the uncertainties of reconstructing palaeogeographies in these environments.

Fragments of tradition: modern pollen studies and the reconstruction of landscape management

M. Jane Bunting¹, Michelle Farrell²

¹University of Hull, Hull, United Kingdom. ²University of Coventry, Coventry, United Kingdom

Abstract

Arguments about the ecology and conservation of the habitats associated with “traditional” cultural landscape use often make assumptions about the antiquity of historically documented and surviving practices. These assumptions could potentially be tested by palaeoecological methods if the pollen signal is actually capable of recording the aspects of interest. Studying the contemporary pollen rain from remnant fragments of habitats such as nature reserves offers a means of testing the detectability of properties of these ecosystems and a framework for developing a tool kit for reconstructing their history from sedimentary records.

Because pollen is widely dispersed, and pollen grains deposited together as an assemblage could have originated from plants growing in quite a wide area around the location, studies in contemporary cultural landscapes can rarely be used as direct analogues for the past. Even if the local vegetation (e.g. within a protected area) is actually a direct analogue for past land cover, the pollen signal will include background pollen sourced from within the wider landscape, which is generally highly industrialised and greatly changed since the mid-20th century. This will affect the utility of the pollen assemblages within analogue-matching analytical frameworks such as ordination analysis to match modern and past assemblages.

Land cover reconstruction methods based on pollen dispersal and deposition models such as the Landscape Reconstruction Algorithm (LRA) and Multiple Scenario Approach (MSA) are explicitly designed to address this problem, but also require that assumptions are made about how the pollen signal forms, and are used to reconstruct the main land cover types using a sub-set of the dominant components of the pollen assemblage rather than using information from the whole assemblage.

This talk will explore a range of approaches to using modern pollen-vegetation data to build up a more objective tool kit for reconstruction of past landscapes from pollen records, mostly through use of a case study of paired pollen-vegetation data collected in surviving patches of three traditional land use types in eastern Yorkshire (UK), traditionally managed hay meadow, grazed heath, and broad-leaved woodland. Detailed vegetation data were collected around each pollen sample at a range of spatial scales following the Crackles Bequest Project method (Bunting et al. 2013), allowing application of a range of methods including ERV analysis to estimate Relative Pollen Productivity, and comparison of pollen and vegetation presence (Hjelle 1997) or biodiversity.

Abstract

Norway spruce (*Picea abies*) is a dominant keystone species in the montane coniferous forests in central Europe, with important ecological and commercial value. Natural disturbances such as wind throws and bark beetle outbreaks have caused major losses in these forests in the last few decades and are becoming more frequent and severe. Holeksa et al. (2016) created a dendroecological dataset from the High Tatra Mountains in Slovakia, which shows several large disturbance events occurred in this region over the last two centuries. Comparing dendroecological data with fossil beetle records from sedimentary archives can provide more specific information on the nature of these disturbances. Reconstructed long-term disturbance patterns can provide information for improved nature conservation and forest management, as they can make use of these natural factors of dynamics and resilience of the forest. From a forest hollow in the High Tatra Mountains in Slovakia, 12 cores were retrieved for a quantitative study on subfossil beetles (Coleoptera), covering the last 1000 years. Correlation and integration of the adjacent profiles was underpinned by repeatable down-core μ XRF geochemical stratigraphy (airfall Pb and other elements). Fossil pollen and charcoal records, obtained from a parallel core, together with the fossil Coleoptera, provide a record of past disturbances that will be compared to the disturbance events recorded in the dendroecological data. The fossil record demonstrates a diverse community of beetles, including many species of bark beetles such as the European spruce bark beetle *Ips typographus* and other saproxylic taxa characteristic of dead wood habitats. Anthropogenic influences, coming from a distant village, are clearly visible in this record as well. Changes in the forest beetle community over the last 1000 years and their relation to disturbance events in the High Tatra Mountains in Slovakia are discussed.

Quantitative vegetation reconstruction in the Neotropics: Opportunities, Problems and Progress

Bronwen Whitney¹, M Jane Bunting²

¹Northumbria University Newcastle, Newcastle-Upon-Tyne, United Kingdom. ²University of Hull, Hull, United Kingdom

Abstract

Analysis of fossil pollen in lake and peat sediments is the fundamental means by which past terrestrial vegetation is reconstructed. Developments in quantitative methods, linking plant abundance to the production and deposition of pollen in sediment archives, have allowed for vegetation reconstructions at a multitude of scales to answer questions of past climate and anthropogenic forcing of land cover change. Efforts in quantitative vegetation reconstructions, however, have been largely restricted to temperate ecosystems in Europe, Asia and North America, where there is a greater abundance of modern pollen-plant data for model calibration and detailed pollen taxonomies to link pollen morphotypes to specific groups of plant species.

Quantitative methods are particularly underdeveloped in the Neotropics, where some of the most pressing questions of past human-environment interactions and past climate-vegetation dynamics prevail. This presentation demonstrates the extensive opportunities for quantitative vegetation reconstructions in the Neotropics, and summarises the inroads that have been made, and problems encountered, in developing quantitative reconstruction methods for these ecosystems. We conclude that to achieve workable reconstruction models for the Neotropics, the problem needs to be approached from the ground up, rather than a blanket application of existing techniques, coupled with community-wide engagement to create, calibrate and test methods for this diverse and understudied region of the globe.

A strengthened East Asian Summer Monsoon during Pliocene warm periods: geological evidence and modelling results

Shiling Yang^{1,2,3}, Zhongli Ding¹, Xiaofang Huang¹, Dabang Jiang⁴

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China. ³College of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, China. ⁴Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

Abstract

The Pliocene epoch (5.3–2.6 Ma) is the most recent geological interval in which atmospheric CO₂ levels were similar to those of the present day (~400 ppmv). This epoch is therefore considered to be the best ancient analog for predicting a future anthropogenic greenhouse world. In order to determine the response of the East Asian Summer Monsoon (EASM) rainbelt during Pliocene warm periods, a 71.9 m-thick aeolian ‘red clay’ sequence at Pianguan was investigated. Magnetostratigraphic data, constrained by lithostratigraphy, show that the polarity zones of the ‘red clay’ section correlate with those between subchrons C2An.2r and C3An.2n of the geomagnetic polarity time scale (GPTS), yielding an age range of 6.9–2.9 Ma. The ‘red clay’ deposits exhibit enhanced weathering intensity over two time intervals, namely 5.23–4.3 Ma and 3.7–2.9 Ma, as evidenced by their well-developed pedogenic characteristics, as well as their high free to total Fe₂O₃ ratios and high redness (a*) values, which in turn indicate an increased summer monsoon intensity during most of the Pliocene. The Pliocene soils at Pianguan show a pedogenic development similar to the S₅ soil unit (~0.5 Ma) at Luochuan in the central Plateau, which is located some 3.7° latitude south of Pianguan, but this development is much stronger than that observed at Yulin in the north, and weaker than that seen at Lantian in the south. This may imply a more northwesterly penetration (~200 km) of the monsoon rainbelt during the Pliocene warm periods compared with the Pleistocene interglacial period (~0.5 Ma ago).

Using the output of the Pliocene Model Intercomparison Project Phase 1 (PlioMIP1), we analyzed the northern edge of the EASM during the mid-Pliocene warm period (~3.3–3.0 Ma). The results show a ~150 km northwestward migration of the northern edge of the EASM during the mid-Pliocene compared to the pre-industrial period, which is consistent with that derived from the comparison of pedogenic characteristics between the Pliocene and Pleistocene soils. Our results strongly support the prediction that the EASM rainbelt shifts northward in a warmer world. In addition, it is inferred that Pliocene warmth was unlikely to have been characterized by a permanent El Niño-like state, but was possibly influenced by a La Niña-like state.

Vegetation and climate transition from late Pliocene to early Pleistocene at Nihewan Basin, north of China

Yuecong Li¹, Guoqiang Ding¹, Yong Wang², Zhenqing Chi², Xiaolan Yang³

¹Hebei Normal University, Shijiazhuang, China. ²Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China. ³Institute of Geography Sciences, Hebei Academy of Science, Shijiazhuang, China

Abstract

Nihewan Basin has been regarded as one of the Early Pleistocene standard strata in northern China, but it is lack for high-resolution environmental changes studies. In this paper, 265 samples for NHA cores (17520~13860cm, 2.92-2.33Ma) in the Nihewan Basin were used for high-resolution pollen analysis. The results showed that there are 3 transition events and the biggest transition event for vegetation and climate occurred at about 2.83Ma, when the *Pinus* pollen content was usually more than 30% and *Picea* were less than 20%, and the deciduous broad-leaved trees had the highest percentage with maximum 37%, some subtropical pollen types such as evergreen *Quercus*, *Carya*, *Melia* can be recorded, indicating that vegetation were dominated by broad-leaved forest mixed with pine and the climate was warm and humid. After 2.83 to 2.71Ma BP, the pollen content of *Picea*, *Artemisia* and Chenopodiaceae increased significantly, with the maximum reaching to 90% for *Picea* and 80% for *Artemisia* and Chenopodiaceae; on the contrary, the pollen content of *Pinus* and broad leaved trees significantly reduced to lower than 10% and 5% separately; which indicates that the regional vegetation became pruce forest or steppe and climate tended to become chilly and dry. From 2.66~2.57 Ma, it was the second transition for vegetation and climate, when the pollen assemblages were dominated by high percentages of *Picea* (more than 80%) once again, other pollen types are very rare, suggesting the vegetation become pruce forest once again and the climate become much colder. From 2.47~2.33Ma, it was the third transition for vegetation and climate, when the pollen assemblages are characterized by high percentages of *Picea* (more than 40%), *Artemisia* and Chenopodiaceae (more than 20%), however there were some deciduous broad-leaved trees can be recorded, suggesting that the regional vegetation in the study area were dominated by forest steppe or spruce forest, and though the climate was cold and dry, but the cold degree was lower than the second cold period. The climate change sequences from 2.9 to 2.3Ma in this study are comparable to the oxygen isotopes change in the deep marine in general. MIS G10, G6, G2, 104, 102, 100, 98, 96, 92, 88 and 86, which represent cold climate can be recognized.

¹Research group for Terrestrial Palaeoclimates, Max Planck Institute for Chemistry, Mainz, Germany. ²Instituto de Geociências e Ciências Exatas, Universidade Estadual Paulista, Rio Claro, Brazil. ³Department of Climate Geochemistry, Max Planck Institute for Chemistry, Mainz, Germany. ⁴Institute of Geological Sciences K. Satpaeva, Ministry of Education and Science of Kazakhstan, Almaty, Kazakhstan

Abstract

Continuous terrestrial records of palaeoclimate over long timescales extending to the Pliocene are rare, and still more so in transition zones between major climatic subsystems such as Central Asia. Charyn Canyon, located in the Ili Basin of southeast Kazakhstan, provides one such archive. Its location straddles the polar front to the north, the Asian monsoon systems to the south and the mid-latitude westerlies. The Charyn sedimentary succession is an 80-m thick exposure of alternating fluvial, alluvial, and loess deposits. Loess thickness increases upwards, suggesting a long-term trend of aridification in this part of Central Asia.

Here we provide high resolution palaeoenvironmental change over the late Cenozoic, which spans ca. 4-2 Ma based on coupled palaeomagnetic and U-Pb datings. Magnetic susceptibility data provide additional chronostratigraphic information. Stable oxygen and carbon isotopes, including clumped isotope analysis of pedogenic carbonate nodules, are used to reconstruct quantitative palaeoclimatic parameters and variability down the sequence. Our combined proxy data approach in the Charyn Canyon sequence enables us to better understand climate system dynamics in arid Central Asia during the late Cenozoic.

The Plio-Pleistocene transition in the continental sequences of south Western Siberia

Vladimir Zykin, Valentina Zykina

Sobolev Institute of Geology and Mineralogy Siberian Branch Russian Academy of Sciences, , Novosibirsk, Russian Federation

Abstract

The Plio-Pleistocene deposits of south Western Siberia (south West Siberian plain and Altai Mountains) are unique archives containing substantial information on the environmental and climatic evolution of this vast territory. The Early Pliocene is characterized by a relatively stable continental sedimentation under river, lake and subaerial conditions. At that time, a sufficiently well-developed, little entrenched drainage system with northward runoff existed at absolute heights considerably higher than the low water level of the modern rivers oriented toward the high ocean level. The soils in the south of the plain were formed under a high level of ground-water according to the type of vertisols. The mammalian fauna corresponds to that of the Ruscinian of the Western Europe. The fresh-water mollusca fauna is characterized by the wide distribution of thermophilic Indo-Chinese and West Siberian endemic genera of East Asiatic origin. The climate that time was relatively stable, temperately warm. At the boundary of Early and Late Pliocene, about 3.2 Ma, the climate in the southern West Siberia became considerably colder and, probably, drier. The result was a radically restructured biota. Nearly all thermophilic species of fresh-water mollusca (10 genera) became extinct. The malacofauna acquired the Palaeartic character. The Ruscinian fauna of mammals was replaced by the Villafranchian fauna with no vole-toothed hamsters. The presence of the relict thermophilic species in malacofauna from 3.2 to 2.6 Ma suggests the climate of that time to be warmer than that of the present day. Those events coincided with uplift of the Tibet, Himalaya, Tien Shan, Altai, the increase in tectonic activity in many regions. Global cooling is marked by extinction of all thermophilic elements of fresh-water mollusca occurred at about 2.6 Ma. In Northern Asia, the only one section which is well-documented paleontologically and where the Gauss-Matuyama boundary was detected is the section on the Irtysh River near Lebjazhie village. Malacofauna obtains its present image. Middle-Villafranchian mammal fauna appeared. In that time the climate became similar to that of the present day or more cool. Early Pleistocene glaciation was spread in Altai Mountains. This follows from finds of faceted boulders buried in the Bashkaus Formation. Paleomagnetic investigations revealed in the latter a wide zone of negative polarity corresponding to the Matuyama Chron in the magnetostratigraphic scale and made it possible to correlate the formation with the Lower Pleistocene. The 2.1 Ma global warming is marked by the emergence of the thermophilic Middle Asian elements among West Siberian malacofauna. Colling at the beginning of Pleistocene about 1.8 Ma is marked by extinction of fresh-water and terrestrial malacofauna. The climate at that time is close to the present one.

Paleoceanographical changes of the Plio-Pleistocene based on marine palynology at ODP Sites 882 and 887, western and eastern North Pacific

Coralie Zorzi^{1,2}, Anne de Vernal²

¹EPHE, PSL Research University, Bordeaux, France. ²GEOTOP-UQAM, Montréal, Canada

Abstract

The growth of glaciers in Alaska during the early Pliocene is in disagreement with the hypothesis suggesting that development of permanent continental ice in the circum-North Pacific is associated to onset of the modern halocline at 2.7 Ma (cf. Haug et al., 2005). However, the paucity of paleoceanography data documenting salinity in the eastern North Pacific prevents full understanding of the relationship between the halocline development and glaciers growth at regional scale. Numerical simulations have led to suggest that a strong contrast over the subarctic gyre during the Pliocene, with warm sea surface temperature (SST) in the east and cold SST in the west (Burls et al., 2017), might explain early ice extend in North America. Here again, the lack of paleoceanographic data is critical. In the view to fill this gap and to better constrain the scheme of the Plio-Pleistocene climate-ocean-ice transition in the northern North Pacific region, we investigated the dinocyst assemblages at Ocean Drilling Program (ODP) Sites 882 and 887, located in the west and east respectively.

Until 4.2 Ma, species associated with subpolar waters, *Pyxidinospis braboi*, *Filisphaera filifera* and *Impagidinium pallidum*, are reported in the western Pacific. The presence of these species contrasts with the occurrence of *Ataxiodinium zevenboomii*, *Impagidinium velorum* and *Impagidinium patulum* in the Gulf of Alaska, which are associated with warm and temperate sea surface conditions. Between 4.2 and 2.7 Ma, the species assemblages at both sites are characterized by the dominance of the cold tolerant taxon *Habibacysta tectata*, which alternates with *Impagidinium detroitense*, and suggests homogenous cooling of the Pacific subarctic gyre until 2.7 Ma. After 2.7 Ma, dinocysts assemblages suggest temperate conditions and seasonal warming at the surface due to enhanced stratification related to the existence of the modern halocline. Concomitant extinction of *Impagidinium detroitense*, which marks a major biostratigraphical limit, is reported simultaneously at both ODP Sites 882 and 887 supporting simultaneous onset of the modern halocline in the North Pacific at 2.7 Ma.

Dinocysts assemblages suggest the presence of warmer sea surface conditions in the Gulf of Alaska during the Pliocene and tend to support strong zonal contrast in the subarctic gyre prior to 4.2 Ma leading to early glaciers growth fostered by high evaporation and moisture supply in the east. However, our results also indicate a reduction of east-west gradient at 4.2 Ma, well before the development of the halocline at 2.7 Ma, which is recorded here for the first time in the Gulf of Alaska.

Iberian margin sea surface temperatures indicate a change in glacial North Atlantic circulation during the Late Pliocene-Early Pleistocene transition

Montserrat Alonso-García^{1,2}, Teresa Rodrigues^{1,2}, Emilia Salgueiro^{1,2}, Mária Padilha^{1,2}, Ana Isabel Lopes^{1,2}, Antje H. Voelker^{1,2}, Henning Kuhnert³, Ursula Röhl³, Francisco J. Sierra⁴, José Abel Flores⁴, Isabelle Gil^{1,2}, Warley Soares^{2,1}, Fátima Abrantes^{2,1}

Abstract

The transition from the Pliocene to the Pleistocene is characterized by the intensification of the Northern Hemisphere glaciation (NHG), which is part of the long term Cenozoic global cooling trend. Records from the North Atlantic show a gradual cooling in sea surface and bottom water temperature indicating a change in the mean climate state. However, most of those studies are from sites influenced by the North Atlantic current, which brings warm water from the tropics to the high latitudes. In this work, we investigate the impact of the intensification of NHG on the Iberian Margin in order to evaluate the evolution of Southwestern European climate and its linkage to North Atlantic circulation changes in the subtropical gyre.

We present a new alkenone-based sea surface temperature (SST) record from the Iberian Margin (IODP Site U1391, 37°21.5'N; 9°24.6'W, 1085 m water depth) encompassing from ~3.4 to 2.1 Ma, combined with the Ca/Ti record obtained through x-ray fluorescence (XRF) scanning of the sediments from the same site. The temperature at the Iberian Margin during the studied interval was considerably higher than at present (18°C), with maximum values of 25 °C. SST values only decreased below present values at ~2.7 Ma, when glacial periods get intensified. From 3.4 to 2.7 Ma, the amplitude of SST variability between cold and warm intervals was small (<4 °C), with oscillations following a precessional pattern. At 2.7 Ma (MIS G6) the amplitude of SST variations shows a remarkable increase, reaching ~8 °C in the subsequent climatic cycles. Temperatures during warm intervals (interglacials) were slightly colder than prior to 2.7 Ma, whereas SSTs during cold intervals (glacials) became much colder than prior to 2.7 Ma. The periodicity of SST oscillations during the Early Pleistocene interval follows obliquity, which indicates that after 2.7 Ma the Iberian Margin climate was coupled to the obliquity-driven ice volume oscillations, whereas before 2.7 Ma it was more controlled by low-latitude mechanisms. The Ca/Ti record shows a similar pattern to the SST reconstruction supporting our SST interpretations. A comparison of our Iberian Margin reconstruction with the alkenone-based SST records from the North Atlantic (Site 982 in subpolar region and Site U1313/607 at mid-latitudes), and the Mediterranean and Tropical stacks led us to propose a change in North Atlantic circulation in the subtropical gyre during glacial periods after 2.7 Ma. This change in oceanographic conditions is probably linked to the equatorward shift of the climatic belts and the contraction of the Hadley cell circulation triggered by the glacial intensification in the Northern Hemisphere.

Stable isotopic composition of large mammal skeletal remains from South and Central Europe: implications for Pliocene/Early Pleistocene paleoclimate

János Kovács^{1,2}, Péter Szabó^{1,2}, László Kocsis³, Torsten Vennemann⁴, Gábor Újvári^{5,6}

¹Department of Geology and Meteorology, University of Pécs, Pécs, Hungary. ²Environmental Analytical and Geoanalytical Research Group, Szentágotthai Research Centre, University of Pécs, Pécs, Hungary. ³Geology Group, Universiti Brunei Darussalam, Darussalam, Brunei Darussalam. ⁴Institute of Earth Sciences, University of Lausanne, Lausanne, Switzerland. ⁵Department of Lithospheric Research, University of Vienna, Vienna, Austria. ⁶Institute for Geological and Geochemical Research, Research Centre for Astronomy and Earth Sciences, Hungarian Academy of Sciences, Budapest, Hungary

Abstract

Stable isotope compositions of skeletal apatite of herbivorous mammals are outstanding archives of paleoecological, paleoenvironmental and paleoclimate conditions. Stable carbon isotopes in apatite reflect the $^{13}\text{C}/^{12}\text{C}$ ratios of plants consumed by the herbivores, thereby providing information about the photosynthetic pathway (C_3 or C_4) and the openness of vegetation or precipitation amount. Stable oxygen isotope composition of apatite depends on that of the ingested water. The $\delta^{18}\text{O}$ value of ingested water is usually very close to that of local precipitation, while the oxygen isotope composition of rainwater reflects regional mean annual temperature. Tooth enamel of large, obligate drinking herbivores is thought to be the best archives because enamel is the most resistant tissue to diagenetic alteration and these mammals track the average $\delta^{18}\text{O}$ value of environmental water most closely.

This study is aimed at reconstructing temporal changes and spatial distribution of the oxygen isotope composition of precipitation ($\delta^{18}\text{O}_{\text{ppt}}$) during the Pliocene and Early Pleistocene in South and Central Europe. These reconstructions are based on measured $\delta^{18}\text{O}_{\text{PO}_4}$ values of mammal teeth. Temporal changes and spatial distribution in vegetation and/or humidity are derived from measured enamel $\delta^{13}\text{C}$ values. To achieve these goals, multiple stable isotope measurements were performed on teeth enamel samples of large mammals, and published data from the literature were also used to extend the spatial range of reconstructions. Most of the fossils belong to *Rhinocerotidae* (about 50% of the samples), *Bovidae*, *Cervidae*, *Gomphotheridae* and *Equidae* families, while few samples are from other families.

All of the $\delta^{13}\text{C}$ values obtained in this study indicate C_3 -plant dominated ecosystems and these values follow spatial aridity gradients and /or changing openness of the vegetation. The measured $\delta^{18}\text{O}$ values depend on many factors in each region, but these are in general higher for the Early Pliocene, and lower in Late Pliocene – Early Pleistocene samples. The spatial distribution of $\delta^{18}\text{O}$ values resembles those of the present day, both in Early Pliocene and Late Pliocene – Early Pleistocene. (Note, however, that we could compare only three regions for the Early Pliocene.) The calculated $\delta^{18}\text{O}_{\text{ppt}}$ values for the MN14-15 biozones are similar to the modern $\delta^{18}\text{O}_{\text{ppt}}$ values, while they are lower compared to the MN16 and MN17 biozones.

The project has been supported by the European Union, co-financed by the European Social Fund: EFOP-3.6.1.-16-2016-00004 and the National Research, Development and Innovation Fund: NKFI K120213, and the Swiss SCIEX program Nr. 13.083.

Oscillating climatic/oceanographic conditions during Heinrich Events inferred from foraminiferal data from the Porcupine Bank slope

Sabrina J. Renken¹, Torsten Bickert^{2,3}, Henning Kuhnert³, Jeroen Groeneveld², Robin J. Edwards¹

¹Trinity College Dublin, Dublin, Ireland. ²University of Bremen, Bremen, Germany. ³MARUM, Bremen, Germany

Abstract

Sediment cores taken from the lower slope (>2700 m water depth) of the Porcupine Bank, eastern North Atlantic, contain abundant evidence of ice-rafted debris (IRD) which has been used as an indicator of ice sheet behaviour during the last glacial period. Located at the interface between the North Atlantic and the western Irish shelf, these cores are ideally positioned to examine the behaviour of the former British-Irish Ice Sheet (BIIS) and its relationship to wider circum-North Atlantic ice sheet change. Heinrich layers are expressed within the core sediments as distinct grey bands of high magnetic susceptibility and are readily distinguishable from the more numerous IRD layers linked to proximal sources such as the BIIS.

We identify four IRD layers linked to Heinrich Events (HE) H1, H2, H4 and H5 and use foraminiferal census data and Mg/Ca palaeothermometry to explore the changing oceanographic / climatic conditions at the Porcupine Bank across these HE. Whilst the dominance of *N. pachyderma* indicates all HE are characterised by cold conditions, a small but significant proportion of warm water species are present in the assemblage, forming distinct double peaks during H2 and H4. Sea surface temperatures (SST) derived by transfer functions and Mg/Ca_{*G. bulloides*} palaeothermometry indicates brief warm intervals of up to 10°C and 14°C during H2 and H4 respectively.

One working hypothesis is that the appearance of warm water species and elevated SST within Heinrich layers along the Porcupine Bank is linked to intrusions of warmer water masses from the south during phases of weakened Atlantic Meridional Overturning Circulation. We conclude by briefly outline ongoing work to test this scenario.

Abstract

The cause of a rapid change in Atlantic Ocean circulation and northern cooling at the onset of Heinrich Stadial 1 18.5 ka is unclear. Previous studies have simulated the event using ice sheet and/or iceberg meltwater forcing, but these idealised freshwater fluxes have been unrealistically large. Here, we use a different approach, driving a high-resolution drainage network model with a recent time-resolved global palaeo ice sheet reconstruction to generate a realistic meltwater forcing. We input this flux to the HadCM3 climate model without adjusting the timing or amplitude and find that an acceleration in northern ice sheet melting (up to 7.5 m/kyr global mean sea level rise equivalent) triggers a 20% reduction in the Atlantic Meridional Overturning Circulation (AMOC).

The result is widespread Northern Hemisphere surface cooling and enhanced seasonality, with regional surface warming and subsurface Atlantic warming. There is also weak southern Hemisphere warming. The simulated pattern of ocean circulation and climate change matches an array of palaeoclimate and ocean circulation reconstructions for the onset of Heinrich Stadial 1, both in terms of rates and magnitude of change. This is achieved with a meltwater flux that matches constraints on sea level changes and ice sheet evolution around 19-18 ka, and suggests that a much more modest AMOC reduction could drive the climate event than previously thought. Furthermore, the results provide the basis for a chain of events to link the recorded climate and ocean circulation changes with ice sheet evolution (the main trigger) and enhanced iceberg calving (a possible feedback).

Since the rates of melting used here are similar to those projected for Greenland by 2200, constraining the melt rates and magnitude of climate change during Heinrich Stadial 1 would provide an important test of climate model sensitivity to future ice sheet melt.

Abstract

Dansgaard–Oeschger and Heinrich events constitute ones of the most enigmatic features of the last glacial period. Many studies have focused on their characteristic millennial climate variability, testing atmosphere-cryosphere-ocean couplings, but major uncertainties and discrepancies still remain. A new scenario, mainly supported by dinocyst-derived paleoreconstructions and freshwater hosing experiments, has recently emerged. Reconciling most of the up to now hypothesized theories, it suggests the occurrence of a regional paradoxical seesaw pattern: cold Greenland and North Atlantic phases coincide with warmer sea-surface conditions and shorter seasonal sea-ice cover durations in the Norwegian Sea, in relation to enhanced subsurface advection of warm Atlantic waters re-emerging in the Norwegian Sea. Here we provide new paleoreconstructions of sea-ice dynamics in the Southern Norwegian Sea (core MD95-2009), over the 35-27 ka BP interval encompassing four interstadials-stadials (including HS3) cycles, based for the first time on the combination of biomarker IP₂₅ concentration and dinocyst-derived sea-ice cover duration. The striking correspondence, over the millennial climate shifts, between these reconstructions derived from two independent proxies, further provides robust evidence for the occurrence of this atypical hydrographical pattern. Reversely, the strong variability of the three PIP₂₅ signals (calculated by combining IP₂₅ concentration with either triene, brassicasterol, or dinosterol concentration), between each other as well as relatively to our two other independent indicators of sea-ice dynamics, highlights the need to better constrain this semi-quantitative proxy of seasonal sea-ice.

Abstract

An open and mostly sea-ice free North Atlantic Ocean acts as a major heat source for the atmosphere during winter. During stadials, winter sea-ice extended as far south as 45-50° N. The loss of the oceanic heat source led to severe winter cooling. However, it remains unclear whether and (if so) how these cold ocean states during stadials should lead to cold European summers as suggested by most but not all proxy studies.

Here we present new results from high-resolution (~100 km) global climate simulations of the late deglaciation conducted with the Community Earth System Model (CESM1) for different (inter-)stadials within the period ~15 ka BP to 9 ka BP. We study how different cold/warm ocean states caused by Atlantic Meridional Overturning Circulation (AMOC) instabilities influence the European summer climate under different orbital/solar and greenhouse gas forcing.

Our simulations show that atmospheric/orographic blocking of westerly flow over the Fennoscandian Ice Sheet (FIS) is a dominant factor during the summer season during all periods of the deglaciation. With a diameter of several thousand km and elevations of more than 2-3 km, FIS acts as a fluid dynamical barrier which enforces a diversion of westerly flow and anticyclonic rotation of the wind field over FIS due to Coriolis forcing. Sensitivity simulations suggest that the blocking by FIS is enhanced by cold ocean conditions through an extended high-pressure build-up while increasing solar insolation leads to a weakening of the blocking.

As a result of blocked westerly winds by FIS, stadial summers show little or no cooling relative to the preceding interstadial across Europe with exception of Ireland and coastal areas of Western Europe which lay outside the blocked wind field. However, with a stronger winter Jetstream, westerly flow recovers early in September leading to strong cooling with the beginning of autumn. The dominance of westerly flow until May results in longer lasting snow cover and strong cooling during May. Stadial climates are hence dominated by a shift to extreme continentality with very short but warm summers and severe and long-lasting winters. In addition, strong ocean cooling and/or large sea-ice extend lead to significant reductions in evaporation over the North Atlantic resulting in a strong decrease in precipitation during stadials as supported by biomarker palaeohydrological proxy data.

Taking the extreme continentality during stadials into account, we reconstructed chironomid-based mean July air temperatures for southern Sweden with different regional European and Russian training sets. We find that July

temperatures inferred from the most continental of the Russian training sets yield considerably warmer stadial summers with values close to the thermal limits of climate indicator plant species (plant macrofossils) which show little or no stadial summer cooling for most sites.

¹UiT – The Arctic University of Norway, Tromsø, Norway. ²University of Cambridge, Cambridge, United Kingdom.

³Beni-Suef University, Beni-Suef, Egypt

Abstract

The western Svalbard margin represents a key area to reconstruct the inflow of Atlantic water into the Arctic Ocean. The piston core HH15-1525PC was retrieved at Vestnesa Ridge, northwestern Svalbard at a water depth of 1273 m. The core covers the time interval from the Marine Isotopic Stage (MIS) 5/4 transition to the late Holocene. The species composition of benthic foraminiferal faunas and the geochemical signature (Mg/Ca) of selected species have been studied to reconstruct past variations in bottom water temperature. The benthic foraminiferal assemblage composition show clear variations in relation to millennial-scale climate oscillations such as Heinrich stadials, when species with an affinity to warmer Atlantic waters dominate, and Dansgaard-Oeschger interstadials, when cold-water species become more abundant. Quantitative temperature estimations have been performed via Mg/Ca analyses in parallel to the faunal studies to confirm the observed trends on foraminiferal assemblage evolution. Moreover, in selected intervals different Mg/Ca analytical techniques and cleaning methods have been implemented to obtain more accurate temperature estimates. This is the first continuous sedimentary record in Vestnesa Ridge covering the last 80 ka, making these results valuable not only for the reconstruction of changes in Atlantic water inflow in relation to past climate change, but also to investigate the ongoing mechanisms on the seabed during abrupt climate oscillations.

O-4076

Heinrich events in the North Pacific Ocean

George Swann

University of Nottingham, Nottingham, United Kingdom

Abstract

Previous research has suggested that the subarctic North Pacific Ocean and North Atlantic Ocean were closely coupled during the last glacial (Kiefer et al., 2001; Praetorius and Mix, 2014). However, less is known about the extent to which Heinrich events are associated with corresponding changes in the North Pacific region. Whilst cores from the coastal north-east Pacific Ocean reveals increases in glacial discharge during Heinrich events (Cosma and Hendy, 2008; Hendy and Cosma, 2008), it remains unclear to what extent this water was transported to and impacted the open waters of the North Pacific Ocean and surrounding gyres.

Recent work, using diatom $\delta^{18}\text{O}$ analyses ($\delta^{18}\text{O}_{\text{diatom}}$), has documented declines in $\delta^{18}\text{O}_{\text{diatom}}$ within the open waters of the north-east Pacific Ocean over the last 50 ka that are broadly synchronous with Heinrichs events in the North Atlantic Ocean (Maier et al., 2018). Here, this work is extended to show that that these large decreases in $\delta^{18}\text{O}_{\text{diatom}}$ occurred throughout the last glacial, providing further evidence that Heinrich events were concordant with the export of significant volumes of glacial discharge from the Cordilleran Ice Sheet (CIS) into the open waters of North Pacific Ocean.

Sea-ice derived from transfer functions based on planktonic foraminifera: are such reconstructions meaningful? A test over the last 50 ka

Frédérique Eynaud¹, Mélanie Wary^{2,1}, Linda Rossignol¹, Sébastien Zaragosi¹

¹EPOC (Environnements & Paléoenvironnements Océaniques et Continentaux) laboratory -UMR 5805, Bordeaux University, Bordeaux, France. ²Institute of Environmental Science and Technology (ICTA) Universitat Autònoma de Barcelona Edifici Z· Carrer de les Columnes Campus de la UAB · 08193 Bellaterra Barcelona · Catalonia, Barcelona, Spain

Abstract

Planktonic foraminifera (PF) constitute key material for paleoceanographers for who they are, since nearly one century, basic tools for stratigraphical and hydrographical reconstructions. Recently, paralleling an effort of diversification of the PF tool, its modern calibration and accuracy were reconsidered and challenged. Apart from geochemical considerations on their tests, major questions were raised regarding values of fossil assemblages to decipher basin-wide hydrological past changes since complex patterns of habitats are known for PF populations (depending on seasonality, water depth...). Working on the basis of high latitude assemblages are, for instance, often hampered by their monospecific diversity.

In this context, approaches relying on the compilation of modern eco-biogeographical databases, derived from the analysis of recently fossilized populations in the topmost oceanic sediment layers, provide comprehensive sets which have considerably improved our bioclimatic knowledges on PF. These modern sedimentary spectra, analysed for their contents/ relative abundances in PF, offer the advantage of integrating regional taphonomic processes, and can furthermore be statistically tested and exploited to provide proxies of oceanic conditions, as done for instance with transfer functions *sensu lato*.

Here we test the robustness of the Modern Analog Technique to reconstruct past sea-ice cover with PF, focusing on the Northern North Atlantic Ocean, thanks to a training set of $n=1007$ modern analogs for which new extractions on oceanic parameters from the NOAA atlas have been obtained. Through a few key archives covering the last 50 thousand years, we will document the coherency of the results obtained on sea-ice evolution at millennial scales in comparison to other tools providing past sea-ice cover reconstructions. The conducted test is especially fruitful and rich of learnings for Heinrich events, underlining clearly the robustness of PF assemblages to provide accurate paleohydrographical contexts, in spite of strong limitation due to the dominance of the polar species *Neogloboquadrina pachyderma* during those events.

O-4078

The isotopic composition of land snails from tropical Mesoamerica as a discrete indicator of land use

Ola Kwiecien¹, Sonya Bahroun¹, Jonas Lehmann¹, Sebastian Breitenbach¹, Keith Prufer²

¹Ruhr-University Bochum, Bochum, Germany. ²University of New Mexico, Albuquerque, USA

Abstract

Land snail shells are a common component of faunal assemblages found in archaeological sites. Whether representing dietary refuse or bycatch of depositional circumstances carbonate shells can provide important environmental information. Although the isotopic composition ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$) of a single land snail shell represents only a short snapshot, it is an established indicator of conditions in which the snail lived, e.g.: precipitation and temperature regime, and vegetation type (C_3/C_4 plants).

Here we present sequential isotope analyses on modern and well-dated ancient shells from a Pleistocene/Holocene archaeological site in tropical Mesoamerica (Belize). The goal of this work is twofold: first we test which species of modern gastropods is most suitable for recording precipitation and vegetation/land cover changes. Next, isotope analyses on ancient shells aim at providing environmental context for the history of human migration and occupation in southern Belize over the last ca. 12 ka.

Comparing and contrasting the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ composition of modern species from different habitats (litter, tree canopies, lower plants, limestone bedrock) with their ecological preferences revealed that the litter-feeding *Neocyclotus* (abundant in archaeological profile) responds with high fidelity to changes in the local environment. The range of $\delta^{18}\text{O}$ values from ancient *Neocyclotus* is relatively stable throughout the last 12 ka, implying little variability in local moisture. In contrast, the $\delta^{13}\text{C}$ record points to a substantial shift in snail diet (from C_3 to C_4 plants) ca. 800 years ago. Not accompanied by moisture changes, this shift, corresponding to the Late Maya proliferation period, suggests the spread of agricultural practices (e.g.: maize farming).

Further, comparison of our results with published continuous time series from the wider region (e.g. speleothems, marine and lacustrine sediments) suggest that the $\delta^{18}\text{O}$ of *Neocyclotus* shells is a valid indicator of seasonal precipitation changes.

Mid-Holocene Pollen records of vegetation and climate change in Chenyaohu Lake, the plain of the lower reaches of Yangtze River

Wei chen^{1,2}, Beibei Li³

¹CAS Key Laboratory of Economic Stratigraphy and Palaeogeography, Nanjing Institute of Geology and Palaeontology, Nanjing, China. ²Center for Excellence in Life and Palaeoenvironment, Chinese Academy of Sciences, Nanjing, China. ³Nanjing University of Information Science and Technology, Nanjing, China

Abstract

The formation and evolution of Peatland is the research focus of Global changes. It also the key carrier to the study of paleoclimate and the carbon cycle. This study will focus on the peatland in the plain of the lower reaches of Yangtze River since the middle Holocene and we hope to explore the formation and development of the peatland and their environmental controlling actors. Palynological analyses of a peat profile in the Chenyao Lake documented the vegetation history and climate change perfectly during the time of peat evolution. Since 6600 cal. aBP the evergreen and deciduous mixed broad-leaved forest dominated by *Quercus* developed in this area and the climate had turned into the warm and humid period. The peat began to develop since 5700 cal. aBP when the sediment environment changed to swamp. After 4850 cal. aBP the broad-leaved forest decreased rapidly, instead the land herbs, mainly the Poaceae, increased. In the meantime peat also disappeared. Based on the pollen vegetation was characterized by the human activities, we consider that human activities should be cause the end of peat evolution in this area meanwhile the nature environment did not changed. Our study provide a new important data and information for the researches on the relation between climate change and peatland formation and development theories in the lower reaches of the Yangtze River.

O-4081

Magnetism signals in a southern China stalagmite and paleorainfall reconstruction during MIS5

Qiong Chen, Tingwei Zhang, Xiaoqiang Yang
Sun Yat-sen University, Guangzhou, China

Abstract

Precipitation variations were suggested to exert great impact on early human migration and occupation. Southern China is a key region of early modern human evolution in China, however, there is a shortage of the precipitation data in the hominin fossil sites of southern China. So far, broad-area precipitation variations in monsoonal China have been reconstructed from speleothem stable oxygen isotope ($\delta^{18}\text{O}$) (Cheng et al., 2009, 2016), and supported by most modeling researches (Li et al., 2013). However, the challenge on the interpretation of speleothem $\delta^{18}\text{O}$ lead to them being an ongoing debate. Thus, a reliable index for high-resolution precipitation reconstruction is required in southern China.

In this study, we conduct the high-resolution environmental magnetism measurement in stalagmites from Tongnei Cave and Xinli Cave located near the hominin occupied area in southern China. Strong magnetic signals were deduced from hysteresis loops and magnetic parameters M_s and H_c . M_s was used to trace the long-term and abrupt rainfall variations in southern China during MIS 5. The M_s record demonstrates that the precipitation changed greatly during MIS 5/4 transition, with gradually increased precipitation in the period prior to 80.5 ka BP and after that a drop to precipitation anomaly. Although we cannot deduce the causal link between the sudden shift of precipitation and hominin evolution in southern China, we can, at least, infer that regional precipitation varied greatly with high frequent extremes during MIS5/4 transition in hominin occupational area in southern China.

O-4082

Investigating human-environmental interrelationships and resilience in the Zagros region during the Early Holocene period – a multi-proxy approach

Maria Rabbani

University of Reading, Reading, United Kingdom

Abstract

The important wide-scale transition from mobile hunter-gatherer to sedentary farmers in the Fertile Crescent during the Neolithic period marked the beginning of a new lifestyle, including plant and animal domestication.

Published palaeoenvironmental records for this region show a similar vegetation trend for the Late-glacial and Holocene period with oak woodland expansion experiencing a delay of about 3000 years in comparison to the Mediterranean region, despite improvements in climate occurring roughly at the same time in both regions. To explain this delay and the extent to which anthropogenic activity and climate change impacted on vegetation cover, it is vital to investigate human-environmental relationships which forms the core of this research.

Available palaeoenvironmental records for the Zagros region are sparse and some records available either have low-sampling resolution or do not cover the Neolithic period, making it difficult to compare palaeoenvironmental records with the archaeological data, and distinguish between anthropogenic and climatic factors that might have impacted on vegetation cover over time.

The aim of this three-year long research is to reconstruct the palaeoenvironmental history between ca.12,000-9000 BP, to identify changes in vegetation cover and correlate them with human activity and climate change which will help placing climatic and vegetational changes as well as human response in the Zagros region within the wider region and context during the Early Neolithic while appreciating local differences across Southwest Asia.

To produce a high-resolution palaeoenvironmental record for Lake Ganau, located in the Raniya plain in Iraq, and Hashilan wetland, which is located in the Kermanshah province of Iran, the lake cores have been subject to different analyses including pollen, non-pollen palynomorph and geochemical analyses (XRF and loss-on ignition).

This research will demonstrate how human activity and climate impacted on vegetation cover, will shed light on human-environmental relationships in the Zagros region, highlight the significance of multi-proxy records, explain the oak woodland delay in this region, and to what extent early human societies were resilient to changes in the environment and climate.

The aim of this session will be to present preliminary results gained from the Lake Ganau and Hashilan wetland cores and their interpretation which will form the framework for this much needed multi-proxy research for this region.

Abstract

Territories within the extent of the last glaciation (young-glacial areas) are among the youngest and most dynamic landscapes on Earth. During the last approximately 20 ka they have been subject to very dynamic transformations. The same time span saw the appearance of humans, and their increasing activity. Interdisciplinary studies (palaeogeographical, palaeoecological, palaeopedological and archaeological) conducted at the Paliwodzizna site (the Dobrzyń Lakeland, north-central Poland) are focused on reconstructing the interplay between landscape evolution and human existence in this geographical zone.

The evolution of the young-glacial landscape started at the end of the Weichselian Glaciation with intense geomorphological processes related to the ice-sheet recession and the formation of till plains, outwash plains, and tunnel- and river valleys. During the Late Glacial period all of these features were transformed according to climate improvement, the degradation of permafrost and dead-ice blocks, the formation of the hydrological network (river and lake systems) and the development of tundra–forest vegetation. This period was also the time of the first appearance of Late-Palaeolithic humans (the Swider Culture, “reindeer hunters”) in this area. Their settlement at the Paliwodzizna site was located in the north of the Grodno Lake tunnel valley, in the contact zone of the till plain and the Drwęca River ice-marginal valley. The period of the Eo- to Mesoholocene was dominated by biological activity in conditions of forest vegetation limiting the dynamics of relief transformation. Preferential conditions for biomass production also resulted in the lake shore zone being transformed into a eutrophic mire. Mesolithic humans occupied the same site as Palaeolithic ones, but they exploited different natural resources (e.g. wood, forest animals, fish). During the Neoholocene, humans’ agricultural activity became an important – and, with time, the main – force driving landscape transformations. At the Paliwodzizna site, deforestation since the Bronze Age (the Lusatian Culture) through the Middle Ages and up to modern times has been recorded in colluvial sediments accumulated in local surface depressions and in the edge zone of the mire. However, phases of settlement were divided by spontaneous forest succession, which is confirmed by the development of the soil cover (Brunic Arenosols, Gleysols, and Histosols).

Recurrent settlement recorded at the Paliwodzizna site attests to the fact that the diverse relief, lithological, hydrological, pedological and ecological conditions offered by the young-glacial landscape were attractive to humans in various epochs, even if their activities were completely differently directed and changed in relation to climate fluctuations and landscape evolution. Places located in contact zones between various landscape units were especially preferred for settlement.

This study was financed by the Polish National Science Centre (NCN), project no. 2016/23/B/HS3/00689.

³University of Basel, Geoecology, Department of Environmental Sciences, Basel, Switzerland. ⁴ETH Zurich, Geological Institute, Zurich, Switzerland

Abstract

Global Change has seen unprecedented environmental change putting freshwater ecosystems at risk. Anthropogenically altered biogeochemical cycles have adverse ecosystem impacts such as eutrophication, hypoxic/anoxic conditions and altered lake mixing regimes. Even though recent anoxia has been well studied, long-term records are scarce because of analytical difficulties and costs. Hence, questions about the occurrence of meromixis in the past, the processes and triggering mechanisms remain open. Here we present a quantitative ultra-high (sub-annual) resolution record of sedimentary pigments preserved in biogenic varves. Moossee is located on the Swiss Plateau, a lowland region with favorable conditions for early (Neolithic and onwards) human settlements and agriculture [1]. We show how and when meromixis/hypoxia has developed throughout the Holocene and what is the role of anthropogenic impacts (deforestation, erosion, nutrient cycling) and climate. We use hyperspectral imaging proxies (HSI), calibrated quantitative total chlorophyll for productivity and Bphe a for meromixis [2]. The core was dated using radiocarbon ages, annual lamination counts and wiggle matching approaches [3]. XRF scans were made at 1 mm resolution. Pollen samples were analyzed at high 10-year resolution for selected sections and lower resolution for the entire core.

Moossee contains a continuously varved paleoproductivity and meromixis record for the past 15,000 years. HSI data show a first increase in lake productivity at around 14,300 BP (Bölling warming), with a drop in Ti suggesting stabilization of the landscape. Productivity increases further after the onset of the Holocene, which is also reflected in Br counts. Meromixis events were observed from 7500 to 2500 BP, starting after the establishment of beech forest in the mid-Holocene (thermal optimum), interrupted by 3 periods of local anthropogenic deforestation (AP < 80%). During these deforestation phases, landscape clearance was followed by increased erosion and thus increased lake productivity. Under such conditions, with AP lower than 80% the lake was mixing annually. Strikingly, with gradual afforestation Bphe a values increase sharply, suggesting that the lake switched from holomixis to meromixis. Br and P increase as well indicating higher productivity and limited mixing. Complete mixing is attributed to high wind fetch during periods of open landscapes with reduced forest covers facilitating full mixing. We conclude that, with gradual reforestation (AP > 80%), wind fetch declined, and the lake switched from holomixis to meromixis. This cycle occurred three times during the Neolithic and/Bronze Age, lasting for 200 to 400 years each time. This unambiguously documents how millennial-old prehistoric human impact had already modified the biogeochemical cycle in the lake.

Subpolar North Atlantic circulation changes during the Younger Dryas and impacts on the cryosphere and atmosphere circulation in north-western Europe

Alice Carter-Champion^{1,2}, David J Thornalley², Ian P Matthews¹, Adrian P Palmer¹

¹Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom. ²Department of Geography, University College London, London, United Kingdom

Abstract

The Younger Dryas is a canonical example of abrupt climate change during the Last Glacial-Interglacial Transition (16-8 ka BP), involving cooling of the northern hemisphere that is thought to have been caused by weakening of the Atlantic Meridional Overturning Circulation (AMOC).

Recent studies have suggested that there may have been different phases to the Younger Dryas cold event, each having different impacts on the climate of the North Atlantic and European seaboard. For example, some studies suggest that a late Younger Dryas AMOC recovery caused retreat of sea-ice and a northward shift in the mid-latitude westerlies which altered the climate of Europe, from Iberia to Scandinavia. Further inland, there is also evidence for intra-stadial changes in hydroclimate at several sites. Other terrestrial lake and glacier records from these mid-latitudes imply that there was a late-stadial ice maxima, most notably in Scotland but with some evidence of two phases of Younger Dryas ice advance in Scandinavia. However, there are few high-resolution marine records of North Atlantic circulation change during the Younger Dryas, which are needed to test how possible changes in AMOC may have driven climatic changes in different regions of the North Atlantic seaboard.

Here, we compile and present new sea surface temperature reconstructions and records of ice-rafted detritus from the subpolar North Atlantic, with particular emphasis on a site south of Iceland (RAPiD-10-1P) and two sites of temperature and sea-ice change in the north-western Atlantic (KNR-158-4-09GC and RAPiD-40-18P). These new high-resolution marine records are directly linked through the identification of the Vedde Ash tephra isochron in combination with a radiocarbon-based Bayesian chronology but show subtly different records of oceanic change. Depending upon location, we reveal two or three distinct stages of the Younger Dryas in the marine records, which appear related to changes in the AMOC and manifest as large changes in surface conditions.

These oceanic circulation changes appear to be associated with several events recorded in the terrestrial systems within the stadial. Using these records, we explore the possible mechanisms responsible for the changes in the subpolar North Atlantic (50-70°N) that occurred during the Younger Dryas and which led to more complex behaviour than just a single cooling and AMOC weakening, followed by a gradual amelioration of sea surface temperatures into the Holocene. Moreover, with our new marine reconstructions we re-evaluate hypotheses related to the coupling of North Atlantic climate with shifts in atmospheric circulation - namely the mid-latitude westerlies - over Europe and further afield.

Abstract

The last deglaciation in the northern hemisphere featured several short climatic oscillations with the Younger Dryas (YD) as the most pronounced cold setback. Due to its abrupt and distinct onset and termination, this period provides valuable insights into climate and landscape evolution at periods of extreme change. High-resolution climate archives like annually laminated (varved) sediments are crucial to decode the rate and response of environmental variations to such rapid climate changes.

Lake Gościąg (central Poland) exhibits an iconic varved lake sediment record since it is one of the longest and best-preserved records in Europe. For re-investigation of this archive, 10 new sediment cores have been obtained along a ~120 m long N-S transect through the deepest part of the lake basin. Here, we focus on the YD/Holocene transition using a combination of high-resolution microfacies analyses, XRF element core scanning, μ -XRF mapping, stable oxygen and carbon isotope and pollen analyses.

The transition from glacial sands to fine-grained lacustrine sediments occurs at varying core depths between ~14 m and ~18 m due to undulating basin morphology. After lacustrine sedimentation commenced in the late Allerød, a slump from the southern shore disturbed the sediments during the early YD. The slump thickness decreases from ca 200 cm in the southern cores to 4 cm in the northern.

Here, we present a first continuous microfacies investigation of the YD in Lake Gościąg. The YD varves consist predominantly of diatom frustules, calcite and re-suspended material, whereas the Holocene varves feature primarily calcite and organic matter. In general, the YD shows higher interannual variability in varve deposition than the Holocene. μ -XRF mapping supports these results. Further, we present XRF element records of Ca/Ti (relative calcite precipitation), Ti (detrital influx), Mn/Fe (oxygenation) and Si/Ti (diatom bioproductivity), as well as bulk stable oxygen ($\delta^{18}\text{O}_{\text{carb}}$) and carbon ($\delta^{13}\text{C}_{\text{carb}}$ and $\delta^{13}\text{C}_{\text{org}}$) isotopes.

At the by pollen defined biostratigraphic YD/Holocene transition, the proxies show differences in the timing of their response and in their amplitudes. First changes occur in Ti ca 70 years before the biostratigraphic boundary, while the varve microfacies changed ca 50 years after the Holocene onset as the last proxy. Besides, the time interval during which each proxy shifts strongly varies from 1 varve year in the varve microfacies to 160 varve years in the Ti record. Here, we discuss causes and the differences in proxy responses and what they imply in regard to the dynamics of environmental change during a major climate warming.

This study is a contribution to the Virtual Institute of Integrated Climate and Landscape Evolution Analysis (ICLEA) of the Helmholtz Association (grant number VH-VI-415). It is further a contribution to a scientific project financed by the National Science Centre, Poland – No. UMO-2015/19/B/ST10/03039.

Abstract

The Younger Dryas (YD) cold period at the end of the Last Glacial, likely initiated by a slowdown of the Atlantic Meridional Overturning Circulation driven by freshwater input in the North Atlantic, provides a natural laboratory to study the difference in regional abrupt responses to hemispheric climate change on continental Europe.

To minimize the effect of differences in proxy response and dating uncertainties we applied the same proxy (the hydrogen isotopic composition (δD) of lipid biomarkers as a proxy for precipitation δD and aridity) on four lacustrine sediment profiles spanning a 900km transect from western to eastern Europe (Meerfelder Maar, Hämelsee, Rehweise, Trzechowskie). All lakes contain annually laminated sediments and share tephra layers, permitting a direct comparison on decadal timescales.

All sites were characterized by lower biomarker δD values during the YD compared to the Allerød and Holocene, reflecting the cooling northern hemisphere and changes in westerly storm tracks over Europe. In western Europe changes began simultaneously with the decrease of $\delta^{18}O$ values in the Greenland ice cores, i.e. the onset of Greenland Stadial 1 at around 12.846 yrs BP, whereas in eastern Europe change is diminished or absent. A second, stronger isotopic decrease was observed in all four sites and occurred simultaneously with the onset of vegetation changes (i.e. the classically defined YD) at around 12.680 yrs BP in western Europe, but a few decades earlier in eastern Europe. The magnitude of isotopic change is halved and decadal variability is less pronounced towards the east. The pronounced multi-decadal isotopic variability during the second half of the YD fades out towards eastern Europe. This suggests less severe change and more stable conditions in eastern Europe. These observations cannot be explained by a southward displacement of the westerly flow due to expanded winter sea ice cover in the Northern Atlantic alone, but require a mechanism stabilizing climate and counteracting westerly airflow in eastern Europe.

Recent high-resolution climate model data suggest strong seasonal and regional differences during the YD caused by the modulation of westerly atmospheric flow by the Scandinavian Ice Sheet (SIS). We therefore suggest that a persistent high-pressure system over the SIS and the associated reorganization of atmospheric circulation over Europe created an atmospheric blocking resulting in more resilient continental climate conditions in eastern Europe in particular during the first phase of the YD. Increasing solar/orbital forcing during the second phase of the YD led to increasingly instable blocking, expressed as a higher variability in our δD records.

Overall, our results highlight differences in the response of hydroclimate across relatively small spatial scales and emphasize the importance of atmospheric circulation changes in transmitting the effect of a hemispheric scale climate forcing abruptly to the local scale of continental Europe.

Investigating the spatial heterogeneity of abrupt cooling events during the Lateglacial Interstadial in Britain and Ireland using chironomids and oxygen-isotopes.

Christopher P. Francis¹, Ian Candy¹, Stefan Engels², Ian P. Matthews¹, Adrian P. Palmer¹

¹Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom. ²Department of Geography, Birkbeck, University of London, London, United Kingdom

Abstract

The Lateglacial Interstadial (c. 14.7-12.9kyr ago), a relatively warm period at the end of the last glaciation, provides an excellent opportunity to study past abrupt cooling events (ACEs), as it was punctuated by several centennial-scale cooling events. Such events, on the basis of their magnitude and driving factors, offer the best analogues for future ACEs triggered by anthropogenic warming. These ACEs, commonly known as GI-1d and GI-1b, are clearly expressed in the Greenland ice cores but have variable expression across Europe and the North Atlantic region. In some areas, GI-1d represents the major climatic event, in other areas GI-1b is the stronger cooling interval. This spatial diversity in ACE expression is likely to reflect the forcing factors that drive them, however, these are currently poorly understood. Only a systematic application of high-resolution proxies applied to sites over varying latitudinal and longitudinal gradients can seek to address this. Although numerous studies of the Lateglacial Interstadial exist, they are frequently generated on a site-by-site basis using various proxies at varying scales of resolution, making inter-comparison problematic. To address these research questions requires consistent application of high-resolution proxies at sites chosen for their geographical importance.

In this study, we have applied Chironomid and Oxygen-isotope analysis at a high-resolution to a number of Lateglacial Interstadial records from spatially diverse locations across the British Isles. When combined with previous studies this generates a palaeoclimatic database that allows the expression of ACEs during this time interval to be studied along both latitudinal and longitudinal gradients. Even across a relatively restricted area such as the British Isles, clear spatial patterns can be observed in ACE strength. GI-1d is at greatest intensity in the North and East of the region whilst GI-1b is most strongly expressed in the South and West. The results highlight the pivotal location of the British Isles in relation to factors driving ACEs and the conclusions allow the driving factors of these events to be discussed in greater detail.

Using chironomids to assess Lateglacial climate evolution in at Burgäschisee, Switzerland

Alexander Bolland¹, Fabian Rey^{1,2}, Willy Tinner², Oliver Heiri¹

¹Geoecology, Department of Environmental Sciences, University of Basel, Basel, Switzerland. ²Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland

Abstract

There are few chironomid-based temperature reconstructions in Central Europe extending back into the Early Lateglacial before 14,700 cal BP, and for northern Switzerland none are reliably dated. This presents a significant knowledge gap, exemplified by new pollen evidence displaying Early Lateglacial warming in the Swiss Plateau lowlands as early as 16,000 cal BP (Rey et al., 2017). Currently, the only independent temperature reconstructions available for comparison are from South of the Alps (Samartin et al. 2012). As such, the production of a well temporally constrained chironomid assemblage record for Switzerland is paramount, as it can provide new information about Early Lateglacial environment and climate evolution on the Swiss Plateau, and can be used as an independent dataset with which to corroborate the new observations of Early Lateglacial warming from pollen and macrofossil data.

Lake sediments from Burgäschisee, a small, well studied lake on the Swiss Plateau, have been sampled for chironomids. Previous work from Burgäschisee has produced a pollen record displaying a transition from tundra to shrub tundra vegetation in the Early Late glacial at 16,000 cal BP (Rey et al., 2017), prior to the onset of the Bölling warming (ca. 14,700 cal BP). Here, we present the first well dated chironomid assemblage record for the Swiss Plateau Early Lateglacial, in parallel and on a centennial scale, exploring lake and climate development throughout the period 14,000 - 18,000 cal BP. Initial results indicate that chironomid assemblages were dominated by the cold stenothermic taxa *Sergentia coracina*-type throughout the period preceding Bölling warming. Despite the persistent dominance of *S. coracina*-type, there are observed changes in the sub dominant taxa during the pre Bölling period, with cold stenotherms such as *Micropsectra radialis*-type and *Paratanytarsus austriacus*-type becoming less abundant while types indicative of relatively warmer conditions, such as *Dicrotendipes nervosus*-type, begin to occur. These changes are concurrent with the vegetational shift from tundra to shrub-tundra at 16,000 cal BP in the Burgäschisee record and are coeval with chironomid-inferred warming and pollen-inferred afforestation in the Ticino lowlands south of the Swiss Alps (Samartin et al., 2012), indicating that circum-alpine climatic warming after the end of Heinrich Event 1 was substantial enough to release major vegetation reorganizations.

Multi-decadal spring season warming precedes sudden summer temperature rise in pre-anthropogenic climate change

Margret Steinhorsdottir^{1,2}, Friederike Wagner-Cremer³

¹Swedish Museum of Natural History, Stockholm, Sweden. ²Stockholm University, Stockholm, Sweden. ³Utrecht University, Utrecht, Netherlands

Abstract

Waning annual seasonality is documented in an up to one-month advance in spring onset since the 1980's in northern latitudes, perturbing ecosystem functioning and socio-economic performance. Summer temperatures, in contrast, have been rising only recently, indicating an offset in seasonal warming. The limited time span of observational data makes this asynchronous pattern difficult to quantify, hindering projections of intra-annual dynamics. We explore temporal phase relations of seasonal warming over the Late Pleniglacial/Bølling and the Younger Dryas/Holocene climate transitions that preceded present anthropogenic warming. We determine past spring onset and thermal properties from dwarf birch paleo-phenology. Reconstructed spring warming led maximum summer warming by about a century during both transitions. Long-term reconstruction of intra-annual temperature regimes provides the perspective required for seasonal response analysis. Our results document that multi-decadal spring season warming precedes sudden summer temperature rise also during natural climate change. The rapidity of present seasonality changes, however, is unprecedented.

Investigating the environmental response to the Preboreal Oscillation through integrating multi-proxy records across Europe

Rebecca Kearney¹, Christopher Bronk Ramsey¹, Paul Albert¹, Richard Staff², Daniel Veres³, Enikő Magyar^{4,5}

¹Research Laboratory for Archaeology and the History of Art, University of Oxford, Oxford, United Kingdom. ²Scottish Universities Environmental Research Centre, University of Glasgow, Glasgow, United Kingdom. ³Institute of Speleology, Romanian Academy, Cluj-Napoca, Romania. ⁴Eötvös Lóránd University, MTA-MTM-ELTE Research Group for Paleontology, Department of Environmental and Landscape Geography, Budapest, Hungary. ⁵Isotope Climatology and Environmental Research Centre (ICER), Institute for Nuclear Research, Hungarian Academy of Science, Debrecen, Hungary

Abstract

Evidence from high-resolution, multi-proxy records over the Late Glacial to Early Holocene transition (~16-8kya) shows abrupt climatic events of centennial to decadal timescales punctuating this period. The abrupt climatic cooling perturbation termed the Preboreal Oscillation (PBO, ~11.3-11.15kya) has been widely detected across Europe, particularly through vegetation response to this abrupt cooling (Björck et al., 1997). However, there are environmental variations apparent in the timing, spatial extent and magnitude of response to the PBO in sites from across Europe.

To provide insight into these spatial and temporal environmental variations in response to the proposed PBO, the INTIMATE database has been used (<https://c14.arch.ox.ac.uk/intimate/db.php>). This chronological tool has allowed vegetation records from dated, terrestrial archives across Europe to be integrated, providing understanding of the temporal and spatial variation of the climate oscillations around this period. Each (¹⁴C) dated record has been handled on their own individual timescale and tied together through the use of known chronological relationships from tephra horizons (in particular the Hasseldalen and Askja-S tephra). In addition, the quantification of chronological uncertainties has allowed regional comparisons to be made, providing insight into the heterogeneity of the past climate. Using data directly from the INTIMATE database, together with statistical tools developed in R, has allowed the timing and environmental response of the PBO to be quantified.

Through selected case studies of multi-proxy sites spanning from western to eastern Europe, we provide insight into the possibility of spatial and temporal variations of the environmental responses to the climatic perturbation of the PBO. By using the INTIMATE database in conjunction with the proposed stratigraphic position of the Hasseldalen and Askja-S tephra bracketing the PBO (Wohlfarth et al., 2006), questions such as time transgression and regional-specific expression of this abrupt climatic oscillation can be investigated.

³Department of Water, Perth, Australia

Abstract

The isotopic composition of groundwater can be a useful indicator of rainfall isotope compositions and help to determine the drivers and impacts of rainfall and climate change. Additionally, as most large groundwater basins can contain 'old' groundwater where extraction exceeds groundwater recharge, knowledge of the past conditions and timing under which groundwater was recharged is needed to sustainably manage groundwater resources. Applying isotopic tools to groundwater contained in regional aquifer systems can provide low-resolution information on recharge intensity, recharge source and past climatic conditions for the region. Furthermore, an understanding of how groundwater recharge and climate have been connected in the past can be used to inform climate adaptation strategies for sustaining groundwater resources during climate change.

Groundwater from south-west Western Australia located at the northernmost extent of the westerly wind belt can help constrain the drivers and impacts of rainfall and climate change in this region. Large regional groundwater systems contained within the Perth Basin in south-west Western Australia were used in this study to provide information on groundwater recharge and climate over the past 35,000 years. This dataset containing groundwater ages ($^{14}\text{C}_{\text{DIC}}$) and stable isotopes of water ($\delta^{18}\text{O}$ and $\delta^2\text{H}$) from two regional groundwater systems within the Perth Basin provides a unique opportunity to produce a low-resolution palaeo-archive of groundwater recharge, and hence interpret rainfall and climate change, for south-west Western Australia. The trends in stable isotopes of water over time in the regional groundwater data are consistent with the groundwater flow line data supporting our hypothesis that groundwater stable isotopes are a proxy for palaeo-recharge. The Southern Perth Basin groundwater isotope record is interpreted to be a low resolution archive of recharge driven by changes in the relative intensity of past rainfall, moisture source from changes in the position of the westerlies and recharge thresholds. This long-term stable isotopic recharge record provides a greater understanding of groundwater palaeo-recharge, and the connection between recharge and climate in the past.

Millennial-scale variability in subtropical precipitation observed in speleothems from central eastern Queensland, Australia

Kevin Welsh¹, Nothdurft Linda¹, Gilbert Price¹, Gregory Webb², Yuexing Feng¹, Russell Drysdale³, Jian-xin Zhao¹
¹University of Queensland, Brisbane, Australia. ²University of Queensland, Brisbane, Falkland Islands (Malvinas).
³University of Melbourne, Melbourne, Australia

Abstract

Australia is the driest inhabited continent with the most spatially and temporarily variable precipitation, it is therefore vital to understand what drives precipitation regimes during periods of global climatic change. The subtropics are a particularly important area for understanding interactions between climate systems. Several studies indicate that high latitude forcing may influence precipitation in the Australian subtropics, however there are significant gaps in our understanding of the nature of this forcing owing largely to the lack of reliable, high-resolution and well-dated records of hydrological variability that span the last glacial cycle. This is because the majority of studies that have been the focus of such investigations rely upon ¹⁴C dating of lake and swamp and marine cores that are less precise than desirable during MIS3. There is also a conspicuous lack of continuous records in the northern subtropics meaning that our spatial reconstructions are limited. Here we present two overlapping stable isotope and trace element records derived from well-dated speleothems from Mt Etna, central eastern Queensland, Australia. U/ Th dating indicate that they collectively span between 46ka and the late Holocene. Mg/ Ca patterns are reproduced across both speleothems. Correlation of carbon stable isotopes and Mg/ Ca support the interpretation that these two proxies are driven by variations in rainfall at this site. These records appear to indicate millennial scale changes in relative precipitation that are coeval with the Northern Hemisphere Heinrich events. The relative rapidity of the changes in Mg/ Ca may support a response to forcing from the Northern Hemisphere rather than Southern Hemisphere in the northern subtropics, probably a change in the mean position of the ITCZ. During the LGM growth rates in both speleothems appear to decline dramatically and little calcite is precipitated which likely indicates a period of relatively low precipitation.

¹University of Adelaide, Adelaide, Australia. ²British Geological Survey, Keyworth, United Kingdom. ³University of Nottingham, Nottingham, United Kingdom. ⁴Queensland Government, Department of Environment and Science, Brisbane, Australia

Abstract

Blue Lake on North Stradbroke Island, Queensland, is a groundwater window lake of major ecological and cultural significance. North Stradbroke Island is the second largest sand island in the world. Blue Lake is unique to the island as it is the only groundwater window lake on the island, and one of the few in Eastern Australia. The lake's strong connection to the regional groundwater table and short residence time (<50 days) underpin a stable aquatic ecology which makes Blue Lake sediments an ideal tracer of subtle changes in the climate and regional environment.

Here we report a new ~7,500 year high resolution C/N and carbon isotope record from Blue Lake, which shows an abrupt shift at ~4 ka from terrestrially-dominated sources of organic matter to predominantly in-lake sources. This shift reflects a decline in rainfall on the island, as documented in a quantitative rainfall reconstruction from nearby Swallow Lagoon. This carbon isotope record is the starting point for further contemporary and palaeoclimatic research at the site.

Ongoing monitoring aims to quantify the relationship between climate, hydrology, and the isotopic composition of Blue Lake sediments. The modern process study is focused on oxygen isotope variation and will quantify the isotope hydrology of the system: from initial precipitation to uptake by plants in the lake. Using this as a foundation, we will create a high resolution palaeo-rainfall record from Blue Lake that will build on previous studies of pollen, macrophytes, and diatoms from North Stradbroke Island and eastern Australia more broadly, which suggest a mid-Holocene shift in rainfall. Quantitatively defining such a shift will enable a more thorough investigation into the impacts of climate drivers such as El Niño Southern Oscillation in eastern Australia.

Regional patterns of hydroclimate variability in southeastern Australia over the past 1200 years

Bronwyn Dixon^{1,2}, Jonathan Tyler³, Benjamin Henley², Russell Drysdale²

¹University of Reading, Reading, United Kingdom. ²University of Melbourne, Melbourne, Australia. ³University of Adelaide, Adelaide, Australia

Abstract

The Australian continent experiences extreme climatic conditions, and is at risk of these extremes intensifying in the coming decades with profound socioeconomic and environmental consequences. Therefore, it is of vital importance to understand the drivers and range of hydroclimate variability through time. The past 2,000 years is advocated as an appropriate period for establishing a baseline of recent natural climate variability. Recent work has compiled the non-annually resolved palaeoclimate records across Australasia. Eight records across southeast Australia have been identified as possessing satisfactory sampling and geochronological resolution for reconstructing multi-decadal to centennial-scale hydroclimate variability during the Common Era. This work employs a two-tiered regional Monte Carlo Empirical Orthogonal Functions (MCEOF) approach to examine the inter- and intra-site coherency of climate signals within southeast Australia. Two identified regional modes of climate variability demonstrate an increase in effective moisture between 900CE-1750CE. Agreement between regional MCEOF 1 and Australian temperature reconstructions suggests suppressed evaporation was a significant influence on regional effective moisture during this time. Regional MCEOF 2 exhibits shorter, centennial-scale oscillations that show some agreement with existing rainfall reconstructions. We interpret MCEOF2 to represent regional-scale rainfall patterns driven by rainfall seasonality and the influence of the Southern Annular Mode over southern Australian rainfall. The findings of this study suggest that although there are few records that are ideal for examining climate during the Common Era, a small subset of quality-controlled records is effective for examining hydroclimate variability in southeast Australia.

Long record of environmental change from the Bassian land bridge between mainland Australia and Tasmania spanning the last glacial period.

Feli Hopf^{1,2}, Simon Haberle^{1,2}, Georgia Roberts^{3,2}

¹Archaeology and Natural History, School of Culture, History and Language, Australian National University, Canberra, Australia. ²ARC Centre of Excellence for Australian Biodiversity and Heritage, Australian National University, Canberra, Australia. ³Indigenous Studies Centre, Monash University, Clayton, Australia

Abstract

Here we present preliminary pollen, charcoal, geochemical and sediment analyses from a record spanning at least MIS4-MIS1 from Remy Boy Lagoon, located near the coast of Ingham Island (Clarke Island) in the Furneaux Island Group, Bass Strait (40°32'32.21"S, 148°13'4.22"E). The site is located in an important region for the movement of people from mainland Australia to Tasmania via the Bass Strait land bridge which was exposed when sea levels were lower; a time when the site would also have been an inland lake ~ 70 km from the past coastline. This new record of environmental change is one of only a few long records from Tasmania and we compare our findings with other terrestrial records from southeast Australia as well as nearby marine records.

The pollen record indicates the changing dynamics of *Eucalyptus*, *Callitris* and *Allocasuarina* dominated vegetation, with expansion of herbaceous vegetation around the Last Glacial Maximum, the coolest, driest period of the record. Peak levels of macrocharcoal occur around 40 kyr BP with a phase of increased rainforest pollen prior to the LGM possibly indicating the expansion of rainforest in the wider region under a warmer/wetter glacial climate. Changes in macrophytic wetland taxa provide insight into local changes in hydroclimate.

Abstract

Continuous continental records are critical to understanding how terrestrial environments responded to the large-scale shifts between glacial and interglacial climate states, providing valuable insights into the interactions between the atmosphere, oceans, cryosphere and biosphere, and the long-term context from which to interpret current and future trends. 160m of overlapping sediment cores were collected from Darwin Crater in Tasmania, Australia. This continuous ~800 ka Pleistocene record provides new insights into glacial-interglacial climatic variability in the Southern Hemisphere. Darwin crater is a palaeolake formed by the collision of a meteorite at 816 ± 7 ka ($^{40}\text{Ar}/^{39}\text{Ar}$ dating of Darwin glass) and infilled with lake sediments throughout several glacial/interglacial climate cycles. The sediment sequence provides a continuous Pleistocene record with multi-proxy signatures of alternating cold and warm climates based on spectrophotometry, grain size, natural gamma ray, palaeo- and rock-magnetism, loss-on-ignition, and pollen analysis. Olive coarse grain sediments with high siliciclastic material and cool climate pollen taxa suggest deposits during glacial periods, while, brown-black fine grained sediments with low siliciclastic material and warm climate pollen taxa indicate interglacial deposits. Here we further investigate these climatic signatures with the use of diatoms in the lake sediment deposits. Diatoms are highly sensitive to environmental change and have shown good preservation throughout the Darwin crater core with minimal dissolution. Preliminary results suggests an aquatic ecosystem response to these glacial-interglacial climates and provide further insight into the palaeoclimate context for the Southern Hemisphere. These results contribute to an ongoing project with future investigation into the chronology and palaeoclimate history of Darwin Crater over multiple glacial-interglacial transitions in the Southern Hemisphere.

Beyond the bipolar seesaw: Unravelling the processes of interhemispheric climate coupling

Sune Olander Rasmussen¹, Guido Vettoretti¹, Joel Benjamin Pedro^{1,2}, Søren Borg Nielsen¹, Markus Jochum¹

¹Physics of Ice, Climate and Earth. Niels Bohr Institute. University of Copenhagen, Copenhagen, Denmark. ²Antarctic Climate and Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia

Abstract

The thermal bipolar ocean seesaw hypothesis was advanced by Stocker and Johnsen [2003] as the 'simplest possible thermodynamic model' to explain the time relationship between Dansgaard-Oeschger (DO) and Antarctic Isotope Maxima (AIM) events. Our intention with this presentation is to take up the challenge of moving from a conceptual toward a process-based understanding of interhemispheric coupling and the forcing of AIM events.

Following our recent critical review of the thermal seesaw [Pedro et al., 2018], we here further test the mechanisms of DO-AIM coupling using a general circulation model (GCM) that exhibits unforced DO oscillations. We present four main results:

1. Changes in Atlantic heat transport during the DO oscillations are largely compensated by opposing changes in heat transport by the global atmosphere and Pacific Ocean. This 'Bjerknes compensation' acts as a negative feedback, which is likely integral to the oscillation
2. Contrary to the prevailing view, the Southern Ocean is not a major heat reservoir during DO-AIM coupling. This is because the Antarctic Circumpolar Current strongly inhibits meridional ocean heat transport.
3. Energy budget analysis indicates that Antarctic warming during AIM events results from increasing poleward sensible heat and moisture transport following surface warming and sea ice retreat in the Southern Ocean.
4. The Antarctic sea ice retreat is itself driven by eddy-heat fluxes across the ACC, amplified by sea-ice-albedo feedbacks. We examine the sensitivity of this eddy-heat transport to seafloor topography and model resolution.

O-4099

Variability of timing and behavioral context of pottery adoption in the Japanese Archipelago.

Kazuki Morisaki

Agency for Cultural Affairs-Japan, Tokyo, Japan

Abstract

In East Asia, transition from Palaeolithic to Neolithic is characterized not by the adoption of village life incorporating farming economies, but by the behavioral change of hunter-gatherer communities from a mobile to a sedentary lifestyle.

In the Japanese archipelago, past researches advocated that hunter-gatherer lifestyle changed with climatic amelioration from the beginning of Holocene which brought warm and wet climatic conditions and stable land/marine food resources. Pottery was also invented during this period to exploit and process these newly available resources efficiently.

However, the discovery of 'ice-age pottery' in the Odai-yamamoto site in northern Japan pushed back the appearance of the earliest pottery in Japan to between 16,500 and 15 000 cal BP at the end of the Last Glacial period, critically challenging the past hypothesis. Now it is known that a small amount of 'ice age pottery' was used by mobile hunter-gatherers in various regions of the Japanese Archipelago just before the Late Glacial warm period.

On the other hand, settlements of sedentary hunter-gatherers comprising several pit-houses with the constant use of pottery suddenly appeared mostly around the Pacific coastal region of the southwestern Japan, just after the climatic warming in the early Late Glacial. This suggests that climatic amelioration did not induce the 'beginning', but prompted the 'development' of sedentary lifestyle with the use of pottery.

Since recent accumulation of archaeological data regarding emergence of pottery suggests that the timing and behavioral context of early pottery adoption in the Japanese Archipelago are variable from region to region and according to climate change, we need to assign chronological position of each archaeological site carefully on the basis of reliable radiometric dates and describe regional variation of correlation between human behavioral change, pottery adoption, and environmental change.

This presentation examines regional difference of the timing and behavioral context of pottery adoption by synchronically comparing two regions on the basis of AMS radiocarbon dating in the southwestern Japan, where plenty of archaeological data has been accumulated.

Stone tool caches and early ceramic producers in the terminal Pleistocene of Japan

Yuichi Nakazawa¹, Takashi Tsutsumi^{2,3}

¹Hokkaido University, Sapporo, Japan. ²Asama Jomon Museum, Miyota-machi, Japan. ³Meiji University Center for Obsidian and Lithic Studies, Nagawa-machi, Japan

Abstract

While spatially definitive features such as dwellings and burials are rarely found from the Pleistocene archaeological sites, stone tool caches defined as small clusters of stone tools that are spatially differentiated from lithic scatters are not particularly unique. Stone tool caches mostly consisting of combinations of bifaces, points, blades, and stone axes are also visible in the terminal Pleistocene (ca. 15,000 – 11,500 cal. BP) archaeological record in the Japanese Archipelago where moist climate and acidic sediments almost entirely prevented to preserve organic record. Despite the presence of stone tool caches in the Japanese archaeological record during the terminal Pleistocene, archaeologists have not adequately evaluated their significance and seldom provided explanations well beyond site-specific analysis. In the present paper, we discuss the variability in patterns of stone tool caches (e.g., discovered context, stone-tool components, spatial patterns, probable chronozones that caches are affiliated with) and their behavioral significance based on a comparative analysis of representative stone tool caches during the terminal Pleistocene in the Japanese Archipelago. Examples of stone tool caches are mostly from the Incipient Jomon assemblages with and without pottery, but their meanings likely vary between spectrum of being functional and symbolic. We will also discuss some pertinent issues regarding human behavioral and organizational responses to ecological diversity among regions of the Japanese Archipelago, such as changes in foraging patterns, and emergence of pottery use. It is also expected that the present study of stone tool caches in the terminal Pleistocene in Japan will illuminate behavioral and organizational variability in prehistoric hunter-gatherers beyond the regional scale.

O-4101

The paradox of pottery in the Kuril Islands

Erik Gjesfjeld

University of Cambridge, Cambridge, United Kingdom

Abstract

The Kuril Islands of Northeast Asia present one of the most difficult natural environments for the production of pottery. The coastal sub-arctic climate of the region has winter seasons that are long and cold, summer seasons that are wet and short, and limited availability of high-quality clay resources. Despite these challenging conditions, archaeological research shows initial pottery production began around 8,000 years ago but widespread use of pottery in the archipelago does not occur until over 4,000 years later. This paper will explore this apparent paradox by reviewing the evidence for pottery manufacture and use in the southern, central and northern regions of the island chain. The comparative approach taken here aims to offer insights into the role that various environmental and cultural factors have on the production of ceramics and the use of pottery vessels. Specific focus will be placed on variability in the decoration and morphological features of pottery that emerged during the Late Jomon and later periods. Preliminary evidence from ceramic analysis and organic residue analysis suggest that despite using the same raw materials, substantial differences exist in how pottery was used between various ecological zones. Finally, the pottery of the Kuril Islands will be contextualized within the broader sphere of Northeast Asian pottery traditions including Japan, the Russian Far East and Siberia. Through this comparison it will be suggested that Kuril pottery highlights many of the same features that are associated with the pottery technology of neighboring maritime foragers. These insights aim to contribute to the growing knowledge base about the emergence and long-term persistence of pottery technology within maritime hunter-gatherer communities.

Ceramic production and distribution before the Younger Dryas: Petrographic provenance research from Tanegashima Island of Japan

Fumie Iizuka^{1,2}, Masami Izuho³

¹University of California, Merced, Merced, USA. ²Tokyo Metropolitan University, Tokyo, Japan. ³Tokyo Metropolitan University, Tokyo, Japan

Abstract

The earliest ceramic vessel technologies in the world, dated to the Late Pleistocene, have been reported from East and Northeast Asia. However, the timings of adoption are debated. For example, in South China, pottery-making may have been adopted by foragers as early as the Last Glacial Maximum, or by people who consumed rice in an early form of domestication as late as the Early Holocene. In the Transbaikal, the debate lies between the Bølling/Allerød period, determined from the evidence of radiocarbon chronology, and the Early to Mid-Holocene transitions assessed from stratigraphy. Additionally, although the earliest pottery dates from the Japanese Archipelago have not commonly been debated, the Oldest Dryas and Bølling/Allerød chronological contexts require further assessment at various sites.

Nevertheless, some regions are currently more suitable than others for reconstructing human behaviors associated with pottery in the Late Pleistocene. For example, southern Kyushu of Japan is a rare place where firm dates for the Late Pleistocene origins of pottery can be determined. There, the Incipient Jomon pottery is encountered below the Satsuma Tephra, dated to 12,800 Cal BP, which coincides with the period of the Younger Dryas. In this project, we studied the Incipient Jomon pottery from southern Kyushu. We selected the Sankakuyama I site on Tanegashima Island, 40km south of the tip of the mainland Kagoshima Prefecture, and about 18km east of Yakushima Island. The Incipient Jomon pottery at Sankakuyama I is dated between ca. 14,000/13,500 to 12,800 Cal BP. Ceramics were used by foragers that also constructed pit-houses and used groundstones. We conducted petrographic analyses of ceramic thin sections. Our results support our previous results, based on a visual observation, that there are local and non-local ceramics. The ceramics include felsic intrusive materials not found as bedrock materials on Tanegashima Island today. Based on recent literature on the timing of sea level rise conducted in Kagoshima Bay which suggests that seawater entered there by 14,300 Cal BP, there is a possibility that, by around the same period, Tanegashima was disconnected from the mainland and Yakushima Island. Both Yakushima and the mainland southern Kyushu have intrusive plutonic rocks. This suggests long-distance transportation of pottery or its raw material, either by sea or land, before the Younger Dryas. Because of the firm chronology in this region, the study serves to provide among the earliest evidence for pottery production and circulation in the world.

O-4103

Final Pleistocene-Early Holocene Population Dynamics and the Emergence of Pottery on the Korean Peninsula

Jangsuk Kim¹, Chuntaek Seong²

¹Seoul National University, Seoul, Korea, Republic of. ²Kyung Hee University, Seoul, Korea, Republic of

Abstract

While located in the heartland of northeast Asia which witnessed the emergence of pottery in the final Pleistocene, the Korean Peninsula lacked comparable archaeological evidence until circa 6000 cal BCE when pottery first appeared on the peninsula much later than neighboring areas. Using radiocarbon dates as a population proxy and focusing on mobile hunter-gatherers' response to environmental changes, we attempt to provide a hypothesis for this issue.

Critical evaluation of available radiocarbon dates for the final Pleistocene and early Holocene of the Korean Peninsula suggests (1) a consistent increase in the number of sites during the Last Glacial Maximum (LGM), (2) a notable drop after the LGM and (3) an almost complete gap during the post-Pleistocene. The lack of early pottery in Korea is likely to have been associated with the paucity of the archaeological record during the post-LGM and post-Pleistocene. We hypothesize that under the harsh environmental conditions during LGM, the Korean Peninsula might have been the population refugium. But as temperature rose toward the end of the Pleistocene (between 15,000 to 9500 cal BCE), many mobile groups would have moved to the north leaving not much evidence for occupation of the peninsula, followed by a lack of occupation during the post-Pleistocene. This population change suggests that while small number of mobile groups dispersed during the final Pleistocene around the cold and dry phase of Younger Dryas, the Peninsula might have been only a seasonally visited place or even deserted during the global warming.

The lack of the archaeological evidence during the post-Pleistocene of the Korean Peninsula is followed by the appearance of pottery and boom of occupations especially along the eastern and southern coasts around 6,000 BCE. We suggest that the appearance of pottery and occupation boom are related with the so-called 8.2 k event known for recognizable drop of temperature that lasted several hundred years. To understand this relationship, we also look into population dynamics of the neighboring areas that early pottery producers had occupied between post-Pleistocene and the 8.2k event. As seen in the population fluctuation on the Korean Peninsula depending on climatic changes during the final Pleistocene and post-Pleistocene, the sudden drop of temperature associated with the 8.2k event would have led to population dispersal or reorganization on a regional scale, eventually resulting in the occupation of coasts of southern part of the peninsula by pottery producing hunter-gatherers. Although where the first pottery producers of Korea were originated from needs a further scrutiny, we suggest that the lack of pottery during the final Pleistocene and post-Pleistocene in Korea and the late appearance of pottery coincident with the 8.2k event be understood in relation with climatic fluctuations and regional-scale responses of hunter-gatherers of northeast Asia.

O-4104

The earliest pottery surrounding Mt. Nanling Region, South China

Youping Wang

School of Archaeology and Museology, Peking University, Beijing, China

Abstract

During last several decades, more early pottery remains have been found in South China, especially surrounding the Mt Nanling area. The new researches indicated that the owners of earliest pottery had occupied this region since 20000BP, as the cases in Xianrendong, Jiangxi Province, Yuchanyan, Hunan Province and Huangmenyan, Guangdong Province. They lived in caves or rock shelter within the huge karst area by the terminal Pleistocene. Together with the pottery, thousands of stone artifacts (mainly pebble tools) were found during the excavations. A large number of antler, bone tools, as well as shell knives, were also found. In addition, fireplaces and occupation surfaces were uncovered in different cultural horizons of many caves. The diversity of the finds indicates that during the terminal Pleistocene, the cave or rock shelter had been used by hunter-gatherers for a variety of activities, including base camps, stone workshops, animal butchery and etc. This paper will briefly introduce the earliest pottery and terminal Pleistocene settlement surrounding Mt. Nanling area in South China, and discuss the complex history of modern human dispersal in this region.

⁴Centro de Investigacións Científicas Avanzadas (CICA), Universidade da Coruña, Coruña, Spain. ⁵Departament de Dinàmica de la Terra i de l'Oceà, Geomodels Research Institute, Facultat de Ciències de la Terra, Universitat de Barcelona, Barcelona, Spain. ⁶Universitat de Barcelona. Dep. Earth and Ocean Dynamics, Barcelona, Spain

Abstract

Rocky and indented coasts host a large number of sedimentary features that typically develop associated with the irregular nature of these coasts, such as small perched lakes and bay-mouth or mid-bay barriers. Besides, the position of these basins relative to mean sea level and the occurrence of infilling transgressive aeolian deposits favor the preservation of valuable sedimentary archives that may contribute to reconstructing the coast evolution over the past, as well as to shed some light over changing regional wind field or storminess regimes.

Here, two examples of coastal barriers and transgressive dune fields fronting perched lakes (Traba and Doniños, Galicia, NW Iberia), are investigated to decipher the main processes controlling their evolution. For that, Ground Penetrating Radar and borehole transects were collected to characterize the sedimentary architecture of both systems. Selected samples were dated using both accelerated mass spectrometry radiocarbon and optically stimulated luminescence dating techniques.

Five dominant radar facies (Rf) and four radar surfaces (Rs) were identified within the radargrams. The identified Rf fall into two groups: (i) inclined reflections and (ii) horizontal to subhorizontal reflections. These Rf are interpreted as transgressive dunes (Rf-1), foredunes (Rf-2), channel infilling (Rf-3), scour and fill structures (Rf-4) and aeolian dune deposits with vertical aggradation or lateral accretion (Rf-5). The identified Rs are grouped into two main types: (i) erosive surfaces and (ii) boundary surfaces. Rs are interpreted as dune scarps (Rs-1), incised channels (Rs-2), water-table (Rs-3) and centimeter-thick layers of organic-rich sediments (Rs-4).

A preliminary conceptual model is suggested to explain their onset and evolution, integrating all available information from both sites. The onset of the system is marked by the anchoring of the barriers ca. 4000 BC and the subsequent formation of a dune field through the inland migration of transgressive dunes starting ca. 3000 BC. This inland migration was not a continuous process, as documented by the presence of interbedding organic-rich layers. They may indicate the temporary cessation of aeolian activity but might have also been related to the fragmentation of a former coastal barrier through the formation of erosive features within the foredunes as blowouts driven by the impact of frequent and intense storms. The latter could also be responsible for the eventual overwash and inundation of barriers as suggested by the sedimentary record. Ancient human intervention opening the barriers can however not be completely disregarded.

The timing of the formation of the different transgressive dune pulses and overwash deposits will be further investigated in order to construct a more constrained storminess chronology within the explored region.

This research is a contribution to projects 08MDS036000PR funded by the Xunta de Galicia and PaleoModes (CGL2016-75281-C2). R. González-Villanueva was founded by the Xunta de Galicia Post-Doctoral Fellowship (Plan12C-ED481B 2018/021).

Late Mesolithic occupation in a Holocene changing landscape: a multi-proxy analysis of sediments from the Sado alluvial plain, SW Portugal

Ana Maria Costa^{1,2,3}, Maria da Conceição Freitas³, Manel Leira³, Ana Cristina Araújo^{1,4}, Mariana Diniz⁴, César Andrade³, Pablo Arias²

¹Laboratório de Arqueociências (LARC)/Direção-Geral do Património Cultural (DGPC) and EnvArch / CIBIO / InBIO, Lisboa, Portugal. ²IIPC (Universidad de Cantabria-Gobierno de Cantabria-Santander), Santander, Spain. ³Instituto Dom Luiz (IDL), Universidade de Lisboa, Lisboa, Portugal. ⁴Centro de Arqueologia (UNIARQ), Universidade de Lisboa, Lisboa, Portugal

Abstract

Roughly between 8400 and 7000 cal BP the major Portuguese estuaries like the Tagus and the Sado were intensively occupied by Late Mesolithic communities, leading to the formation of sites known as shell middens. These sites resulted from successive accumulation of shells consumed during the Mesolithic stays as well as other remains related to the exploitation of the environment. Palaeodiet studies ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) performed in individuals buried in some of these shell midden sites confirm that marine resources were a food-component of their diet.

During the Mesolithic occupation of these palaeoestuaries coastal landscapes suffered major changes mostly due to sea level rise. An estimated mean rate of ca. $8.1 \pm 0.7 \text{ mm yr}^{-1}$ until 7500 cal BP – decreasing to a rate of ca. $3.4 \pm 1.0 \text{ mm yr}^{-1}$ between 7500 and 6900 cal BP – is known, promoting the flooding of the valleys formed during the lower than present sea-level stages and the formation of marginal tidal environments.

The multi-proxy study (texture, organic chemistry, magnetic susceptibility, organic matter and CaCO_3 contents, diatoms and ^{14}C dating) of six sediment cores recovered from the Sado alluvial plain, close to Mesolithic shell middens (fig.1), aims to characterize the extension of the marine influence in the Sado valley and the landscape evolution during the Holocene. Preliminary data point to the presence of estuarine conditions between Arapouco and São Bento sites (fig.1) since the beginning of the Mesolithic occupation and until ca. 3300 cal BP, favourable to the collection of marine species in the vicinity of their settlements. Further upstream fluvial conditions prevailed at least since ca. 4400 cal BP, reflecting the contraction of the estuarine area after sea level rise deceleration.

It is important to highlight that during the ca. 1500 years of Mesolithic occupation in the Sado area sea level rose ca. 12m driving constant changes in the exploited environments and reflecting the resilience of these hunter-gather communities upon estuarine environments.

Figure 1 - Location of the Late Mesolithic shell middens (black circles) and of the studied sediment cores (black stars), Sado, Portugal.

Reconstructing the Holocene evolution of the Lower Danube floodplain

Alfred Vespremeanu-Stroe¹, Laurențiu Țuțuianu¹, Luminița Preoteasa¹, Tiberiu Sava², Cătălin Lazăr¹, Sabin Rotaru^{1,3}, Florin Zăinescu¹

¹University of Bucharest, Bucharest, Romania. ²Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering, Bucharest, Romania. ³Geoecomar, Bucharest, Romania

Abstract

The sedimentary deposits of the large rivers are some of the most interesting Quaternary records because they provide valuable information not only about river and floodplain dynamics but also about the complex response to autogenic (solid and liquid discharge, thalweg slope, floodplain width, etc.) and allogenic factors (climate change, sea level rise, anthropic activity). In this study we present the measurements performed on 10 cores sampled along ca. 100 km within the Danube floodplain, immediately upstream of Danube delta. The multi-proxy analysis includes geochronology based on absolute ages (AMS), sedimentological (grain-size, loss on ignition, magnetic susceptibility), geochemical and paleo-ecological (pollen, seeds, ostracods, forams, dinoflagellates) methods which were mainly focused on the changes observed in the sedimentary records. The results allowed for the identification of the main evolutionary phases from the estuarine conditions which followed the sudden Black Sea level rise induced by the invasion of the Mediterranean Sea till river floodplain development via Danube delta front advance. Thus, most of the floodplain stratigraphies show similar patterns with turning points induced by the dramatic change from a configuration to another: continental floodplain - estuarine bay – delta front advance – shoreline – river floodplain – lake and marsh inception. Different proxies, but especially the sedimentation rates derived from the age-depth models show marked differences correlated with local water history (dependent on sea level and tectonics) and later (since Neolithic) with the human history especially via land-use change (deforestation, crops). The latest have been also documented by means of paleo-ecology which allowed to assess the agriculture activities based on pollen and cereals seeds.

Crypto tephra in the sediments of Paleolake Gorgana, Romania – a trigger for paleoecological changes of the lake environment

Dirk Nowacki, Andreas Batliner, Julia Fischer, Ronja Lappe

Department of Physical Geography, Faculty of Geosciences, Goethe University Frankfurt, Frankfurt/Main, Germany

Abstract

Research in the Lower Danube valley in southern Romania, a large paleolake, Lake Gorgana, was discovered. The sediments of this lake represent an excellent geo-archive for the reconstruction of the paleoenvironment. Connected to the catchment area of the Danube and equipped with a water surface of over 2400 km², this geoarchive reflects major changes of the paleoecological conditions.

A prominent dark section in the sedimentary record of Lake Gorgana that was deposited between the 7th and 4th millennium BC in the Atlantic period, was the special focus of the research. Using a multi-proxy approach based on the analyses of several corings using XRF, XRD and $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotopes the complex evolution, including input of crypto tephra, of this dark section was revealed. The input of volcanic material into the former lake triggered some serious ecological changes in the lake, for example immense acidification followed by eutrophication of the lake. Considering the dimension of this effect it must be assumed that the volcanic event affected the whole catchment area of the lake.

Dark deposits of similar shape are described in several studies of other authors for European and Mediterranean geoarchives for the Atlantic period. These dark deposits are mostly characterized by high proportions of organic material, indications of anaerobic conditions and poorly preserved or corroded pollen. However, these deposits are interpreted in different ways by the corresponding authors.

In this paper, we will present evidence that the development of the dark layer in the sediments of Lake Gorgana was initially triggered by a volcanic event that might have been of global influence on ecosystems.

Late Quaternary relative sea-level changes and evolution of the Lacepede Shelf, southern Australia

Nuria Lahuerta Pineiro, Colin Murray-Wallace, Adriana Garcia
School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia

Abstract

The River Murray, part of the Murray-Darling Basin, the largest river system in Australia to reach the sea (1,060,000 km²), debouches onto the Lacepede Shelf, in SE South Australia. The Lacepede is a wide (180 km), shallow (≤ 150 m), tectonically stable shelf, part of the largest modern temperate cool-water carbonate depositional province in the world. During the Quaternary, the dominant geomorphological changes resulted from transgressive/regressive events with minimal isostatic effects in this far-field environment. At times of lower sea-level in the Middle and Late Pleistocene, the former Murray extended farther south on the exposed shelf. Therefore, its sedimentary record allows reconstruction the history of the palaeo-river, which encompasses changes in sea-level and shoreline extents during the last glacial cycle. Multiproxy analyses including taxonomy, taphonomy, dating (¹⁴C-AMS and AAR) of foraminifers and bivalve shells, sedimentological and mineralogical data were performed on five cores located along the palaeo-channels of the ancient river system. The results indicate a sea-level position at ~ 3 m APSL at the beginning of the Last Interglacial (125 kyr), 55-60 m BPSL at ~ 45 kyr, ~ 110 m BPSL during the Last Glacial Maximum, and 40-50 m BPSL during the Pleistocene-Holocene transition (~ 12 kyr). Climatic and environmental conditions during the Last Interglacial Optimum (~ 125 kyr) were similar to present with the shoreline located ~ 2 km inland, where the inner land of the modern Coorong occurs. A lagoon-estuarine system was established, dominated by *Ammonia aetana* intermittently exposed (signs of bleaching). During one interstadial of MIS 3 at ~ 45 kyr, the mid shelf (80 km from the present shoreline) revealed a high-energy shallow neritic environment (highly reworked sediment) with dominance of *Elphidium advenum*, close to a lagoon with abundant by *A. aetana*. During the LGM, colder and drier conditions left the shelf almost completely exposed, with the river mouth situated at ~ 150 km off the present shore towards the west, defined as a neritic environment dominated by *E. advenum* and *Cibicides refulgens*. The preservation of foraminifera shells at that time, indicated signs of transportation associated with tidal fluctuations. At the end of the Pleistocene, the climate was relatively warm and the inner part of the shelf (~ 60 km from the present coastline) showed a fast transgression from a lagoon-estuarine system dominated by *A. aetana* and *E. excavatum* (with signs of reduction) to a typical shore marine environment on the actual shoreline about 2 ka (~ 14 -12 kyr). Finally, the continuous transgression through the Holocene established the shelf into the present typical high-energy marine environment, with coarser bioclastic sediments, higher carbonate and quartz percentages, an increase in abundance, richness, and diversity of marine foraminifers; while at the edge of the shelf, planktonic species as *Globoconella inflata*, *Globigerinoides ruber* and *Cibicides* spp. are abundant, indicating a deep-water environment.

Holocene coastal evolution of beach ridges in the sheltered Hervey Bay embayment, Southern Queensland, Australia

A Y Annie Lau, Hannah Bennett, James Shulmeister

School of Earth and Environmental Sciences, The University of Queensland, Brisbane, Australia

Abstract

There are significant and increasing populations inhabiting the low-lying coasts around Hervey Bay, a 100 km wide embayment about 270 km north of Brisbane on the east coast of Australia. We investigated the progradation history of the coastal plain NW of the Burrum River to decipher the Holocene coastal evolution of Hervey Bay and to investigate the long-term storm hazard on this coast.

The area was mapped with the assistance of airborne LiDAR data and recent changes along the coast were determined from historical aerial photographs. The stratigraphy of the coastal plain and beach ridges was investigated using ground penetrating radar (GPR) surveys. OSL ages were recovered from the sandy beach ridges while cores collected in the back-barrier SE of the Burrum River were dated using C14 and analysed for grain size, optical characteristics and elemental composition.

Preliminary results show while the higher shoreward ridges were built in early Holocene, most of the strand plain was formed in the late Holocene. Only one specific storm layer was identified, which dated to before 5415 ± 30 yrs BP. This general pattern supports the concept of declining sea-levels in this part of eastern Australia after a high stand at about 6.5 ka. At the southern end of the strand plain, 20 ridges younger than 670 ± 110 yr spread over 1.4 km, suggesting rapid progradation at a rate of over 2 m/yr, which is one of the highest recorded among strand plains studied in Queensland. This high rate is attributed to a sea level fall of approximately 0.5 m in near historical times and to an increase in sediment availability in Hervey Bay. Given that a similarly high sedimentation rate is recorded SE of the river, it appears that sediment delivery from the river has increased substantially in the last 1000 years.

Direct dating of human fossils and the ever changing story of human evolution

Rainer Grün, Mathieu Duval

Research Centre for Human Evolution, Griffith University, Nathan, Australia

Abstract

When dating valuable human fossils, any damage has to be kept to an absolute minimum. Over the years, we have developed virtually non-destructive protocols for ESR and U-series analyses. This has given us access to a number of important human fossils, including those from Florisbad, Naledi, Irhoud and Mislya. This presentation gives an overview how ESR and U-series dating has changed some of the perceptions of modern human evolution.

Abstract

Coastal alluvial fans (CAFs) in northern Chile are of crucial interest for studying the Quaternary environmental evolution of the hyper-arid Atacama Desert. This research, however, is limited by the small amount of chronological data currently available to constrain these CAF deposits. Optically stimulated luminescence (OSL) dating of quartz has proven challenging in these deposits due to unsuitable OSL signal properties. Therefore, we aim to establish a chronostratigraphic framework for CAFs between 21°S and 25°S by using a combination of post-infrared infrared (pIRIR) stimulated luminescence dating of K-feldspar and electron spin resonance (ESR) dating of quartz. Samples were taken from alluvial deposits, as well as from marine and aeolian sediments embedded in the CAF.

Preliminary numerical dating results can be summarized as follows: pIRIR dose distributions of alluvial fan samples are characterised by relatively high overdispersion and positive skewness, in contrast to marine and aeolian deposits. Measurement of modern analogue sediments indicates that this can be attributed to partial signal resetting, due to different transport mechanisms. Following the quartz multiple centre (MC) ESR dating approach, both the Al and the Ti centres were measured in order to evaluate whether full bleaching of the different centres has been achieved prior to deposition. While the Ti-H centre provides lower doses than the Ti-Li centres, in most cases the Al centre provides the highest dose values. This pattern is consistent with their respective bleaching kinetics and suggests that the Ti-H signal most likely provides the closest estimate to the true burial dose.

ESR ages (Ti-H, Ti-Li) are consistent with the luminescence dating results at 1σ for most of the samples. Differences between pIRIR and ESR age estimates might be explained by incomplete bleaching of the ESR signals during short-term debris-flow transport. First numerical ages date the lowermost marine terrace to the MIS 5, providing a maximum age for alluvial fan deposition directly at the coast. Marine terraces give insights into the tectonic activity in the area during the Late Pleistocene, leading to estimated uplift rates of ~ 0.3 m/ka. Aeolian sand interbeds in the alluvial fan complex and alluvial fan deposits date to ~ 60 -30 ka and ~ 15 ka, giving insights into the palaeoclimate, regional geomorphology and wind pattern in the study area.

To conclude, our results show the need to develop reliable dating approaches in environments where the standard OSL dating procedures do not work. In this context, the conjunction of pIRIR and MC ESR dating can be considered as a promising tool to decipher Late Pleistocene landscape dynamics along the northern coast of Chile.

Amino acid racemisation dating of mammalian enamel: a UK proboscidean geochronology

Marc Dickinson¹, Adrian Lister², Kirsty Penkman¹

¹University of York, York, United Kingdom. ²Natural History Museum, London, United Kingdom

Abstract

Construction of chronological frameworks capable of robustly estimating the age of mammalian remains are imperative to understanding a range of palaeontological enquiries. Direct dating of mammalian remains is extremely difficult beyond the limits of radiocarbon dating (~50 ka). Analysis of the predictable breakdown of proteins and amino acids in wide variety of calcium carbonate (CaCO₃) based biominerals has been a powerful tool for Pleistocene age estimation (back to ~2.5 Ma), but to date, its application to mammalian remains has been challenging. By targeting a proteinaceous fraction found within the crystalline structure of biominerals (the intra-crystalline fraction), the difficulties associated with contamination, leaching and environmental influences are circumvented. We have assessed the suitability of tooth enamel for intra-crystalline protein decomposition (IcPD) dating by testing both the protein breakdown and the intrinsic properties of the inorganic crystal structure of enamel through simulated degradation experiments. We have found that a fraction of amino acids can be successfully isolated from enamel that are expected to remain stable over long time scales.

A geochronology based on the extent of amino acid racemisation in proboscidean enamel has been constructed from known age material, with an age range that shows the technique successfully dates material from the UK up to Late Pliocene in age. It is therefore now possible to provide direct age estimation for unknown age proboscidean material from the same temperature region (likely to be Northern Europe) through comparative assessment based on our existing framework. Enamel AAR has the potential to be expanded to a range of mammalian species and can be developed for additional geographic regions. The focus of this framework has been on Quaternary age samples, but due to the slower breakdown of the enamel proteins, the dating range of this method may extend much further back in time.

Abstract

Meaningful reconstructions of Quaternary palaeo-climate and -environmental reconstruction rely heavily on accurate and precise chronologies. Long and continuous lake sediment sequences are outstanding archives of past climatic change but, unless varved, depend on the development of detailed age models. Such models estimate the age-depth-relationship of the sequence from a limited number of dated horizons, which often carry large associated errors, age reversals, or minimum/maximum age constraints.

Approaches to chronology development for sediment sequences have seen major improvements such as more nuanced Bayesian accumulation models but still rarely reach the resolution and precision desired for the study objectives in the context of high-resolution palaeo-climatic correlations of global events. This is particularly true beyond the limits of the well-established and more precise radiocarbon dating method. Sediment archives older than 50 ka have often not been used to its full potential for the lack of chronology estimates. In such cases, alternative methods including correlative and relative dating methods may need to be employed. Currently, a standardised method of integrating absolute dating with wiggle-matched curves of comparable proxies between the unknown and a dated sequence is lacking.

Here we address this problem in the context of the Orakei maar palaeolake sequence from Auckland, New Zealand. This sediment record is a high-quality example of one of the rare high-resolution and continuous lacustrine archives of climatic variations in the southern hemisphere mid-latitudes over much of the last glacial cycle. Based on previous estimates, the Orakei sequence spans the interval ca. 126 cal ka BP to 9 cal ka BP.

The presented Orakei chronology is based on absolute ages from tephrochronology, radiocarbon dating and post-IR IRSL luminescence dating. Prior to 40 ka, tuning of relative palaeomagnetic intensity changes and meteoric Beryllium-10 flux to the global PISO-1500 palaeointensity stack between absolute age markers allows to establish a novel accumulation model for the Orakei sequence.

This approach allows us to generate a high-resolution age model suitable for correlation of millennial-scale oscillations from the SW Pacific to global records of past climate such as polar ice core, tropical lake and speleothem archives.

³Yamaguchi University, Yamaguchi, Japan. ⁴Geological Survey of Japan/AIST, Tsukuba, Japan

Abstract

Past activity of active faults is typically estimated from deformed Quaternary sediments, containing a combination of measurable displacement markers and dateable material. In crystalline bedrock areas undergoing rapid erosion, faults can be observed geologically or geomorphologically without overlying dateable Quaternary units. For such faults, there is currently a lack of broadly applicable methodology to evaluate their activity indices, which in turn poses a threat to infrastructure and densely populated areas. In this study, we introduce a novel concept to evaluate fault activity from trapped charge in quartz – specifically, the optically stimulated luminescence (OSL) and electron spin resonance (ESR) signals. The level of saturation of these signals, alone or in combination, has the potential to quantify the activity of faults where slip rates are presently poorly constrained or unknown.

We show preliminary results for an outcrop of the Atotsugawa Fault (active fault in the central Japan). The fault core consists of fault gouge and breccia including granite clasts. Four test samples were taken, including a location previously dated by quartz OSL (Ganzawa et al., 2013) to 200 ± 200 years, (broadly consistent with the last large earthquake at 1858). The equivalent dose (D_e) and dose response curves were obtained using pulsed OSL to minimise signal contamination by feldspar OSL. Relatively uniform D_e values and n/N were calculated for all samples, and ranged between 42 ± 11 ka and 56 ± 19 ka, except for one younger sample with a higher environmental dose (19 ± 5 ka). Although all the apparent ages appear ca. two orders of magnitude older than those of Ganzawa et al. (2013), the relatively uniform values (mean age: 47 ± 4 ka; mean fraction of saturation: 0.33 ± 0.02) can be considered as representative of the activity of the Atotsugawa Fault during a similar timescale. These apparent ages, together with a trap depth of 1.66 ± 0.03 eV and a frequency factor of $1 \times 10^{13} \text{ s}^{-1}$ (Murray and Wintle, 1999), and an estimated recurrence interval of Atotsugawa Fault of 2.5 ka (Research Group of Atotsugawa Fault, 1989), were used to predict the fault shear heating that has repeatedly occurred during past large earthquakes. Our modelling suggests that flash heating of the fault gouge during each large earthquake is broadly equivalent to $250 \text{ }^\circ\text{C}$ for 10 s. Inverting our exercise, we suggest that if one can estimate the degree of recurrent flash heating independently (e.g. via shearing experiments), it is in turn possible to calculate a recurrence interval for a given fault.

Implementation of violet stimulated luminescence (VSL) in sedimentary environments with complex behaving quartz

Alicia Medialdea¹, Dominik Brill¹, Georgina King², Anja Zander¹, Christoph Burow¹

¹Institute of Geography, University of Cologne, Cologne, Germany. ²Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland

Abstract

Over the past decades, optically stimulated luminescence (OSL) dating has become a key tool in the study of the Quaternary. It can provide absolute ages ranging from decades to several hundred ka using standard procedures. Despite the power of the technique, demand for extending the age range has increased, resulting in a large concentration of effort in this respect. Violet stimulated luminescence (VSL) has been proposed as one approach for meeting this objective. It has been shown that VSL yields a luminescence response that saturates at higher doses than the conventional blue-OSL signal from quartz. This study focuses on the application of VSL to a sedimentary profile in the Atacama Desert which, based on the stratigraphy and previous knowledge of the area, is expected to extend beyond the age range of standard OSL.

Initial measurements on quartz extracts from the upper-most units, expected to be within the age range covered by blue-OSL, show complex behaviour. The derived signal is not dominated by the fast component and a given dose cannot be recovered using standard procedures. Based on this observation, it can be concluded that blue-OSL is not suitable for this sedimentary material and cannot provide reliable ages. In contrast, VSL from the same quartz extracts have a reproducible response. An extensive experimental study using VSL, including analyses on the effect of the stimulation temperature, the normalizing dose or the bleaching of the signal among other tests have been carried out to determine the most suitable measurement protocols and to confirm the reliability of the method to recover a given dose. Based on the results, equivalent doses using VSL and the corresponding ages have been estimated for eight units of this profile.

Ages have also been estimated from infrared stimulated luminescence (IRSL) of K-feldspar fraction from the same samples. Analysis on the effect of fading of the IRSL signal was not conclusive, hence no fading corrections were applied. However, dose recovery tests show the suitability of the applied protocol to recover a given dose.

Based on the experiments, both approaches appear to be suitable for measuring the equivalent doses of these samples but discrepancies between the derived ages are observed; IRSL ages are approximately 30 % larger than those from VSL. Both approaches show similar agreement with the geological context: 5 out of 7 of the IRSL and 6 out of 7 VSL ages are stratigraphically consistent however, given the lack of independent age control, further research is necessary to determine the sources of variability in the responses.

This study shows the complexity of luminescence dating of sedimentary material from the Atacama Desert and the need for a thorough study in order to obtain accurate independent age estimates.

Bulk sediment IRSL screening applied for high-resolution and fast age assessment of fluvial deposits in the Upper Rhine Plain

Daria Klekovkina¹, Daniela Mueller¹, Frank Preusser¹, Claire Rambeau^{1,2}, Ritu Sah¹, Gilles Rixhon², Ferréol Salomon², Laurent Schmitt²

¹University of Freiburg, Freiburg, Germany. ²University of Strasbourg, Strasbourg, France

Abstract

For the reconstruction of past river dynamics it is essential to determine the age of fluvial deposits. Over the last two decades, luminescence dating has developed towards the most important geochronological tool in this context. As luminescence dating is laborious, the number of samples that can be processed are limited considering time and finances. Hence, luminescence chronologies are usually only punctual and delimited by sampling along obvious stratigraphic boarders (hiatuses). However, hiatuses are not always easy to recognise and their chronological hierarchy is usually not cognoscible. As a consequence, one may miss phases of deposition and by this bias the interpretation. The ultimate goal would be to establish close-to- continuous chronological records of fluvial deposition. While this is in principle possible using portable luminescence readers, this technique does not correct for variability in luminescence intensity caused by changes in sediment composition (e.g. feldspar content).

Presented here is case study from the Upper Rhine Plain where complex patterns of Holocene fluvial dynamics can be easily recognised on high-resolution elevation data (LIDAR). Investigated are six cores drilled along a transect through the Holocene flood plain of River Rhine near the town of Drusenheim. Besides sedimentological investigations we applied the approach of May et al. (2018) who use Ln/Tn IRSL measurements of natural sediment samples. By systematically sampling every 5 cm we receive high-resolution semi-quantitative age records that are complemented by proper IRSL and radiocarbon dating.

FAULT2SHA – Linking field geologists with seismic hazard modelers

Oona Scotti¹, Laura Peruzza²

¹IRSN, Fontenay-aux-Roses, France. ²OGS, Trieste, Italy

Abstract

- Use of fault-related information in the assessment of seismic hazard is slowly finding its way in Europe. Progress is slow because the data collection process is time-consuming, the quality of data used to represent faults in databases is heterogeneous and methodologies to incorporate fault information in hazard studies are not necessarily agreed upon across Europe. Nevertheless, the motivation is high, spurred by the need to capture as best as possible the potential occurrence of larger-magnitude events, beyond those recorded in historical and instrumental seismicity catalogues or based on the “segmentation” concept in which the size of earthquake ruptures is controlled by segment geometries. Indeed, complex ruptures observed in recent events confirm the need to relax the “segmentation” concept. The 2016 Mw 7.8 Kaikōura, New Zealand earthquake, actually ruptured 21 different faults over 180 kilometers, a world record. This event raised numerous questions in the seismic hazard community, in terms of its capacity to anticipate such complex events. Complexity in terms of rupture geometry and slip distribution both at depth and at the surface is also characteristic of the most recent events that affected the Italian 2016 Central Apennines earthquake sequence. Thus one of the keys to improving the reliability of probabilistic seismic hazard assessment (PSHA) based on faults is not only mapping and characterizing faults (geometry and slip rates) but also considering all combinations of rupture scenarios that are physically possible in the seismic hazard estimates.
- In order to face these challenges the FAULT2SHA ESC WG (<https://fault2sha.net/>) is establishing natural laboratories, (i.e. Italy, Spain), where transdisciplinary issues are discussed among geophysicists, earthquake geologists, geodesists and seismologists. On the fault modelling side, the feasibility of methodologies (SHERIFS, FRESH and SUNFISH) to solve for the long-term rate of earthquake ruptures reflecting the complexity of fault systems (3D geometries and slip rate heterogeneities) was recently demonstrated. The objective of such methodologies is to maintain observed fault complexity, relax the segmentation hypothesis and empower earthquake geologists and geodesists to build fault-based seismic hazard models supported by field observations. Reliability of such approaches depend on the quality and quantity of available fault slip rate estimates, magnitude scaling relationships considered, as well as the knowledge of fault geometries at depth and of their mechanical behaviour (i.e. seismic versus aseismic). Comparing modelled results with available independent data is essential, to ensure that modelled fault-seismicity rates reflect at best our present day understanding of fault mechanics and crustal deformation processes in a given region. Comparison with instrumental, historical or paleoseismic seismicity rates, geomechanical results, geodetic data, and earthquake rupture dynamic simulations, are needed to collectively help in selecting the best choice among the different physically possible sets of rupture scenarios.

O-4121

Constraining earthquake recurrence using lacustrine sediments: How many events do you need?

Jasper Moernaut¹, Philipp Kempf²

¹University of Innsbruck, Innsbruck, Austria. ²Geological Survey of Belgium, Ghent, Belgium

Abstract

It remains a topic of debate whether the inferred quasi-periodicity in many historical and paleoseismic records may be the result of the limited number of recorded events, or whether quasi-periodicity represents the typical nature of earthquake recurrence for most faults. In recent years, several long paleoseismic and paleotsunami records in lakes have been constructed that may encompass sufficient events to reliably assess recurrence parameters. Due to the typical continuous sedimentation regime in deep lakes, lacustrine records can provide a stable environment for the creation and preservation of paleoseismic data. Moreover, it can allow for excellent temporal resolution, so that variability in recurrence intervals can be accurately constrained.

Here, we firstly present the research strategy behind the construction of a long paleotsunami (Lake Huelde, 17 events) and paleoseismic (“shaking”) record (Lake Riñihue, 35 events) in South-Central Chile. Both records show some degree of quasi-periodicity with a coefficient of variation (CoV) of 0.68 and 0.50, respectively. Lake Huelde exhibits a bimodal pattern of tsunami recurrence intervals, whereas the Lake Rinihue data follows a more “classic” unimodal Weibull distribution. This difference can be explained by the different nature of the paleo-events, i.e. strong tsunami vs. strong shaking, and how this relates to the spatial distribution of tsunamigenic and seismogenic faults on a subduction zone.

Secondly, by developing synthetic recurrence patterns, we simulate the required amount of events to be able to accurately constrain some basic recurrence parameters. We find that this number strongly increases with recurrence pattern complexity and/or time independence. In case of a rather complex supercycle model or the time-independent Poissonian model, it seems that the standard deviations of the mean become possible to be estimated with 95% certainty only beyond a sample size of 10 and 16, respectively. More simple (unimodal) recurrence patterns may be constrained with similar certainty with only 5-6 events. We further evaluate these simulations by reviewing long lacustrine paleoseismic records worldwide. The influence of record length is analyzed by step-wise extending the most recent part of these records towards the entire record. For records that are believed to follow a Poissonian (CoV ~ 1) or clustered (CoV > 1) pattern, it seems that the CoV can only be reliably assessed beyond an event number of $\sim 15-20$. Records that are believed to be quasi-periodic (CoV 0.5-0.7) have a stable CoV after already $\sim 8-10$ events. These findings based on both simulated as empirical data highlight the importance of sufficient event numbers in paleoseismic records for reliable assessment of earthquake recurrence parameters.

Active faulting in the Upper Rhine Graben: geomorphological and geophysical evidence

Klaus Reicherter¹, Stephane Baize², Joachim Ritter³, Sarah Mader³, Jochen Hürtgen¹

¹Inst. of Neotectonics and Natural Hazards, RWTH Aachen University, Aachen, Germany. ²Institut de Radioprotection et de Sûreté Nucléaire, Fontenay-aux-Roses, France. ³KIT, Geophysikalisches Institut, Karlsruhe, Germany

Abstract

The Upper Rhine Graben (URG) is the central part of the Central European Cenozoic Rift System (ECRIS) and one of the tectonically active regions in Europe. The URG extends from the Jura thrust and fold belt in the South near Basle city (Switzerland) to the Rhenish Massif in the North near Frankfurt and is limited by sinistral strike-slip faults on either sides. Seismic studies suggested the fault system at the eastern margin to be active, as the Basle earthquake 1356 AD was situated there. Ongoing earthquake activity testifies to active faulting, however, there are many faults and fault strands, many of them are regarded as normal faults, others as reactivated normal faults with a sinistral sense of movement. The URG is a low-strain setting with long recurrence intervals of large earthquakes. Moreover, the fault morphological signal is perturbed by anthropogenic land-use, the climate of the area, which is located in the temperate zone, and the erosion and sedimentation of the Rhine River. The eastern margin faults lack any neotectonic and paleoseismological investigations, in contrast to the western border faults that have been examined during the last decades, while the area encompasses critical facilities in a vulnerable region such as, dense population, agriculture, mining, geothermal facilities. Our projects in the frame of an IRSN study and the DFG-SPP AlpArray aim to fill this gap of knowledge in large and infrequent earthquakes, through a paleoseismological investigation of eastern side faults.

We used a multidisciplinary approach to improve the input data of seismotectonic models, which include faults and their activity potential in the calculation of seismic hazard assessment and are based on a weak data set at the moment. First results of different locations around Freiburg in the southern URG and around Karlsruhe are presented: the Rhine River fault system about 20 km SW of Freiburg, NE of Freiburg at the eastern border fault system about 10 km. At both sites we used a digital elevation model (DEM) derived from LiDAR-data (5x5m) and together with geophysical measurements performed with ground-penetrating radar (GPR) and electrical resistivity tomography in order to track and identify possible fault scarps. A detailed geomorphological study of the DEM was performed to identify and map superficial expressions of the neotectonic activity of the faults and deformed and offset alluvial terraces and fans. We apply ERT and GPR for imaging the geophysical contrasts at depth, such as faults and stratigraphy in detail. Nevertheless, for the unambiguous verification of these structures and the determination of key fault parameters, such as magnitude, age of last events, slip rate and return periods, additional paleoseismological trenches are needed, which will be the next step of the project.

Surface faulting pattern anomalies: lessons learned from the 2016 Central Italy seismic sequence

Anna Maria Blumetti¹, Carlo Alberto Brunori², Marco Caciagli³, Valerio Comerci¹, Pio Di Manna¹, Luca Guerrieri¹, Eutizio Vittori¹

¹ISPRA, Roma, Italy. ²INGV, Roma, Italy. ³INGV, Bologna, Italy

Abstract

With the aim to better understand the significance of local anomalies of coseismic surface faulting pattern and size, we have reviewed the characteristics of surface tectonic ruptures occurred along the Mt. Vettore - Mt. Bove – Mt. Banditella fault system during the seismic sequence hitting Central Italy in 2016.

The sequence was characterized by three main shocks on Aug. 24th (Mw=6.0), Oct. 26th (Mw=5.9) and Oct. 30th (Mw=6.5). Surface faulting associated to the first main shock was observed along the southeastern portion of the system (M. Vettore-M.Vettore fault), with vertical displacements up to 25 cm and ruptures continuous for at least 4.5 km.

The second main shock reactivated the northwestern part of the fault system: vertical displacements up to 10 cm were observed along the Cupi and Cornaccione faults, for an end-to-end rupture length of about 12 km.

The third main shock (Oct. 30th) ruptured the entire fault system for about 28 km and average vertical displacements in the order of some tens of cm, that locally reached about 2 meters.

In general, the overall pattern and size of observed surface faulting are consistent with the expected surface ruptures scenario associated to the observed magnitudes in a normal faulting environment with focal depths in the order of 5-10 km. However, a more detailed analysis has pointed out two anomalies:

- purely tectonic vertical displacements reaching values of about 2 meters, as those measured along the Cordone del Vettore fault, are generally associated to larger events ($M > 7$). Such large offsets may better explained with a significant contribution of gravity, considering that the fault scarps are located at about 700 m above the base of a steep slope;
- rupture lengths associated to the Oct. 26th event (Mw=5.9) are generally constrained within a few km. Thus, an end to end rupture of about 12 km cannot be easily explained as purely tectonic: for this reason, some Authors have interpreted the ruptures along the Cornaccione fault as a not tectonic effect caused only by seismic shaking. However, our data collected on Oct. 28th along this fault point out a strong consistency in terms of location with surface faulting occurred on Oct. 30th along the same fault, even if with a significant difference of displacement amounts. Moreover, the aftershocks distribution indicates that also the ruptures produced during the 26th shock along the Cornaccione fault are mainly tectonic effects. These two examples of local anomalies of surface faulting pattern and extent show that this phenomenon may be very complex as it is influenced by several factors at local scale. This notion stresses once again the need of great care for a reliable assessment of seismic and fault displacement hazard based on paleoseismological investigations.

O-4124

The seismicity models for the 2019 national Italian seismic hazard model

Francesco Visini¹, Bruno Pace², Carlo Meletti³, Warner Marzocchi⁴

¹Istituto Nazionale di Geofisica e Vulcanologia, L'Aquila, Italy. ²DiSPUTer, Università degli Studi "G. d'Annunzio", Chieti-Pescara, Chieti, Italy. ³Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy. ⁴Università di Napoli Federico II, Napoli, Italy

Abstract

In 2015, the CPS (*Centro Pericolosità Sismica*, Seismic Hazard Centre) of the Istituto Nazionale di Geofisica e Vulcanologia started to promote and coordinate the activities of a project aimed at producing the new national probabilistic seismic hazard model for Italy. We present the results of the activities of a task of this project, task 3: "seismicity models", that is focused on the definition of a set of seismicity models and on the analysis of their uncertainties. More than 30 researchers subdivided in 12 working groups produced 11 seismicity models covering the entire Italian territory, 1 models built *ad hoc* for the volcanic Etna area, 1 model for the seismicity of the Calabrian Arc, and 1 model for sources external to the Italian territory. The national models are built using different types of sources, methods, and input data. In particular, 5 models are based on area source and, with different approaches, on expected seismicity rates by means of fit of observations of the historical earthquake catalogue; 2 models are based on a mixed fixed-radius and adaptive radius and on Woo methodology for smoothing seismicity; 2 models used faults and background seismicity and; 2 models are based on geodetic data and they are independent from the historical seismicity.

Surface rupture associated with a moderate intraplate earthquake: the Mw 6.2 Parina event (December 1st, 2016) in the Peruvian Altiplano

Carlos Benavente¹, Stéphane Baize², Enoch Aguirre¹, Laurence Audin³, Briant Garcia¹, Sam Wimpenny⁴, Lorena Rosell¹, Fabrizio Delgado¹, Xavier Robert⁵, Alex Copley⁴

¹INGEMMET, Lima, Peru. ²IRSN, Fontenay-aux-Roses, France. ³IRD, Grenoble, France. ⁴University of Cambridge, Cambridge, United Kingdom. ⁵IRD, Lima, France

Abstract

Fault displacement and Seismic hazard analyses employ empirical relationships to predict potential earthquake magnitude (e. g., Wells and Coppersmith, 1994), probability functions of surface rupture and surface slip amount (e. g., Youngs et al; 2003). Those relationships share the common issue that they rely on a limited number of moderate-to-large magnitude (≥ 6.5) and pre-2000 cases. Earthquakes from western US and Japan are largely represented, and intraplate cases are few. Here, we report surface faulting evidence that occurred during an intraplate and moderate earthquake in Peru. We present field and high-resolution data that improve the geodynamic knowledge of the region and provide clues to upgrade seismic hazard.

The 2016 Mw 6.2 Parina normal-faulting earthquake occurred within the high Andes of southern Peru, in a region with sparse seismicity and little geodetic horizontal strain. Field observations and high-resolution DEMs of the surface ruptures allow investigating the relationship between slip on the Parina Fault, local geomorphology and the regional tectonics. We mapped one major NW-SE-trending and 6-km-long segment, with up to ~ 30 cm vertical slip (downthrown to the SW) and ~ 25 cm tensional opening. Beyond a 4-km-long gap of surface rupture, a minor 2-km-long segment ruptured with smaller slip values (up to 8 cm), along the same fault zone. Surface slip is not much distributed off the major fault. The two mapped rupture traces directly coincides with the up-dip projection of the same co-seismic fault plane inferred from SAR interferograms, and therefore they may represent two distinct sections of the primary earthquake fault, separated by a surface gap. This gap occurs where surface geology is constituted of loose sediments. Interestingly, the ruptures coincide with 10-20 m high scarps cutting through Late Pleistocene fluvio-glacial deposits that are downthrown to the SW, and they form the southeastward extension of the larger Lagunillas-Mañazo fault system that trends NW-SE across the Peruvian Altiplano. A preliminary estimation leads to infer a repeated normal-sense slip on the Parina Fault since the last major glaciation ($\sim 10-30$ ka), implying a vertical slip rate ~ 1 mm/y.

Besides its regional interest in terms of active tectonics and geodynamics (Wimpenny et al., 2018), the Parina surface rupture constitutes a new case to enrich the pending SURE database with new accurate data, especially for intraplate events. This case also illustrates that the use of high-resolution techniques allows significantly the improvement of surface rupture characterization, potentially questioning the quality of datasets gathered in the past with vintage approaches. Those are arguments to support a deep revision of empirical relationships, based on catalogues of modern earthquakes.

Postglacial faults in Finnish Lapland

Raimo Sutinen¹, Antti Ojala², Jussi Mattila², Mira Markovaara-Koivisto², Maarit Middleton¹, Timo Ruskeeniemi², Jukka-Pekka Palmu²

¹Geological Survey of Finland, Rovaniemi, Finland. ²Geological Survey of Finland, Espoo, Finland

Abstract

Airborne LiDAR surveillance has revealed several postglacial fault (PGF) systems and a number of earthquake-induced deformations, such as paleolandslides and liquefaction features in the interior of the former Fennoscandian Ice Sheet. PGFs illustrate high-magnitude (up to $M_w \approx 8.2$) earthquakes attributable to the release of lithospheric stresses within the glacial isostatic adjustment (Arvidsson, 1996). We applied shallow geophysics, trenchings and drillings to assess mechanisms and timing of PGFs and adjacent deformation morphologies in Finnish Lapland.

The PGF zones are characterized by a number of discrete 0.2–9.1 km long fault scarp segments which form longer PGF systems. A set of PGF systems further forms a PGF complex that is typically tens of kilometers long. At the moment, 18 PGF systems making up 9 PGF complexes have been discovered with general strike trending SW–NE (Mattila et al., 2018). Several trenched sites indicate that multiple rupturing events have taken place within PGF complexes. Stratigraphy of the trenched PGF segments and the age data of landslide-buried organic materials indicate that the non-stationary seismicity occurred episodically throughout the Holocene. Based on the ¹⁴C datings at least three seismic episodes (9–11, 5–6 and 1–3 ky ago) have been found in western Finnish Lapland (Ojala et al., 2018). By applying scaling laws for faults from stable continental regions, we consider that a realistic moment magnitude range for the earthquakes that took place in Finnish Lapland are in the range of $M_w \approx 4.9–7.5$. These estimates are in accordance with maximum moment magnitude $M_w \approx 6.9–7.5$ calculations based on the landslide volume-area data (Ojala et al., 2019). Since the fault instability over Fennoscandia occurred 13–9 ka BP (Wu et al., 1999), some bedforms, such as the Pulju moraine, may indicate subglacial seismic events (Sutinen et al., 2019).

Variations in the character and geometry of grounding-zone wedges: a continuum of subglacial deposits?

Kelly Hogan¹, Robert Larter¹, Martin Jakobsson², James Smith¹, Claus-Dieter Hillenbrand¹, Zoe Roseby³, Christine Batchelor⁴, Julian Dowdeswell⁴

¹British Antarctic Survey, Cambridge, United Kingdom. ²Stockholm University, Stockholm, Sweden. ³National Oceanography Centre, Southampton, United Kingdom. ⁴Scott Polar Research Institute, Cambridge, United Kingdom

Abstract

Grounding-zone wedges (GZWs) in marine palaeo-ice stream settings are now widely accepted as subglacial deposits formed at the palaeo-ice sheet margin as it stabilised for short periods during overall retreat. Thus, they are used as strong evidence for an episodic style of deglaciation, although they are often not well dated. Current models of GZW formation describe the build-up of asymmetric, often prograded deposits just beyond the grounding line when it is fronted by an ice shelf. The ice shelf is thought to be necessary in order to provide accommodation space at the grounding line in which a deposit can form; no such accommodation space is present at a tidewater margin. Here, we review the different styles of GZWs found on both northern and southern hemisphere palaeo-ice stream beds and discuss the reasons for the observed variability. We present new data from a suite of GZWs in Anvers Trough on the Western Antarctic Peninsula just beyond Palmer Deep and compare geometries, volumes and some aspects of their sedimentology with other well-studied examples from Antarctica and Greenland. Overall, the aim of this work is to progress ideas on GZW formation and their interpretation in the palaeo-glaciological record. We are interested in answering questions including: (1) What factors control the formation and geometry of GZWs? (2) Are the quoted formation times (decades to centuries) and volumes ($10\text{-}10^2\text{ km}^3$) really representative for these landforms? (3) When is a GZW just a till sheet – do these landforms form a continuum of subglacial deposits? (4) What are the future avenues for this research?

Paleo-ice streams in Northeastern Iceland

Ólafur Ingólfsson¹, Ívar Örn Benediktsson¹, Skafti Brynjólfsson², Hreggviður Norðdahl³, Nína Aradóttir¹

¹University of Iceland, Faculty of Earth Sciences, Reykjavík, Iceland. ²Icelandic Institute of Natural History, Akureyri, Iceland. ³University of Iceland, Institute of Earth Sciences, Reykjavík, Iceland

Abstract

Ice streams exercised critical control on the dynamics of the Weichselian Icelandic Ice Sheet. Our project aims to advance our understanding of the configuration, geomorphologic imprint, dynamics and recessional history of palaeo-ice streams in NE-Iceland. Our approach is to study glacial landform associations and sedimentary records, using multiple glacial geological, geomorphological, remote sensing, geophysical and chronological methods. The project is designed to elucidate the relative timing and spatial distribution of fast ice flow, the absolute timing of ice-stream/ice-sheet recession and thinning, and the mechanisms contributing to fast flow and the genesis of streamlined subglacial bedforms. We have identified areas where ice streams have run partially uncontrolled by local topography. These include onset zones with reticulated ridges and ribbed moraines and trunk-flow zones with highly-attenuated streamlined bedforms, characterized by swarms of large drumlins. The flow patterns are highly convergent and distinct. The geomorphic record also shows time-transgressive shifts in ice stream directions, where their location got more topographic focusing, perhaps signifying change from glacial maximum situation to large-scale, rapid deglaciation. Sedimentological and stratigraphical studies have highlighted extensively deformed sediments associated with the ice stream paths, as well as evidence of basal sliding and heavy scouring of bedrock. The paleo-ice streams have terminated in the ocean, probably reaching towards the shelf edge. Presently, high-resolution bathymetrical-/geophysical-/sediment data are lacking from the shelf areas. The project can provide insight into marine-ice sheet instability and the vulnerability of marine-terminating ice streams to sea-level rise, and further our understanding of ice sheet deglaciation dynamics. An important benefit of this project will be the value of its results for constraining numerical models aimed at illuminating subglacial landform development and the evolution of the Iceland ice sheet during the last deglaciation.

Glacigenic Debris Flows along the NE Atlantic Margin Indicate Continuous High Sediment Supply during Shelf-Edge Glaciations

Benjamin Bellwald¹, Sverre Planke^{1,2,3}, Lukas Becker⁴, Reidun Myklebust⁵

¹Volcanic Basin Petroleum Research AS (VBPR), Oslo, Norway. ²Centre for Earth Evolution and Dynamics (CEED), University of Oslo, Oslo, Norway. ³Research Centre for Arctic Petroleum Exploration (ARCEX), UiT The Arctic University of Norway, Tromsø, Norway. ⁴University of Bergen, Bergen, Norway. ⁵TGS, Asker, Norway

Abstract

High-latitude trough mouth fans are high-resolution paleoclimate and ice-sheet monitors. The stratigraphy of the North Sea Fan, a trough mouth fan at the northern North Sea margin, is dominated by glacigenic debris flows (GDFs), which indicate shelf-edge glaciations of the Norwegian Channel Ice Stream. The aims of this contribution are to characterize, quantify and date GDFs formed during the last glaciation. We use 16,000 km² of high-resolution processed 3D seismic data collected in 2017 and 2018 from the proximal North Sea Fan. These data allow to image the buried GDF packages in a resolution of 8 m vertically and 20 m horizontally. Chronologies previously established by piston cores from the distal part of the North Sea Fan allow constraining the ages of these debris flows. Six seismic horizons of GDFs have been picked with an in-line spacing of 150 m, followed by gridding, horizon attribute extraction, sediment volume calculations, and seismic geomorphological interpretation. The GDF package related to the last glaciation has a thickness of up to 400 m and is characterized by a homogenous seismic facies intercalated by five continuous high-amplitude reflections, which separate the package into six sub-units. The structure maps of these reflections show multiple sharp, 5-20 m deep channels. These SE-NE-oriented channels can be traced to the shelf break and occur with a lateral spacing of 5-20 km. Characterized by a low sinuosity, these channels diverge and converge over short distances. Structure maps show flat terrains between the channels. Maps generated by seismic attributes, however, show well-developed elongated bars and lobe-shaped features next to the channels as well as densely-spaced circular depressions with diameters of c. 30 m. The correlation of the five horizons with sediment cores of the distal part of the North Sea Fan indicate an age of 19-23 ka for these sediments. The up to 400 m thick GDF package, deposited within 4 kyr, correlates with a sedimentation rate of up to 100 m/kyr, and a sediment flux of 1500 km³/kyr for the study area. The six sub-units within the GDF package indicate that the Norwegian Channel Ice Stream oscillated six times during the last glaciation. Channels identified at multiple levels within the GDF package indicate that the sediment delivery from the Norwegian Channel Ice Stream was continuous, and did not occur in pulses of several decades. Channel-fed levees and debris lobes characterize the paleo-seafloor between the channels. The circular depressions, interpreted as pockmarks, indicate fluid escape events in some intra-channel areas during the deposition of the GDFs. This study highlights the capacity of high-quality 3D seismic data for the reconstruction of sedimentary processes and past ice-sheet dynamics significant for the climatic and oceanographic evolution of the study area.

Do glacial landforms have bed roughness signatures?

Francesca Falcini¹, David Rippin¹, Maarten Krabbendam², Katherine Selby¹

¹University of York, York, United Kingdom. ²British Geological Survey, Edinburgh, United Kingdom

Abstract

Palaeo-glacial landforms can give insights into bed roughness that cannot be captured underneath contemporary ice streams. The bed of palaeo-ice sheets can be observed using high resolution Digital Terrain Models (DTMs) in its entirety, but the opportunity to learn more about bed roughness has yet to be fully realised. A few studies have focused on measuring bed roughness of palaeo-ice streams but palaeo-ice streams contain large areas of landforms, allowing glaciologists to measure bed roughness at high resolution. Using palaeo-glacial landscapes, we can test whether specific landforms have characteristic bed roughness signatures. If specific glacial landform assemblages have a characteristic bed roughness signature, these roughness attributes can be used to suggest where certain landform assemblages exist underneath contemporary ice sheets. Glacial landforms have been identified underneath very small areas of contemporary ice streams, but using bed roughness signatures could increase the known areas where landforms exist. This would provide more detail about contemporary ice sheet beds, such as the link between ice speed and types of landforms, and could improve the reconstruction of palaeo-ice streams.

In order to test these hypotheses transects were established over glacial landform assemblages (including mega grooves, mega scale glacial lineations and drumlins) in the UK and high resolution NEXTMap DTM (5 m) was used to calculate bed roughness. Transect spacing and orientation were investigated to ascertain if they affected roughness measurements. We find that landforms composed of sediment are smoother compared to bedrock derived landforms. Landforms with a higher elongation ratio have a more anisotropic bed roughness than landforms with a lower elongation ratio. The results show how transect orientation in relation to palaeo-ice flow direction is likely to be an important part of defining landform bed roughness signatures. The combination of total roughness and anisotropy of roughness (difference between roughness parallel and orthogonal to ice flow) does suggest that some landform assemblages do have a characteristic roughness signature.

Reconstructing the dynamics of palaeo-ice stream lateral shear margins from landforms and stratigraphic records

Martin Ross¹, Shawn Scott¹, Janet Campbell², Honjing Chen¹, Richard Kelly¹, Michel Chouteau³, Pejman Shamsipour³, Tyler Hodder⁴

¹University of Waterloo, Waterloo, Canada. ²Natural Resources Canada, Ottawa, Canada. ³École Polytechnique de Montréal, Montréal, Canada. ⁴Manitoba Geological Survey, Winnipeg, Canada

Abstract

Lateral shear margins (LSM) form along the sides of an ice stream due to the steep velocity gradient across the narrow boundary separating fast and slow ice flow. Processes taking place along these margins are thought to play an important role in the long-term behaviour of ice streams. For example, migration of LSM can affect ice stream width, which can lead to changes in ice and sediment discharge to ice stream terminus. It is still unclear what controls the initial location of LSM, but their behaviour appears to be sensitive to basal conditions and feedbacks between migration rate and the local temperature field. We have examined the geological record of a number of palaeo-ice stream LSMs from the Canadian glacial landscape to get insights into their long-term dynamics. We used geomorphological mapping, airborne and ground geophysics, as well as targeted stratigraphic and till provenance analysis and data classification techniques. Our results show evidence for lateral migration of LSM, especially for the large palaeo-ice streams thought to have operated over several thousand years. Certain LSM are characterized by stratified drumlins containing stacked till sheets of contrasting dominant provenance (i.e. proximal vs distal), which we interpret as evidence of oscillations in the position of the LSM across zones a few kilometers wide. Some of these zones are located along regional fault systems suggesting a possible bedrock control on LSM position, notably in upstream regions. Other LSM investigated in this study show less evidence for lateral migration and, in some cases, better developed LSM moraines. The relationship with bedrock structures and properties, and other potential controlling factors (e.g. scale of ice stream, duration) will need to be further investigated.

Ice streams in the Laurentide Ice Sheet during the last deglaciation

Martin Margold¹, Chris R. Stokes², Chris D. Clark³

¹Charles University, Prague, Czech Republic. ²Durham University, Durham, United Kingdom. ³University of Sheffield, Sheffield, United Kingdom

Abstract

The Laurentide Ice Sheet (including the Innuitian Ice Sheet) constituted the largest ice mass in the Northern Hemisphere during the Last Glacial Maximum. Reconstructions based on the geomorphological record show that it was drained by a network of ice streams not dissimilar from those observed in the present day ice sheets in Greenland and Antarctica. The configuration of the ice drainage network changed with the ice margin retreat during the deglaciation, which we reconstruct using the available ice margin chronology. The regional stability of the ice drainage network was dependent on the pace of the ice retreat. Marine margins in the north featured topographically controlled ice streams occupying pronounced troughs on the continental shelf and operating long into the Late Glacial. In contrast, ice streams draining towards the terrestrial margin in the west and southwest were more transient. The most dynamic changes in the ice drainage network were seen in connection with the collapse of the saddle between the Cordilleran and Laurentide ice sheets on the Interior Plains. Here, a rapid change in the direction of ice streaming is recorded in multiple cross-cutting ice stream tracks. The retreat of the western Laurentide margin onto the rigid bed of the Canadian Shield marked a pronounced change in the ice streaming network; ice streams became broader and less frequent. The final collapse of the ice sheet after the Younger Dryas was accompanied by brief deglacial ice streams that likely originated in response to the rapid changes in the ice sheet geometry. Future research might attempt to replicate our empirical results with high-resolution numerical models. Successful numerical modelling of the last deglaciation that would match the reconstructed ice sheet evolution, including its ice drainage pattern, would allow for producing reliable scenarios of the long-term fate of the modern ice sheets.

The onshore imprint of the Northeast Greenland ice stream and 79N ice ice shelf

David Roberts¹, James Smith², Stewart Jamieson¹, Michael Bentley¹, Brice Rea³, Tim Lane⁴, Chris Darvill⁵, Louise Callard¹

¹Durham University, Durham, United Kingdom. ²British Antarctic Survey, Cambridge, United Kingdom. ³University of Aberdeen, Aberdeen, United Kingdom. ⁴Liverpool John Moores University, Liverpool, United Kingdom. ⁵Manchester University, Manchester, United Kingdom

Abstract

Understanding the impacts of climate change on ice sheets and the subsequent changes to global sea-level over 100 - 1000yr timescales are fundamental scientific and societal challenges. This project focuses on the Northeast Greenland Ice Stream (NEGIS); a key sector of the Greenland ice sheet (GrIS) because it controls ice flux into the NE Atlantic (an area sensitive to freshwater input) and it holds a sea-level equivalent (SLE) of ~1.4m. This sector of the ice sheet is predicted to be vulnerable to future climatic changes and is also known to have undergone dramatic retreat during the Holocene Thermal Maximum. The project aims to reconstruct the past behaviour of NEGIS in order to calibrate and validate the sensitivity of 3D numerical models that can predict ice stream-shelf dynamics over 100 - 1000yr timescales.

Along the north edge of 79N abraded terrain, erratic spreads and lateral moraines record warm-based ice up to 600-850m asl, with the ice stream coalescent with local ice caps to the north as ice moved offshore at the LGM. During early deglaciation a series ice contact deltas mark ice stream/ice cap decoupling, surface thinning and the formation of ice-dammed lakes along the margin of 79N. These may mark an upstream response to early ice recession from the continental shelf edge around 19.7 – 15.6 ka cal. BP.

The transition from ice stream to ice shelf in 79N occurred between 12 – 10 ka cal. BP, and the migration of the ice stream/shelf system onshore can be tracked using new geophysical and sedimentological data. Once within the confines of the 79N fjord the ice shelf retreated and disintegrated ~80 km upstream of the present ice shelf margin by ~ 8.0 ka cal. BP. This led to a period of open marine conditions in 79N fjord during the Holocene Thermal Maximum, as demonstrated by epishelf lake and marine sediments which contain whale, seal, mollusc and fish remains. However, post 4.0 ka cal. BP Neoglacial cooling triggered ice stream/shelf regrowth resulting in eastward grounding line migration and the cessation of marine conditions in the epishelf lake at Blaso. This ice advance/thickening phase culminated in the formation of prominent LIA ice shelf moraine systems adjacent to the 79N ice shelf.

³Heidelberg Academy of Sciences, Frankfurt/Main, Germany. ⁴Tübingen University, Tübingen, Germany. ⁵Trier University, Trier, Germany. ⁶CENIEH, Burgos, Spain

Abstract

Dispersal events of early humans are diagnosed on the basis of evidence of their presence in time and space, i.e. spatiotemporal shifts in the geographical distribution of hominin fossils. Corresponding to the punctuated distribution of the evidence large scale shifts like Out of Africa events and the initial occupation of the Eurasian continent are predominantly described on large spatial and temporal scales. For modelling purposes, diffusion models directed by features of the environment seem to be considered appropriate to reflect dispersal on such scales.

Large scale shifts result, however, from regional shifts of populations and seasonal and/or rather local mobility patterns of groups. They need to be studied on smaller scales and they require more sophisticated quantitative models for spatiotemporal movement patterns. Two basic strategies of mobility of hunter-gatherer groups are distinguished, i.e. logistical and residential strategies. A residential strategy is pursued when resource availability is predictable and does not undergo major shifts, while humans follow a logistical strategy, when resource distribution is patchy and changes radically in a seasonal manner. Hominin groups should therefore adopt different mobility strategies, depending on the extent of seasonal shifts in habitat productivity. The resulting hypothesis is tested by linking the Neanderthal archaeological record with seasonal shifts in habitat productivity around the last interglacial.

Both strategies moreover involve different spatial requirements and should therefore lead to different migration behaviors. Migrations will be targeted towards areas with improved resource availability. Moreover, particular routes can be inferred. Migration routes which are not entirely circular (i.e. do not involve returns to the exact point of departure) lead to dispersal. On this level, encounters with other groups and as well as human and non-human competitors should be integrated. The interpretation of dispersals resulting from group based mobility strategies and seasonal migrations requires more sophisticated modelling approaches, than represented by diffusion models.

Environmental models should reflect changes in food resource availability, e.g. by being based on relative changes in productivity and a migration analysis of large herbivores. In such environments, groups of agents should pursue mobility strategies and chose them in accordance to resource availability. Therefore, agents should explore their environment through movement and vision. They should monitor the actual state of the environment and share this information with other group members. Furthermore, they should be able to save past states of the environment within their exploration area to decide the appropriate mobility strategy.

In this contribution a variety of quantitative models will be presented. Furthermore, we examine links between them and explore their potential to be transferred into an agent-based modelling context.

Abstract

The Early Middle Pleistocene transition (EMPT) occurs between about 1 to 0.6 million years and is characterized by drastic climatic changes which affected the structure and organization of ecosystems on a global scale. Stone tools and human fossils from sites located in southwestern Europe (i.e. Guadix-Baza Basin and Atapuerca, Spain; Pirro-Nord, Italy) document hominin presence in Europe at least at 1.4 million years. However, occupation patterns throughout the EMPT ranging approximately from 1.6 to 0.4 million years remain unclear as a consequence of significant technological shifts and hiatus of occupations possibly derived from multiple arrivals of populations. Due to the punctual structure of the fossil and archeological records across large time spans, it is challenging to derive the dynamics of the occupation patterns in Europe exclusively on this basis. In order to understand past hominin distribution, it is necessary to assess driving factors and mechanisms behind the spatial interactions of hominins. We apply agent-based modeling to address the question of hominin occupation patterns during the EMPT in Europe. This method permits integrating up-to-date environmental models with models of spatial interactions in dynamic simulations.

In this talk, we present two exemplary models on different spatio-temporal scales that have been developed within the “Modeling Environmental Changes and Hominin Dispersals around the Mid-Pleistocene Revolution” (METHOD) IFG. Firstly, we present the “MPR Hominin Dispersal ABM” designed to examine the dispersal of stone tool technologies from Africa into Eurasia. Here, the agents represent hominin groups that exchange tool technology in various ways. Because of the large spatio-temporal scale of the model, the dynamically changing environment takes into account warm and cold phases as well as changing sea levels. Secondly, we use the “MoReDoH ABM” where an agent represents a hominin individual moving across the landscape to gather resources. We compare different mobility strategies of a hominin group within a particular region of the Baza Basin (Spain). In this case, the environmental dynamics reflect seasonal changes because this model considers mobility and migration on a regional scale.

These two examples led us to discuss about the application of agent-based modeling to test hypotheses of spatial interactions at different scales. Once a model is implemented, we can assess the effect of certain factors by explicitly

including or excluding them. With the aid of computational simulation we may then support or refuse common hypotheses in order to help in gaining an understanding about the spatial and foraging behavior of extinct hominins.

A Multiagent Framework for Simulation-Based Analysis of Early Human Mobility Strategies

Jan Ole Berndt¹, Ericson Hölzchen², Christine Hertler², Ingo J. Timm¹

¹Trier University, Trier, Germany. ²Senckenberg Research Institute, Frankfurt am Main, Germany

Abstract

Hunter-gatherer populations need to be mobile. They have to forage in small parties for food and other resources as well as adapt to seasonal changes by moving larger groups to places with advantageous conditions. There are two extreme strategies known for this spatiotemporal behavior (with a range of mixed variants in between): The logistic strategy (1) in which groups remain in one area while focusing mainly on foraging activities to fulfill their needs and the residential strategy (2) in which entire groups move frequently from one area to another while depending less on foraging parties. Which strategy is most beneficial depends on resource abundance, heterogeneity, distribution (i.e., patchiness), as well as amount of seasonal change. For recent hunter-gatherer populations, these behavioral strategies are directly observable. In contrast, early human spatiotemporal behavior in the Pleistocene can only be assessed from the sparse archeological record that results from specific mobility patterns.

In order to complement the archeological evidence of human mobility, we present a multiagent-based modeling and simulation framework for analyzing different movement strategies. Our framework allows for representing reconstructed as well as artificially generated environments for systematic spatiotemporal strategy evaluation. We show how to implement seasonality and man-made changes in the environment which drive the agents' mobility patterns. Moreover, we present an agent architecture which facilitates complex behavior of agent groups. By making individual decisions, the agents adapt to the environmental conditions, resulting in optimally fitted strategies. Using artificial intelligence methods, particularly machine learning and evolutionary computation, our framework thus provides a testbed for hypothesis-driven experimentation with early human mobility.

To demonstrate its application, we furthermore present the design and results of a simulation-based mobility strategy analysis. Specifically, we evaluate the hypothesis that small seasonal changes in environmental net primary productivity (i.e., resource availability) favor logistical mobility patterns whereas higher change rates and more patchy resource distributions result in a tendency toward residential mobility strategies. We present the results of that study and discuss how our simulation framework can be used to analyze such a research hypothesis.

Modeling ancient cannibals as optimal foragers

Jesús Rodríguez, Ana Mateos

National Research Center on Human Evolution (CENIEH), Burgos, Spain

Abstract

Cannibalism is a practice documented in several hominin species since the Early Pleistocene. However, the causes and meaning of consuming other humans are still hotly debated. The reasons proposed to explain this behaviour range from social and cultural motivations to purely nutritional causes. Behavioural Ecology provides a theoretical framework to understand human behaviour based on the assumption that humans, like any other animal, act to increase their reproductive fitness. In that theoretical framework, the Optimal Foraging Theory (OFT, Pyke et al., 1977) establishes that foragers confronted by a number of options adopt the strategy that maximizes their fitness and that this is equivalent to maximize nutrient return and minimize acquisition cost. We show here how cannibalism may be understood in the context of the OFT taking as an example the oldest case of cannibalism registered in the archaeological record.

The remains of seven hominins (*Homo antecessor*) with unquestionable signs of cannibalism were found in the TD6.2 unit of the Gran Dolina site (Sierra de Atapuerca, Spain), dated to c. 0.9 Ma. The TD6.2 fossil assemblage also includes a large collection of fossils of other 16 species of large mammals, and nine of them show cut marks and other evidence of human consumption. We apply a Prey Choice model based on MacArthur and Pianka's (1966) diet breadth model to the TD6.2 assemblage to evaluate whether *Homo antecessor* behaved as an optimal forager and selected its food resources according to their energetic return rate, as predicted by the model. Analyzed in this way, humans appear as a high-ranked prey type, i.e. a prey which produces a high energetic return at a low cost. Moreover, the abundance of the different prey types in the TD6.2 assemblage is proportional to the abundance of those resources in the environment (their estimated population densities), as predicted by the OFT. Thus, cannibalism in *Homo antecessor* may be explained just because *H. antecessor* behaved as an optimal forager and humans were a high ranked resource type.

However, although it is an optimal behaviour to obtain energy, cannibalism is not an optimal strategy to increase reproductive fitness if it is practice as a habit. Other humans are also potential sexual mates and necessary allies to warrant survival. Thus, OFT allows us to explain why anthropophagy is present in many ancient human societies, but behavioural ecology also explains why cannibalism cannot be a dominant practice.

Featuring hominins as actors in the MPR scenarios

Ana Mateos, Jesús Rodríguez

National Research Center on Human Evolution, Burgos, Spain

Abstract

The Mid-Pleistocene Revolution (MPR) was a period of profound ecosystem reconfiguration around 1 Ma. It is generally accepted that those environmental changes affected the survival opportunities and the distribution patterns of humans in Europe. Modeling the behavioural responses of humans to the changing environments of the MPR entails the energetic characterization of hominins. By “energetic characterization” we mean that it is necessary to infer their daily energetic requirements as well as their energetic expenditure.

The energetic requirements of a hominin are determined by its palaeophysiology, and they are mainly affected by the species body size, but also vary with age, sex and physiological stage. However, palaeophysiology also affects the energetic cost of the daily activities necessary to survive and reproduce. The energetic requirements of ancient hominins may be estimated by extrapolation of the predictive equations experimentally developed for recent humans and based on body size, age and sex.

Concerning the cost of daily activities, however, a specific research program on experimental energetics is required. That experimental program should involve the re-enactment of the basic daily activities of a hunter-gatherer in a number of volunteers to measure their energetic cost and to identify the possible influence of body composition and architecture on the energetic expenditure. Eventually, those experimental data may be extrapolated to ancient hominins. Such an experimental research program is currently under development at CENIEH. The activities recreated up to date include the catchment of raw materials (Vidal-Cordasco et al. 2017a), gathering of vegetable resources (Prado-Nóvoa et al, 2017a), and stone knapping (Mateos et al. 2018). Other experimental studies were carried out to estimate the cost of walking and burden transport during foraging activities (Vidal-Cordasco et al, 2017b). Additional research, currently under development, include the energetic expenditure of butchering animal carcasses and digging in search of underground plant resources, as well as further experiments on locomotion. All these experiments are performed by individuals of different ages (adults, adolescents and children), both genders and in different reproductive stages (e. g. pregnant and lactating women), since all those factors affect energetic expenditure. The objective of this ambitious research program is to establish the daily energetic expenditure profile of any individual in a hunter-gatherer population as a function of its age, sex and physiological stage.

Evolutionary response of early human behavior during the Mid-Pleistocene Transition in East Asia

Shi-Xia YANG

Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China.
Department of Archaeology, Max Planck Institute for the Science of Human History, Jena, Germany

Abstract

Mid-Pleistocene climate transition (MPT), occurring at ca. 1.25–0.8 Ma¹⁻³, is an important stage of Quaternary period. After MPT, into the Middle Pleistocene, the length and intensity of the glacial-interglacial cycles significantly increased, with the dominant periodicity of high-latitude climate oscillations changing from 41 ka to 100 ka¹⁻³. During the MPT, a series of changes documented in the archaeological records as well, such as the density of the artifacts and the technique innovations changed dramatically from the beginning to the end of the MPT.

Recent years, a series of archaeological researches, revealed several important sites and provide a comprehensive understanding of the cognitive ability of early humans East Asia⁴⁻⁶. In North China, a sample of the Nihewan sites will be selected in order to assess the cognitive ability of early humans. For example, the Cenjiawan site, with a relative high refitting rate of stone artefacts (33.4 %, 462 pieces in 1383), can be used to reconstruct knapping sequences, which in turn allows evaluation of planning depth⁴. The Donggutuo site, with a high percentage of retouched pieces (10.2%), can also be used to learn about tool production skills of early hominins⁵. In Central and South China, Yunxian Man site and sites in Bose Basin give good examples to evaluate the cognitive ability of early human populations. The Large-cutting-tools (LCT) of Bose Basin represent a target morphology and increasing LCT refinement⁶.

The MPT should be a key period tied directly to the archaeological records, and a series of questions should be highlighted, including assessment of how early hominins adapted and survived in changing environments of East Asia; whether early humans innovated their technologies and landscape behaviors over MPT.

Testing palaeoclimate reconstructions for the Acheulean in southern Africa using climate models

Michaela Ecker¹, Hiromitsu Sato²

¹Archaeology Centre, University of Toronto, Toronto, Canada. ²Department of Earth Sciences, University of Toronto, Toronto, Canada

Abstract

Recent palaeoenvironmental reconstructions at the archaeological significant site of Wonderwerk Cave, in the interior of South Africa, revealed a significantly wetter environment and non-analogous vegetation structure in the Early Pleistocene. This includes the presence of grasses following the C₃ and the C₄ photosynthetic pathway, whereas after the mid-Pleistocene transition C₃ grasses are declining¹. They are not a part of the local vegetation during the Holocene at all. This contribution is exploring the drivers behind such a shift in vegetation using a vegetation model (LPX) driven by General Circulation Model (GCM) climate reconstructions. We modelled vegetation for glacial climates under different levels of CO₂ to test if a change to lower CO₂ levels at c. 800ka led to the spread of C₄ grasses at the expense of C₃ grasses due to more severe stress. The largest change was observed between 150ppm and 250ppm CO₂. Our results confirm the trends observed in the palaeoenvironmental studies for the southern Kalahari region. Other areas of eastern South Africa and East Africa, which already have a substantial C₄ grass component before the mid-Pleistocene revolution, are less effected. This has implications for hominin responses during the later phase of the Early Stone Age as seen in the rich Acheulean cultural record of the Wonderwerk Cave region, which contrasts with a much sparser late Pleistocene record.

Past glacier fluctuations in the Rwenzori Mountains, Uganda, and implications for tropical temperature during and since the last ice age

Margaret Jackson¹, Meredith Kelly¹, James Russell², Alice Doughty³, Susan Zimmerman⁴, Robert Nakileza⁵

¹Dartmouth College, Hanover, USA. ²Brown University, Providence, USA. ³Bates College, Lewiston, USA. ⁴Lawrence Livermore National Laboratory, Livermore, USA. ⁵Makerere University, Kampala, Uganda

Abstract

The tropics comprise nearly half the Earth's surface and are the primary source of latent heat and water vapor to the global atmosphere. Through phenomena such as the El Niño Southern Oscillation, the region is also the dominant control on modern interannual climate variability. The tropics today are undergoing rapid change; high-altitude regions are warming at a rate nearly twice the global average. Determining how the tropics will respond to future warming is fundamental to projecting accurately the impacts of global climate change, and has direct ramifications for the billions who live in low-latitude regions. One approach to assessing the likely impact of the tropics in future climate scenarios is to establish their role in previous climate transitions using proxy records of past temperature. Tropical glaciers are particularly sensitive to changes in temperature and thus make excellent paleo-thermometers. Determining the timing and magnitude of past changes in tropical glacier extent therefore provides a window into past temperature in the low latitudes. The equatorial Rwenzori Mountains, Uganda, represent the most extensive alpine-glacier environment in Africa. We use beryllium-10 surface-exposure dating to determine a chronology of glacier fluctuations in the Rwenzori during and since the Last Glacial Maximum (~30 ka to present), the most detailed such chronology from Africa. We also compare these results to similar chronologies produced from the South American tropics. Our results indicate that glaciers across the tropics, both in Africa and the low-latitude Andes, fluctuated in unison during and following the last ice age. This pattern indicates that tropical glaciers responded to a common forcing mechanism over this time, most likely temperature. The apparent synchrony of temperature change in the low latitudes over the last ~30 ka has direct implications for the roll of greenhouse gases and high-latitude ice-sheet and sea-ice dynamics in setting tropical, and global, temperature over millennial timescales.

Diatomite evidence for a southern African late Quaternary palaeolake at 3,400m.asl

Jennifer Fitchett¹, Anson Mackay²

¹University of the Witwatersrand, Johannesburg, South Africa. ²University College London, London, United Kingdom

Abstract

The eastern Lesotho highlands is commonly termed the 'water tower' of southern Africa. The region experiences a mean annual rainfall of >1,600mm, and supplies the South African highveld with water via the Lesotho Highlands Water Project. Unique for a region with such abundant moisture availability, is the absence of natural lakes. Mafadi Summit hosts the highest altitude wetland in southern Africa, located at the bottom of a bowl-shaped depression at 3,480 m.asl. Palaeoenvironmental reconstructions for the site, based on pollen, diatoms and sedimentary properties, reveal considerable fluctuations in hydrology and the spatial extent of this wetland. For example, diatom and pollen records suggest that the depression was occupied by standing water about 8,400-8,000 cal yr BP. However, upslope of this wetland are a number of notable diatomite outcrops at varying elevations. These are hypothesised to represent palaeo-water levels, and if this is correct, reveal a substantial palaeolake at the site which would likely date to the Last Glacial Maximum, when regional moisture levels were heightened. Here we report on satellite remote sensing of the diatomite deposits, and diatom analysis from two sediment cores extracted from these diatomite outcrops. The primary aims are to determine the age and spatial extent of the diatomite outcrops, and the depth of the standing surface waters, which may uncover the first definitive lake in the eastern Lesotho Highlands. This record also contributes to the paucity of palaeoclimatic records for the Maloti-Drakensberg.

⁵University of Reading, Reading, United Kingdom

Abstract

Our understanding of African hydroclimate dynamics on time scales longer than a few decades is largely dependent on natural climate archives. While still at least an order of magnitude lower than in the northern temperate zone, central and southern Africa have seen a substantial increase in the number of published paleoclimate reconstructions in recent decades, many of which have been extracted from (paleo-) lake deposits. Arguably the most universal relationship between climate and a lake ecosystem, especially in endorheic basins, is the control of the precipitation-evaporation balance (P-E) on lake volume (itself a function of lake depth and surface area). We present a research data base of published information on lake depth ('lake status') of more than 50 (paleo-) lake sites in eastern and southern Africa over the last 50,000 years. This data base provides a tool for assessing hydroclimatic changes at multiple time scales which can be compared to other syntheses of ecosystem change or to paleoclimate modelling products. Importantly, the inclusion of details on chronological and proxy support for each individual site allows a necessary quality control of the available paleolimnological evidence. Using the data base, we elucidate and discuss spatio-temporal patterns of hydroclimate change in eastern and southern Africa during globally recognized decade- to millennium-scale events. A first focus is the deglaciation, during which a sequence of events (Heinrich Stadial 1, Younger Dryas) brought severe hydroclimate disruption to much of the African continent. A second focus is the last millennium, for which the spatial patterns of wetness and drought throughout equatorial East Africa are examined more deeply, illustrating the complicated hydroclimatic variability that strongly impacts the region's ecosystems on time scales relevant to human societies.

A multiproxy record of Meghalayan change from a paleommarsh at the southern margin of the Kalahari.

Magdalena Sobol¹, Michael Chazan¹, Sarah Finkelstein¹, Louis Scott²

¹University of Toronto, Toronto, Canada. ²University of the Free State, Bloemfontein, South Africa

Abstract

In this study we investigate the timing and nature of relatively wet conditions in the late Holocene by examining a multiproxy paleoenvironmental record from Kathu Pan, a paleommarsh located at the southern edge of the dry Kalahari region. In a region where organic proxy records are scarce, Kathu Pan provides a unique record of changes in past environmental conditions. Pollen, spore, charcoal, and stable isotope records were obtained from organic deposits from Kathu Pan and examined within a radiocarbon-constrained chronological framework. Kathu Pan records register a wet phase occurring between 4.8 ka and 2.5 ka cal BP. Local environmental conditions at Kathu Pan shift gradually starting around terminal Northgrippian ~4.8 ka cal BP. With the beginning of the Meghalayan Stage (~4.2 ka cal BP), Kathu Pan reaches peak values for positive moisture balance indicating local marsh conditions; these changes are marked by increased organic content, dominance of Cyperaceae pollen, presence of freshwater fungi, and $\delta^{13}\text{C}$ values consistent with C3 vegetation. The wet phase lasts ca. 2000 years until an abrupt shift to arid conditions occurs c. 2.5 ka cal BP leading to a change in local hydro-climate that effectively terminates the accumulation of organic matter.

Desert lakes in the late Quaternary: Hydroclimate variability in the southern African interior.

Sallie Burrough¹, Joy Singarayer², Charlie Williams³, Martin Hipondoka⁴, Rob Bryant⁵, Frank Eckardt⁶

¹University of Oxford, Oxford, United Kingdom. ²Reading University, Reading, United Kingdom. ³University of Bristol, Bristol, United Kingdom. ⁴University of Namibia, Windhoek, Namibia. ⁵University of Sheffield, Sheffield, United Kingdom. ⁶University of Cape Town, Cape Town, South Africa

Abstract

Despite a long history of investigation, late Quaternary hydroclimate of southern Africa's dry interior, remains poorly understood. This is due in part to a lack of robust palaeo-archives, and in part to the complexity of local hydrological & ecological responses to climate change. An increasing suite of climate model simulations suggest a wetter than present Last Glacial Maximum and a drier than present mid-Holocene "African Arid Period" in the interior of southern Africa. In addition, there appears to be distinct sub-continental spatial variability of rainfall patterns governed by the differing behaviour of the tropical rainbelt over continental and coastal regions. In some cases, model data suggest large catchments, such as that of the Makgadikgadi basin, may integrate these differing spatial patterns of rainfall in their basin response adding a level of complexity to regional palaeoenvironmental records. Major hydrological change is predicted at a number of scales including on a ~20 kyr precessional cycle and a high-amplitude response to millennial/submillennial-scale forcing at high latitudes. Using available palaeo-hydrological-records, we test these model driven hypotheses and attempt to shed light on southern Africa's elusive hydroclimate history.

Enhanced Mediterranean water cycle explains increased humidity during MIS 3 in North Africa

Mike Rogerson¹, Yuri Dublyansky², Dirk L. Hoffmann³, Marc Luetscher⁴, Christoph Spötl², Paul Paul Töchterle²
¹University of Hull, Hull, United Kingdom. ²University of Innsbruck, Innsbruck, Austria. ³Department of Human Evolution, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany. ⁴Swiss Institute for Speleology and Karst Studies (IS SKA), La Chaud-de-Fonds, Switzerland

Abstract

We report a new fluid inclusion dataset from Northeast Libyan speleothem SC-06-01, which is the largest speleothem fluid inclusion dataset for North Africa to date. The stalagmite was sampled in Susah cave, a low altitude coastal site, in Cyrenaica, on the northern slope of the Jebel Al-Akhdar. Speleothem fluid inclusions from latest Marine Isotope Stage (MIS) 4 and throughout MIS 3 (~67 to ~30kaBP) confirm the hypothesis that past humid periods in this region reflect westerly rainfall advected through the Atlantic storm track. However, most of this moisture was sourced from the Western Mediterranean, with little direct admixture of water evaporated from the Atlantic. Moreover, we identify a second moisture source likely associated with enhanced convective rainfall within the Eastern Mediterranean. The relative importance of the western and eastern moisture sources seems to differ between the humid phases recorded in SC-06-01. During humid phases forced by precession, fluid inclusions record compositions consistent with both sources, but the 52.5–50.5ka interval forced by obliquity reveals only a western source. This is a key result, showing that although the amount of atmospheric moisture advections changes, the structure of the atmospheric circulation over the Mediterranean does not fundamentally change during orbital cycles. Consequently, an arid belt must have been retained between the Intertropical Convergence Zone and the mid-latitude winter storm corridor during MIS 3 pluvials.

How Bayesian modelling can revolutionise the science behind past climate change

Andrew Parnell, Niamh Cahill
Maynooth University, Maynooth, Ireland

Abstract

Climate scientists are famous for their poor use and understanding of statistical approaches. In this talk I will discuss some of the common problems in the statistical reconstruction of past climate and point out how Bayesian inference can partly solve some of these challenges. Examples will be provided from the reconstruction of past climate from pollen proxies and the estimation of past and present sea level rise.

O-4149

Combining a proxy synthesis and climate simulations for spatial reconstructions of European climate using Bayesian filtering

Nils Weitzel^{1,2}, Andreas Hense², Christian Ohlwein²

¹Institut für Umweltphysik, Universität Heidelberg, Heidelberg, Germany. ²Institut für Geowissenschaften und Meteorologie, Universität Bonn, Bonn, Germany

Abstract

Probabilistic spatial reconstructions of past climate states are valuable to quantitatively study the climate system under different forcing conditions because they combine the information contained in a proxy synthesis in a comprehensible product. Unfortunately, they are subject to a complex uncertainty structure due to complicated proxy-climate relations and sparse data, which makes interpolation between samples difficult. Bayesian statistics features promising properties to handle these issues like the possibility to include multiple sources of information and to quantify uncertainties in a statistically rigorous way.

We present a Bayesian filtering framework that combines a network of pollen and macrofossil samples with a spatial prior distribution estimated from a multi-model ensemble of climate simulations. Different formulations of the prior distribution, which are motivated by data assimilation and postprocessing literature, are compared. To transfer the vegetation data into (local) climate information, we apply a forward version of the probabilistic indicator taxa model. The Bayesian inference is performed using Markov chain Monte Carlo methods.

Mean temperature of the warmest and coldest month in Europe during the mid-Holocene are reconstructed using a published pollen and macrofossil synthesis in combination with the PMIP3 mid-Holocene ensemble. The performance of the different prior distribution formulations are assessed using identical twin and cross-validation experiments. Our framework is flexible and extensions like including additional proxy types and extended paleosimulation ensembles can be envisaged.

O-4150

Searching for the deglaciation: sampling spatio-temporal climate uncertainty for simulating ice sheet evolution

Lauren Gregoire¹, James Salter², Daniel Williamson², Tamsin Edwards³

¹University of Leeds, Leeds, United Kingdom. ²University of Exeter, Exeter, United Kingdom. ³Kings College London, London, United Kingdom

Abstract

Ice sheet models fail to reproduce reconstructed patterns of Northern Hemisphere ice sheet retreat through the last deglaciation (21,000-6,000 years ago) without tuning of the climate input. This is the main barrier to understanding the role of ice sheets in past abrupt climate and sea level changes. The primary reason for this failure, is the large uncertainty in past climate change, which cannot be tackled by conventional uncertainty quantification methods because of the complexity, multidimensionality and large volume of climate data.

We developed a novel statistical method at the cutting edge of machine learning to systematically explore the uncertainty in the temporal and spatial evolution of temperature through the last deglaciation. It combines output from transient General Circulation Model (GCM) simulations of the last 21,000 years (from the FAMOUS and CCSM3 climate models) with proxy records of surface temperature changes. The method consists of decomposing the pattern of variability through time and space within the ensemble of transient climate simulations. Bayesian statistical methods were used to combine these patterns of variability to generate thousands of time-evolving climate fields that match reconstructed temperatures within their envelopes of uncertainty. We used this ensemble of plausible deglacial climates to drive 1500 simulations of the North American ice sheet evolution 21,000-6,000 years ago, where climate and ice sheet parameters were simultaneously varied. We designed a metric to assess how well the results match the reconstructed evolution of ice sheet extent (Dyke, 2004) and ice volume. Three waves of simulations were run, refining the uncertain climate inputs and ice sheet parameters after each wave to find simulations that best matched reconstructed ice sheet evolution. A subset of the best simulations shows that ice extent is well simulated at the last glacial maximum (21,000 years ago). Some errors occur in the pattern of ice retreat in the interior of the continent, calling for further refinements of this innovative method and more climate model and observational data (currently being generated internationally).

Our work demonstrates how observations and models of climate and ice sheets can be combined within a Bayesian statistical framework to better understand the co-evolution of climate and ice sheets in the past. This approach of running ensembles of simulations is crucial for understanding the response of ice sheets to past climate changes and the potential triggering of ice sheet instabilities, which lead to rapid sea level changes.

O-4151

Quantifying the Information Content of Relative Sea-level and Geodetic Data for Constraint on North American GIA Models

Lambert Caron¹, Erik Ivins¹, Corné Kreemer², Geoffrey Blewitt², William C. Hammond²

¹JPL/Caltech, Pasadena, USA. ²University of Nevada Reno, Reno, USA

Abstract

The data required for making substantive improvements to glacial isostatic adjustment (GIA) models over the North American continent and environs are now available. New data include the traditional relative sea-level (RSL) records of the last glacial cycle, enriched in value by expansions in spatial and temporal coverage, and those derived from modern geodesy, including spaceborne gravimetry and land motion recorded by GPS stations. Recent analysis of the latter by Kreemer et al. (2018) reveal that an untapped source of potential GIA constraint may emerge by examining the horizontal velocities and strain rate field, both in model and data representations. Using Bayesian statistics and concepts derived from information theory, we analyze results from an ensemble of thousands of forward GIA models. From the resulting statistics we are able to characterize, quantify and intercompare the information content provided by each subset of data for constraining GIA. There is great value in isolating each of the subsets of RSL, vertical and horizontal GPS velocity fields (and horizontal strain rates) as such illuminations provide information for planning additional field work at remote shorelines and potentially viable new geodetic sites.

We consider variations of ice history, through a set of scaling coefficients, as well as the mantle viscosity profile. Our goal is to estimate the relative gain in model confidence that each dataset provides for better constraining mantle structure and ice history input parameters, the range of common solutions between all datasets as well as the redundancy of information between them.

Estimating global sea level over the late Holocene using a spatio-temporal empirical Bayesian hierarchical framework

Erica Ashe¹, Nicole Khan^{2,3}, Benjamin Horton², Robert Kopp¹

¹Rutgers University, New Brunswick, NJ, USA. ²Nanyang Technological University, Singapore, Singapore. ³University of Hong Kong, Hong Kong, China

Abstract

Many global, regional and local-scale processes affect relative sea-level (RSL) change across the globe, and constraining the magnitude of these contributions, their variability, and the recent effect of climate in the past can give insight into future sea-level rise. To our knowledge, no global sea-level (GSL) change estimates, based on the statistical synthesis of a global database extend back over the last ~4,000 years. The increasing availability and geographical coverage of continuous, high-resolution RSL reconstructions provides a new opportunity to formally estimate GSL in relation to climate and quantify the contributions to RSL change over this time period.

Using the semiempirical, hierarchical model of Kopp et al. (2016; K16), we re-asses the relationship between temperature and GSL variability over the late Holocene (past ~4000 years). We have compiled a global atlas of late Holocene sea-level index points from near, intermediate and far field sites. The atlas consists of over 6,000 sea-level index points, which show relative sea-level (RSL) varied between > 50 m and < -8 m over the past 4000 years. We apply the K16 model to the atlas and compare the results to the temperature reconstruction of Marcott et al., 2013.

This statistical model deconstructs RSL, quantifying contributions from global, regional linear, regional non-linear, and local-scale processes using a spatio-temporal empirical Bayesian hierarchical framework with prior distributions defined by various glacial isostatic adjustment (GIA) models. We assess the sensitivity of the model to these priors as well as to the information gain from potential new data at various times and spatial locations. We produce a GMSL estimate for the last 4000 years, compare it to global temperature time series, and place the current rates of GSL rise in the context of the recent geologic past.

Bayesian improvements to ^{210}Pb dating

Marco Antonio Aquino Lopez, Maarten Blaauw
Queen's University Belfast, Belfast, United Kingdom

Abstract

Dating with ^{210}Pb has been instrumental in providing chronologies for sedimentary deposits back to around 100-150 years ago — a key period to understanding recent human and environmental dynamics yet where ^{14}C dating is often problematic owing to major wiggles in the ^{14}C calibration curve. Currently popular ^{210}Pb age-models such as the Constant Rate of Supply (CRS) or Constant Initial Concentration (CIC) are incapable of including alternative types of dating information, and are often in disagreement with other dating information.

Through simulations of sediment accumulation, we highlight these and other problems of the CRS and CIC models, such as the underestimation of age uncertainties, the dependence on correctly estimating a core's entire ^{210}Pb inventory, and issues with separating supported from unsupported ^{210}Pb .

We present a Bayesian age-modelling approach (Aquino et al. 2018) that solves the above problems, and show how our method can include other types of dating information such as from ^{137}Cs or radiocarbon, produce more reliable uncertainty estimates, and extend ^{210}Pb chronologies decades further back in time than currently possible.

Abstract

Throughout the most extreme environments on Earth, such as the Kalahari Desert or the Arctic, hunter-gatherer populations found resourceful ways to acquire dietary requirements provided by plant consumption (fibers, vitamins and minerals). Here, we demonstrate that something similar occurred in the Atacama Desert, arguably the driest place in the world, where wild plants are scarce and unevenly distributed across distinct eco-geographical zones. We assembled available archaeobotanical data from sites dating back from the initial regional colonization (ca. 13,000 cal yrs BP) until the Inka times (ca. 450 cal yrs BP) to generate the most exhaustive database for the long-term exploitation of plants in the Atacama. Our sequential analysis shows that both mobile hunter-gatherer and agro-sedentary populations not only acquired and managed plant resources from different regional eco-geographical zones (coastal, intermediate and high Andean regions), but also from distant regions (>600 km) such as trans-Andean tropical forest ecosystems. Indeed, from very early on in the cultural sequence, the Atacama's people established long-distance interaction routes for accessing a diverse array of plant resources. Several cultivars (e.g. *Capsicum* sp., *Chenopodium quinoa*, *Ipomoea batatas*, *Lagenaria siceraria*, *Manihot esculenta*, and *Zea mays*) started to appear in the region by the Late Archaic (6,000-3,700 cal. yrs BP). The consolidation of a wide range of farming crops took place during the regional Formative period (3,700-1,500 cal yrs BP), now including *Amaranthus* sp., *Arachys hypogaea*, *Cucurbita maxima* and *C. moschata*, *Erythroxylum* sp., *Phaseolus* spp., *Solanum* spp., as well Leguminosae trees (*Prosopis* and *Geoffroea decorticans*). All crops recorded in the Atacama were seemingly introduced from other Andean regions or even Mesoamerica, rather than locally domesticated. Albeit the irrigated-agriculture was progressively adopted, it came to complement hunter-gathering strategies as the use and management of wild resources did no cease (i.e. Cyperaceae, Cactaceae, *Tessaria*). By contrasting the trends of plant utilization with socio-cultural changes, paleodemographic and climatic fluctuations, we show that the "Green Revolution" of the Formative period coincides with an exponential increase in the number of social groups inhabiting the Atacama Desert, as well as with the transformative process that characterizes most of the spheres of these communities. The cultivation of this set of edible plants persisted even under the rule of centralized societies such the Inka, implying that for them, agricultural transformations were more related to the intensification of the production of target crops instead of innovating with new cultigens. Even today, the plant-based part of our diets heavily relies in many of these cultivars, particularly maize, squash, gourd, and beans. This means that a relevant part of our life can be traced back to at least 3,000 years ago, to the times of the "Green Revolution".

Living in Andean dead ends: human-environmental interactions at the fringes of the Northern Ice Field.

Amalia Nuevo Delaunay¹, César Méndez¹, Omar Reyes², Antonio Maldonado³, María Eugenia de Porras⁴, Robert McCulloch¹

¹Centro de Investigación en Ecosistemas de la Patagonia, Coyhaique, Chile. ²Universidad de Magallanes, Punta Arenas, Chile. ³Centro de Estudios Avanzados en Zonas Áridas, La Serena, Chile. ⁴Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales, Mendoza, Argentina

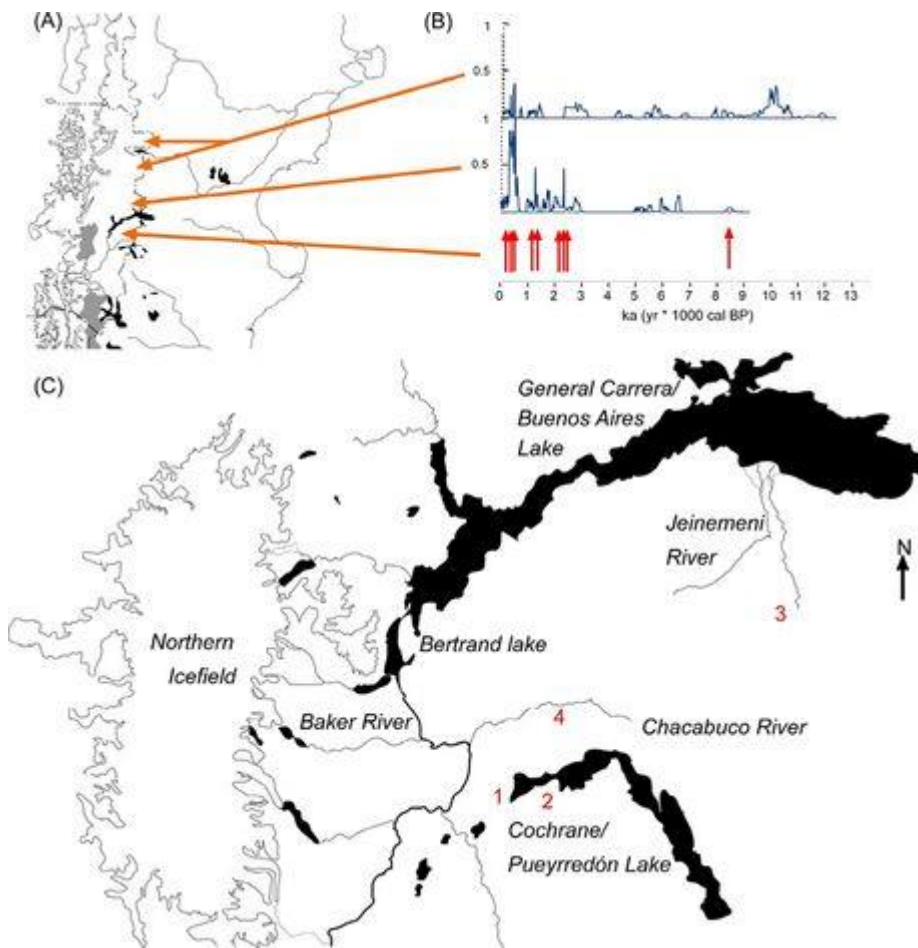

Abstract

Andean dead ends in Central Western Patagonia (CWP) represent ideal landscapes to address the differential role of hunter-gatherer occupations and human/environment interactions, yet they remain understudied. As marginally occupied areas, these are highly sensitive to changes in mobility and land use, and thus informative of human processes occurring at broader spatial scales. The sector bounded by the General Carrera/Buenos Aires (GCBA) and Cochrane/Pueyrredón (CP) lakes, the Baker River (BR) and the Northern Ice field (NIF) stands as a remarkable example of dead end. Our goal is to study human/environmental interactions by combining archaeological (occupational redundancy, variability in technology and subsistence, and changes in mobility) and paleoenvironmental (pollen, charcoal) records.

Paleoenvironmental records based on pollen records located within the forest do not show major changes particularly during the Holocene due to the over-representation of *Nothofagus* pollen. However, those located at the forest-steppe ecotone further north (44.5°S; Lago Shaman and Mallín El Embudo) show the gradual development of the forest after 14ka peaking between 8-5ka as a response to higher humidity and unmarked seasonality, while the late Holocene was characterized by highly variable conditions. At 47°S, the pollen record of Mallín La Frontera, also in the forest-steppe ecotone, shows an initial amelioration in environmental conditions after ca. 8.2ka followed by a reversal to colder conditions between ca. 7.4-6.5 ka followed by variable climatic conditions up to 3.7ka. After 3.7ka and up to the present, a gradual shift to more stable and temperate conditions occurred. Mire pollen records within the forest at 47°S (Laguna Anónima and Mallín Casanova) show a decrease of forest pollen after 2ka.

The spatial characteristics of the area east of the NIF and the distribution of known archaeological sites suggests geographical barriers such as the GCBA and CP Lakes, as well as the BR, acted as bounds constraining mobility during the Holocene. The initial exploration of this area occurred ca. 8ka as indicated by the earliest records of Alero Entrada Baker and sites south of the CP Lakes. This occurred once these environments became attractive to populations of eastern steppes. Cave sites, however prone to accumulate anthropogenic sediments and artifacts, are characterized by temporal discontinuities, with limited periods of sustained human presence during the late Holocene.

Abstract

The Atacama Desert encompasses contrasting arid bioclimates across the abrupt relief that rises up rapidly from the Pacific coast of South America to the high-elevation Altiplano. Albeit this rugged landscape imposes harsh living conditions for humans, this territory has been occupied since the early peopling of the Americas, allowing the establishment of different socio-economic systems (i.e. hunting-gathering, agriculture, industrialization). In this sense, an evolutionary study in deep-time for the human-environment interaction in the Atacama provides a meaningful perspective for exploring feedback mechanisms accounting for the long-term dynamic of socio-ecological systems in extreme environments. By means of integrating archeological and paleoenvironmental records for the inland Atacama Desert (18°-25°S), we discuss how social behaviours and biophysical systems have been reciprocally influenced during the past 14,000 years. This task involved the systematization of data for: 1) long-term paleodemographic trends, 2) technological production/innovations, 3) natural environmental variability, and 4) anthropogenic disturbances. We verify that the paleodemographic dynamic over the last 14,000 years was coupled to changes in the regional hydroclimate. Nevertheless, by adjusting/incorporating adaptative strategies or technologies, these societies could sustain continuous population growth and social wealth, even when relatively adverse climate conditions persisted at different timescales. Such progressive cultural changes improved their capacity for engineering regional ecosystems through time, particularly in productive environments such as wetlands or ravines. Indeed, activities maintained either by hunter-gatherers or agrarian societies around these areas, led to cumulative and pervasive impacts on different biophysical patterns including biodiversity, water storages, air-quality, nutrient cycling and land-use. Our results preclude the notion of pristine landscapes before the regional Industrialization (ca. 1850 AD), but more importantly, suggest that the recent socio-environmental history of the inland Atacama is the result of long-term processes that operated uninterruptedly since Pre-Columbian times. We evince several regimes shift and tipping points in the coevolution of the human-environment interaction (e.g Neolithization, Inca expansion, Spaniard colonization), all of which were conducive to scale up the anthropogenic impact on ecosystems. This implies that contemporary environmental issues represent an inevitable regime shift resulting from long-term positive feedback loops between socio-cultural and ecological inheritances.

Abstract

The presence of human groups in a given ecosystem promotes complex interactions and feedbacks between cultural innovations and the social and natural systems they inhabit. Due to a low prehistoric population followed by a drastic increase in historical times, it is often assumed that the Mediterranean ecosystems of central Chile, which today dominates most of the country's production and economy, are classic examples of "natural" versus "anthropogenic" impacts during the late Holocene. A strong anthropic impact has indeed occurred since the Spanish colonization (450 b.p) onwards, with animal husbandry, ranching, farming and more recently forestry plantations among the activities most responsible. Archaeological studies in central Chile, however, have shown that the development of agricultural activities began c. 2000 cal yr BP. This would have been accompanied by an important demographic increase and intensification of resource use. Such an increase in human activity would have acted as major agents of change in these ecosystems which could predate by at least a thousand years previous assumptions regarding these impacts.

We present an approach to reconstructing the paleodemography of central Chile through the use of a summed probability distribution (SPD) of archaeological dates (integrating radiocarbon and thermoluminescence dates) that spans the last 3000 years. We compare our regional SPD to two lacustrine sedimentary records: Lago Vichuquén and Laguna El Piojo. The Vichuquén record reflects human activity in this easily accessed coastal basin since before the Spanish conquest, whereas the high-elevation Laguna El Piojo is difficult to reach and its climate precludes long-term settlements. Pulses of increased human activity beginning c. 2000 cal yr BP can be evidenced from increased local fire frequency (macro-carbon particles) and through biogeochemical indicators associated with shifts in nutrient cycles and sources ($\delta^{15}\text{N}$, $\delta^{13}\text{C}$ and C/N). These cultural and ecological landscape transformations are relevant for the long-term assessment of mediterranean ecosystems, as productive activities have only increased in magnitude and intensity in these regions over time.

Reconstructing Vegetation Changes in Response to Holocene Climatic Variability in East Turkana, Kenya.

Rahab Kinyanjui¹, Emmanuel Ndiema², Purity Kiura¹, David Braun³, Marion Bamford⁴

¹National Museums of Kenya, Nairobi, Kenya. ²National Museums Of Kenya, Nairobi, Kenya. ³George Washington University, Washington D.C, USA. ⁴University of Witwatersrand, Johannesburg, South Africa

Abstract

During the Holocene the East African region experienced rapid climatic events, driven principally by orbital forcing and the monsoon insolation. The most prominent event recorded is the African Humid Period (AHP) during the early Holocene (~10ka to 8ka). The mid Holocene (~8ka to 5ka) was characterised by rapid shifts between wetter and drier climates. Dry climates have so far been consistent since late Holocene to present. Archaeological evidence from the Holocene deposits, the Galana Boi, indicate changes in subsistence activities from hunting, gathering and fishing during the early Holocene wetter period, to pastoralism in the mid-late Holocene period. High mobility and resource exchange is also associated with drier climates.

Little is known about the vegetation structure and the response to changing climates. This paper presents phytolith data analysed from five Holocene sites occupied during different time periods: FxJj108 (~9.6ka-~6ka), FxJj27 (~9.3ka to ~4.2ka), Gajj4 (~4.2ka), FwJj25 (~4.2ka to ~1.34ka) and FwJj5 (~0.93ka). Although phytolith counts were low, especially grass short silica cells (GSSCs), it was possible to identify changes in vegetation structure/habitats and their temporal variation using both a general abundance approach and phytolith indices: aridity index (Iph) and tree density (D:P).

Our data show that Holocene vegetation structure was generally dominated by woodlands/ shrublands with some grasslands. However, early- and mid-Holocene assemblages had significant proportions of aquatic indicators: palms, sedges, sponge spicules and diatoms, which suggest the existence of riverine/riparian habitats with fresh/spring water resources and episodes of seasonally high humidity.

Late Holocene assemblages indicate grasslands dominated by Chloridoideae arid grasses that have persisted to present. Iph index shows high variation especially during the mid-Holocene period while the D:P indices have shown the tree cover was mostly moderately to highly dense, which resembles present day Sudanian vegetation structure (grassy woodlands/shublands). The results concur with previous studies, that Holocene climates were highly variable.

Human impacts on chironomid communities in Irish lakes across timescales

Aaron Potito, Karen Taylor, Carlos Chique, Daisy Spencer, Seamus McGinley
National University of Ireland Galway, Galway, Ireland

Abstract

Resolving human and climatic influences on lake sedimentary records is an ongoing challenge in palaeolimnology, especially in an Irish context where humans have had a substantial influence on the landscape since at least the mid-Holocene. This comparative study focuses on the interpretation of chironomid (non-biting midge) subfossils in lake sediment records in Ireland, where agriculture, and particularly pastoral farming, has been a predominant control on lake ecology since the transition to farm-based economies in the Early Neolithic ca. 3700 BCE. Due to their unique life history traits, chironomids are effective indicators of past environmental change. Chironomid communities are affected by a variety of inter-related environmental variables including temperature, lake water dissolved oxygen, benthic substrate and lake nutrient status, and disentangling the climate signal from direct human influences can be challenging.

This study integrates previously published and new records from the recent and distant past to investigate the utility and performance of chironomids as ecological indicators of land-use change through time. Chironomids are combined with lake sediment geochemistry ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$ and C:N), fossil pollen and other analyses to investigate the impacts of land-use change on lake ecology. Sediment records from seven lakes across Ireland were used to ascertain regional trends from prehistoric to modern time periods. Redundancy analysis (RDA) and partial RDAs showed that $\delta^{15}\text{N}$ and non-arboreal pollen indicative of grassland/pasture (NAPP) were the predominant controlling factors of chironomid community compositional change during the Irish Neolithic (4000 - 2500 BCE) and Bronze Age (2500 - 750 BCE). Bronze Age farming had a considerably greater impact on all lake systems than Neolithic farming, as indicated by a higher proportion of eutrophic taxa and a geochemical signal consistent with increased erosion and nutrient inputs. Cultural eutrophication also led to the local extirpation of several oligotrophic chironomid taxa present in the natural pre-impacted lake systems. Relative impacts increase in the modern records, where threshold-style changes in lake ecology correspond to local and national-scale changes in land use practice, such as increased use of fertilisers and agricultural intensification. Correspondence Analysis (CA) with modern inter-lake and intra-lake chironomid surface samples shows that Irish lakes typically reach 'modern' conditions ranging from the late Medieval (1150 - 1550 CE) to the mid-20th century.

Within this context of impacted Irish landscapes, we review attempts at Irish summer temperature reconstructions for both the distant and recent past. Strategies for rectifying the climate and cultural eutrophication signals in Irish lakes are explored. We conclude with recommendations for integrating multi-proxy indicators to more effectively disentangle chironomid-inferred temperature and eutrophication records from lakes within human-impacted landscapes.

Abstract

During the Late Pleistocene-Early Holocene an extensive humid event known as the Central Atacama Pluvial Event (CAPE II) characterized by increased rainfall on the western slope of the Andes resulted in higher lake levels above 4000masl and increased groundwater table levels, leading to the formation of extensive wetlands at ca. 3000 masl. A large number of early sites were found during this period (ca. 12.6-11 and 10.5-9.5ka) along the borders of the Imilac and Punta Negra high altitude basins (ca. 3000 masl). However, at the end of the early Holocene (8.5ka), humid environmental conditions turned into extreme arid ones, coinciding with the abandonment of the sites, once the favorable conditions and resources disappeared. However, little is known about the occupations in higher altitudes during the Late Pleistocene-Early Holocene even when the presence of several ravines that drain into both high altitude basins and therefore, could have facilitate an easy mobility between the highlands and the Imilac and Punta Negra basins. Recent surveys conducted in the heads and highlands of the ravines (Guaqueros, Zorras, Zorritas, Lullailloco, 3.900-4.200 masl) showed a high abundance of biotic resources (specially vicuñas and guanacos) and the presence of early sites in each of them. Among the recovered diagnostic elements, monofacial artifacts widely represented in the early occupations of Imilac and Punta Negra stand out, as well as triangular projectile tips, typical of early occupations at local and regional scales. However, there are large differences in the lithic raw materials since these would be rather local or belonging to other sources different from those located in the Punta Negra (basalt) and Imilac (calcedony). The sites correspond mostly to open-air camps located on fluvial terraces around dejection cones that may have been active during times of high humidity. To date, only one site corresponding to the mid Holocene has been recorded under a rockshelter located at the head of the Lullailloco ravine. Palaeoenvironmental evidence from highlands including fossil rodent middens records and palaeowetlands deposits into the ravines support the climatic scenarios of the Late Pleistocene-early Holocene at the local scale and provided a clear idea of landscape and depositional environments evolution from the early occupation stages to the final abandonment during the mid-Holocene. Implications of climate variability in Patagonia and Tierra del Fuego for the interpretation of paleo-climate records

Christoph Schneider

Humboldt-Universität zu Berlin, Geography Department, Berlin, Germany

Abstract

Patagonia and Tierra del Fuego provide a unique natural laboratory to explore climate, climate variability, and climate history of the mid to high latitudes of the Southern Hemisphere. Actually, the *cono sur* of South America forms the only relevant land mass at these latitudes, connecting Pacific and Atlantic Ocean through the Strait of Magellan, and exhibiting close links to climate variability at nearby Antarctic Peninsula. Highly relevant for our knowledge within the global climate system is the response of glaciers to climate forcing in the area as it is related to global sea level and regional climate feedbacks both for the past, the current transient climate, and future climate projections.

Since the turn of the century and based on groundbreaking earlier works a multitude of paleo-climate information has been established based on dendro-climatology, sediments, stalagmites, bore cores, from sediment stratigraphy, moraine mapping and through many other investigations. Glacier studies both empirical and based on modeling have revealed a multitude of information on glacier variability in recent decades. Despite these impressive advances in our understanding of climate variability and glacier response in past, present and future, considerable uncertainties and relevant knowledge gaps are existent. Many, especially the more remote areas of Patagonia and Tierra del Fuego remain, if not uncharted then nonetheless seriously understudied with only few study sites being explored in details, and only few established and still existing long-term monitoring sites. These limitations make it difficult to bring paleo-climate records into proper context regarding both, their temporal and spatial significance. Especially, tremendous climatic east-west and north-south gradients across and along the Andes mountain zone make it difficult to provide stringent and consistent interpretation of paleo-climate records from disjunctive locations.

The keynote lecture tries to bring together some of the more recent findings regarding climate and glacier modeling and climate characterization with relevance to paleo-climate record interpretation, and related to climate variability and glacier change in the late Holocene. Implications of inter-annual climate variability related to Antarctica (Southern Annular Mode) and tropical to sub-tropical forcing (El Niño Southern Oscillation) will be discussed related to both, the glacier mass balance and snow cover variability and the temporal patterns of weather types over Patagonia and Tierra del Fuego.

Abstract

Whilst a number of detailed geochronological records have been produced that constraint the horizontal and vertical dimension of the Patagonian Ice Sheet (PIS) during the last glacial period, all but two chronologies have been established at the former eastern terminating margins. The western portion of the PIS covered the hyper-humid terrestrial-marine transition area where glacier dynamics were probably very different from the semi-arid eastern terrestrial counterparts. Strong correlation exists ($r=0.8$) between southern westerly wind strength and precipitation west of the Andean divide (Garreaud et al., 2013), making glacier chronologies from the PIS' former western terminating margin more suitable to answer question about local to hemispheric palaeoclimatic shifts during the Quaternary. In order to better understand glacier-climate interactions in southern Patagonia comprehensive chronologies of glacier expansion and recession across a range of longitudes and latitudes are needed. In this study, erratic boulder, bedrock and pebble samples were collected marking glacier extent and thickness at sites on the previously un-studied western-most Chilean Islands (52-55°S, 67-73°W). Cosmogenic surface exposure ages (¹⁰Be, ²⁶Al, ³⁶Cl) from these samples provide insight into the suitability of the geochronological approach as well as a first order understanding of latitudinal (a)synchronicity of glacier extension and thinning rates in the hyper-humid fjords of south-western Patagonia.

Abstract

We present a new geomorphic map, moraine chronology, and modeling results for a glacial valley in central Chilean Patagonia (45°S) representing the first detailed geomorphic study of the valley. The Ñirehuao lobe of the former Patagonian Ice Sheet left behind a series of moraines that allow us to reconstruct the timing and magnitude of climate changes during the last two glaciations in the area. Geomorphic mapping combined with field observation demonstrates that two glacial lobes coalesced during MIS 6, and potentially MIS 8, but were bifurcated by bedrock during MIS 2. We date the MIS 6 advance at 154 ± 9.8 ka (mean and 1 sigma uncertainty; n=10; no outliers omitted) using precise ¹⁰Be surface exposure dating of glacially deposited moraine boulders. We date the MIS 2 advance at 23.9 ± 2.6 ka (mean and 1 sigma uncertainty; n=15; no outliers omitted). The youngest intact MIS 2 moraine has an exposure ages of ~21 ka and is fringed by ice margin channels and shorelines of a paleo proglacial lake. We apply the University of Maine Ice Sheet Model to estimate the temperature and precipitation departures necessary to allow the glacier to expand to the dated and mapped extents, and compare Ñirehuao model results with those from the southern tip of South America at the Strait of Magellan. Paired with prior work, we help define the timing of Patagonian glaciations during MIS 8, 6, 4 and 2. Establishment of such detailed glacier records and modeling studies for southern South America are necessary to test proposed mechanisms for Quaternary glacial cycles, and ultimately to help us understand variability in the global climate system.

O-4165

Anatomy of climate reversals and changes in the Southern Westerly Winds during the Last Glacial Termination in northwestern Patagonia

Patricio Moreno, Carla Henríquez, Emilia Fercovic, Javiera Videla
Universidad de Chile, Santiago, Chile

Abstract

Paleoclimate records from the middle and high latitudes of the Southern Hemisphere have documented a (or several) climate reversal(s) during the Last Glacial Termination (T1: 17.8-11.7 ka, ka=1000 cal yr BP). Its (their) very existence, timing, direction, and geographic extent have been debated in the literature for decades, including the mechanisms involved in its (their) origin and propagation. Empirical and modeling studies have proposed that variations of the Southern Westerly Winds (SWW) were key drivers of climate changes through T1 at zonal, hemispheric and global scales. The timing, structure and geographic variability of paleoclimate signals through T1 in Patagonia, however, have not been studied in detail. Here we examine the vegetation and fire regimes before, during, and after the Antarctic Cold Reversal (ACR: 14.8-12.9 ka) and Younger Dryas (YD: 12.9-11.7 ka) chronozones, using multiple pollen and macroscopic charcoal records from small closed-basin lakes located along climatic gradients in northwestern Patagonia (NWP, 41°-43°S). Paleoclimate records from this region are relevant for documenting past changes in the SWW because local precipitation is strongly correlated with low-level wind velocities, affecting the modern vegetation, disturbance regimes and glacier mass balance along the western coast of southern South America. Palynological studies indicate that evergreen temperate rainforest expanded rapidly into the lowlands of NWP in response to warming and collapse of the Patagonian Ice Sheet at 17.8 ka. Vegetation changes ensued, including spread of the cold-tolerant hygrophilous conifer *Podocarpus nubigena* during the most recent half of T1.

We examined the chronology and relative magnitude of the *Podocarpus nubigena* signal in 19 NWP sites and observe the following: (i) all sites show very low abundance or absence before to the ACR (17.8-14.8 ka); (ii) all sites show significant increases during the ACR, the largest-magnitude increases are evident in the wettest sectors; (iii) the majority of sites (11) show steady declines during the YD; and (iv) all sites feature further declines and/or virtual disappearance during the early Holocene. We also observe that most sites show increases in fire activity during the YD and the early Holocene.

We conclude that a cold reversal took place between 14.8-11.7 ka in NWP with cold/wet conditions during the ACR and cold/dry conditions during the YD, brought by increased SWW influence and a subsequent decline, respectively. These results correspond in timing with readvances of Patagonian glaciers during the ACR and subsequent recession during YD time. We posit that the SWW were a fundamental link between the middle and high latitudes of the Southern Hemisphere during T1 and, according to some authors, the tropics and the Northern Hemisphere.

O-4166

Glacier dynamics during a phase of Late Quaternary warming in Patagonia reconstructed from sediment-landform associations and surface exposure dating

Julian R. V. Martin, Bethan J. Davies, Varyl R. Thorndycraft
Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, United Kingdom

Abstract

The geomorphological record in glaciated landscapes can provide important information for the study of the response of glaciers to rapid climate change. This study presents a new reconstruction and chronology of the glacial history of the northern Monte San Lorenzo ice cap, southern South America during a period of accelerated warming and deglaciation (ca. 13.0-11.0 ka) following the Antarctic Cold Reversal. We use both remote sensing and field geomorphological mapping to produce a detailed geomorphological map of the valleys to the north of Monte San Lorenzo. Sediment-landform assemblages identified and mapped include lateral and terminal moraine ridges, flutes, deltas, ice-contact fans, palaeoshorelines, kame terraces and outwash plains. We map 14 primary ice limits, 7 newly identified, and 7 extended from previous studies. We devise landsystem models to formalise and document spatial and temporal changes in glacial process and environments. These show an evolution through glaciolacustrine to land-terminating, mountain valley and paraglacial landsystems, with local and regional topography, ice-dammed lakes and climate acting as key controls on landform and landsystem development. Newly acquired cosmogenic nuclide surface exposure ages of boulders found on moraine ridge crests, alongside recalculated and recalibrated ages from the published literature, allows us to develop a Bayesian age model from 4 ice limits to constrain rates of glacier recession. Combining this and further existing chronological data with detailed geomorphological mapping, we produce a spatial and temporal reconstruction of the northern ice margin of the Monte San Lorenzo ice cap during rapid deglaciation. Our work underpins a numerical model (PISM) of the ice cap, and provides an important insight into the response of temperate Patagonian glaciers to rapidly-warming climate.

Abstract

During the last glaciation, the north-south transect of Patagonia was influenced to varying extents by the Southern Westerlies, which supplied precipitation to the Patagonian Ice Sheet. The latitudinal transect of Patagonia can provide a natural laboratory to study past equatorial or poleward shifts in the position of the Southern Westerlies during the last glaciation, and the associated responses of the ice sheet to precipitation changes. Here we target the unstudied region 42°S to 44°S at the NE sector of the former Patagonian Ice Sheet (70-71°W) to assess whether ice limits in this region are in-phase with southern Patagonia. If the Southern Westerlies shifted towards the equator during the last glaciation, we could expect that the maximum extent and subsequent deglaciation in the northern region of the former Patagonian Ice Sheet was out-of-phase with the southern sector. Here we present new age constraints on multiple limits of ice lobes in the Epuen (42 °S), Esquel (43 °S) and Rio Pico (44 °S) valleys using luminescence and cosmogenic nuclide dating. There is excellent agreement between the cosmogenic nuclide ages for the moraine boulders and luminescence ages for the associated outwash plains. The new ages suggest that multiple ice limits are preserved between 42 - 44 °S and were deposited from ca. 27 to 17 ka. This is similar to ice limits in the Chilean Lake District (41-43 °S, 72-73°W; Denton et al. 1999), at Lago Buenos Aires (46 °S; Douglass et al. 2006; Kaplan et al. 2004; Smedley et al. 2016), Lago Pueyrredon (47 °S; Hein et al. 2010), the Strait of Magellan and Bahia Inútil (53 °S; Kaplan et al. 2010; McCulloch et al. 2005). Therefore, it is unlikely that latitudinal shifts in the Southern Westerlies caused asynchronous ice expansion across the north-south transect of Patagonia during the last glaciation. However, it is possible that the influence of the Southern Westerlies works on shorter timescales than the millennial-scale timescales studied here; thus, we require higher-resolution datasets to detect past changes in ice extent.

Extensive glacier advance in Patagonia during the Antarctic Cold Reversal

Monika Mendelova¹, Andy Hein¹, Ángel Rodes², Rachel Smedley³, Sheng Xu²

¹The University of Edinburgh, Edinburgh, United Kingdom. ²es Environmental Research Centre, Glasgow, United Kingdom. ³The University of Liverpool, Liverpool, United Kingdom

Abstract

Constraining the timing and spatial extent of millennial-scale climate events during the Late Glacial is crucial for deciphering the underlying drivers of climate change. Late Glacial ice marginal positions remain poorly constrained in central Patagonia, and palaeoecological proxies show equivocal evidence for the nature of climate change. Here, we present geomorphological mapping along with new ¹⁰Be ages and optically stimulated luminescence (OSL) ages that constrain the timing of glacial advances and palaeolake development at Lago Belgrano (47.9°S) on the eastern side of the San Lorenzo massif. ¹⁰Be ages from prominent arcuate moraines bounding Lago Belgrano reveal an extensive re-advance toward the end of the Antarctic Cold Reversal (ACR, ~ 14.5 – 12.9 ka). Subsequently, ice retreated rapidly to near its present day configuration during the northern hemisphere Younger Dryas (YD; ~12.9-11.7 ka). ¹⁰Be ages from lateral moraines ca. 7 km from the present day glacier margin suggest a period of stabilization during the YD. This stabilization was brief on the basis of ¹⁰Be dating of raised shorelines and OSL dating of glaciolacustrine sediments, which indicate an ice-dammed lake formed, and then drained during the YD. Our data provide firm evidence for extensive ice in central Patagonia until the end of the ACR and suggest close climate coupling of the southern mid-latitudes and Antarctica.

Abstract

Environmental variability has been hypothesized to play an important role as a driver of evolution, specifically through its role as a selective agent towards adaptation to unpredictable environments. In particular, variability selection has been proposed as an important factor in the radiation and extinction of hominins in Africa. To date, most attempts to evaluate the variability selection hypothesis have examined correlations between evolutionary events and either theoretical drivers of variability, such as insolation, or single paleoenvironmental indicators with an eye towards identifying episodes of higher variability. Here we report on a meta-analysis of patterns of variability in 30 long (>400 kyr) and highly resolved paleoenvironmental records from on and around the African continent spanning the last 5.3 Ma. These records include published marine and lacustrine cores, as well as outcrop archives of sedimentological, geochemical and paleoecological change. Our analysis uses a new normalization metric (comparison of binned standard deviations in detrended z-score time series) to allow comparison of different types of data across the Plio-Pleistocene study interval. The variability mean time series is strongly correlated with available long SST records around Africa, the $\delta^{18}\text{O}$ global marine stack and insolation, but not with CO_2 . Consistent with prior studies (Potts and Faith, 2015), we observe a strong 400 kyr cyclicity in the variability means time series, strongly suggesting orbital forcing as an important driver of Neogene environmental variability in Africa. However, this cyclicity is superimposed on a long-term trend toward increasing variability throughout the last 3.5 Ma. Furthermore, major increases in variability predate the onset of significant Northern Hemisphere glaciation. Our findings suggest that if environmental variability selection during the Plio-Pleistocene in Africa has been an important evolutionary selective agent, then it is likely that those selective pressures have intensified through much of the course of human evolution.

Climate change and early hominin evolution: is the fossil record of suitable quality to test climate-forcing hypotheses?

Philip Hopley, Simon Maxwell
Birkbeck, University of London, London, United Kingdom

Abstract

In recent decades, a number of studies have compared Plio-Pleistocene palaeoclimate records with various aspects of the early hominin fossil record, including speciation, extinction and species diversity. When events within the palaeoclimatological and palaeontological domains are temporally coincident, a causal relationship is often assumed, and hypotheses are put forward to explain the possible evolutionary mechanisms for these relationships. Key to this approach is the assumption that the observed pattern of hominin speciation, extinction and diversity reflects genuine evolutionary processes. Alternative explanations for the observed macro-evolutionary patterns, such as uneven geological and anthropogenic sampling, must also be investigated.

We present a detailed examination of early hominin diversity dynamics through time, including both taxic and phylogenetically corrected diversity estimates. We also compare these estimates to sampling metrics for rock availability (hominin-, primate-, and mammal-bearing formations) and collection effort, in order to assess the geological and anthropogenic controls on the sampling of the early hominin fossil record. Taxic diversity, primate-bearing formations, and collection effort show strong positive correlations, raising the possibility that some features of hominin diversity may, in fact, represent systematic sampling biases, rather than a genuine evolutionary signal. We find no evidence of pulsed turnover in the early hominin fossil record or any link to climate proxies and, instead, argue that the appearance of pulsed change is an artefact of uneven sampling.

The results demonstrate that the hominin fossil record is currently characterised by highly uncertain stratigraphic ranges and inaccurate estimates of hominin diversity, influenced primarily by fluctuations in local and regional sampling intensity. It is clear that a far more complete hominin fossil record is required before hypotheses of climate forcing can be rigorously tested; in the meantime, inferences based on larger faunal or archaeological datasets may provide more reliable comparisons with discreet climatic events.

Abstract

Evidence for tool making at the Lomekwi-3 archaeological site and C₄ dietary inputs between 4-3 Ma signal exploitation of open ecosystems prior to genus *Homo*. In the Turkana Basin (Kenya), the mixed C₃-C₄ feeding *K. platytops* has significantly lower enamel carbonate d¹⁸O (EC) values than those of the C₃-feeding *A. anamensis*, which may signal changes in water dependency, faunivory and/or habitat structure use. *Homo erectus* at the Oldowan site complex, Lokalalei-1 and 2C, shows the lowest d¹⁸O_{EC} value of all Turkana hominins sampled to date and a mixed C₃-C₄ diet. In this study we contextualize hominin diet shifts and technological innovations by comparing new and previously published pedogenic carbonate (PC) d¹³C and d¹⁸O values and mammalian d¹³C_{EC} and d¹⁸O_{EC} values collected in proximity to the Lomekwi-3 archaeological site (~3.3 Ma) to those of Kanapoi paleontological site (~4.1 Ma) and the Lokalalei archaeological site complex (~2.3 Ma) located in the western Turkana Basin. Mammalian taxa sampled include: Hippopotamidae, Elephantidae, Giraffidae, Rhinocerotidae, Alcelaphini, Aepycerotini, Homininae. We find comparable d¹³C_{PC} values from all site environments; d¹³C_{EC} values indicate that only hominins changed feeding category. Pedogenic carbonates and mammalian taxa, including hominins, show a ~2‰ shift in d¹⁸O_{PC/EC} values between Kanapoi and Lomekwi-3, and return toward previous d¹⁸O_{PC/EC} values at Lokalalei. Moreover, new factorial correspondence analysis based on abundance of specimens among bovid tribes and mesowear studies on the fossil mammal communities in the area from 3.97 to 2.53 Ma show a similar trend. These data are suggestive of a large-scale climatic change, potentially the Mid-Pliocene Warm Period.

U–Pb-dated flowstones restrict South African early hominin record to dry climate phases.

Robyn Pickering

Department of Geological Sciences, University of Cape Town, Cape Town, South Africa

Abstract

The Cradle of Humankind (Cradle) in South Africa is home to a rich collection of early human (hominin) fossils, preserved in dolomite caves. Flowstones, horizontally bedded layers of calcium carbonate, are ubiquitous features at all the sites. The flowstone serve the dual purpose of providing ages for the fossiliferous sediments sandwiched between them (via uranium-lead dating) and as indicators of past climate regimes by their presence alone, being associated with increased effective precipitation. Massive flowstones of several meters thick are not uncommon and hint at prolonged periods of significantly increased precipitation. Uranium-lead (U-Pb) dating of cave carbonates has reached a level of maturity where it can be applied with ease and precision. Flowstones from eight caves across the Cradle have produced a total of twenty eight U-Pb ages. This represents the most comprehensive and direct chronology to date for these sites and associated early hominin fossils. The flowstone layers can be seen as analogous to the tuff layers in east Africa, which are used to both correlate and date the fossil bearing sediments. To solve the problem of necessarily large uncertainties on individual ages, a kernel density estimate is used to sum together the U-Pb age data into a single record of flowstone growth intervals (FGIs). This record spans from 3.2 to 1.3 million years ago, with six major FGIs identified, with flowstone forming in at least two caves during the same time interval. These intervals are interpreted as major wet phases, during which caves were most likely closed and not receiving sediments/bones from outside, allowing for massive flowstone development. The six interceding time windows are interpreted as drier phases, during which the fossiliferous sediments accumulated into open caves. This implies that the fossil record from these caves is highly punctuated, with much time unrecorded. This makes it impossible to falsify hypotheses of punctuated equilibrium and turnover pulses. The fossil bearing deposits also carry an inherent 'dry phase' bias, placing the hominins in a dry adapted fauna. The inability to observe behaviours during wet periods constrains our ability to evaluate hypotheses of hominin adaptation using the Cradle record. While the periods of cave closure leave temporal gaps in the South African fossil record, the flowstones themselves provide valuable insights into both local and pan-African climate variability.

Abstract

There is much debate regarding the role of climate and environmental change in human evolution and dispersal. Despite eastern Africa being regarded as a key location in the story of the emergence of anatomically modern humans (AMH) and their subsequent dispersal out of Africa, there is a paucity of long, well-dated climate records in this region. To address this issue, duplicate deep-drill sediment cores were retrieved from the Chew Bahir basin in the south Ethiopian Rift, extending to 279 m and 266 m below the present sediment surface. Chew Bahir is located in a climatically sensitive region, lying between the boundaries of various influencing air masses and wind systems (i.e. the Intertropical Convergence Zone (ITCZ), the Congo Air Boundary, and the Indian Ocean monsoon). Critically, the site is also located close to the earliest eastern African AMH site of Omo Kibish, and close to the proposed dispersal routes for AMH out of Africa.

The climate and environmental history of Chew Bahir was reconstructed from a ~290 m composite core using various proxy datasets, including core-scanned XRF geochemical data, XRD mineralogy, MSCL logging, grain size analysis, biological proxies, and isotopic datasets (see other papers on Chew Bahir at this meeting). Key to these sensitive records of climate and environmental change is the establishment of a reliable chronology. The Chew Bahir sediments were directly-dated using multiple chronometers, including radiocarbon, argon-argon, and optically stimulated luminescence dating, combined with correlations to known-age tephtras. A Bayesian age-depth model was developed based on these ages. The resulting chronology forms one of the longest independently dated lacustrine sediment records from eastern Africa, spanning the entire timescale of modern human evolution and dispersal, and encompassing the transition from Acheulean to Middle Stone Age (MSA) technology, and subsequently to Later Stone Age (LSA) technology.

Abstract

Most current hypotheses of climatic influence on human physical and cultural evolution focus on the role of climatic variability in selecting for behavioural flexibility and cognitive development. Those changes are thought to have allowed selected populations to expand geographically and exploit a wider range of habitats, prey and material resources. Similarly, abrupt climatic transitions may have caused differential survival among and within human populations, depending on their vulnerability to climatic extremes, with water resources being especially critical.

Located close to the Omo Kibish, site of the earliest known *Homo sapiens* fossils in east Africa, Chew Bahir, a playa lake in the south Ethiopian Rift, has yielded a 290 m-long core record that spans the last ~600,000 years. That time interval covers the entire history of modern human origins and dispersal, encompassing a number of significant behavioural innovations. With a high temporal resolution of up to tens of years, geochemical and biological indicators from the Chew Bahir core allow close examination of changing amplitude and frequency of past hydroclimatic variation and the rapidity of climatic change. By analysis of the core data across critical transitions in the archaeological record, we aim to show how the Chew Bahir record can contribute to a developing understanding of the consequences of climatic change for early human populations.

³University of Melbourne, Melbourne, Australia

Abstract

The role played in human evolution by climate and its fluctuations has significant implications regarding the fundamental niche and behavioral plasticity of early *Homo* that ultimately led to out-of-Africa dispersal and global colonization. From an evolutionary perspective, the concordance of range boundaries and niche limits suggests that adaptation (or intraspecific evolution) is necessary for range expansion. At the same time, this implies that natural selection serves as a constraint on dispersal. It is clear there are still outstanding and mutually exclusive hypotheses regarding the role that the environment may have played in promoting early pan–continental migrations of *Homo*. Early *Homo* either had a poor capacity for adaptation to novel environments, resulting in dependency on grasslands to provide a biogeographical corridor; or was capable of rapidly adapting to novel extrinsic factors through intrinsic, and/or behavioral factors unique to humans.

'Ubeidiya, Israel, is an early Pleistocene site dated to 1.6 – 1.2 Ma and has revealed extensive lithic artifact and faunal assemblages as well as scant hominin remains. Excavated since 1959, there have been several paleoecological reconstructions of the site with discordant results. Here we present results from new suite of ecometric methods obtained on both large and small mammals including stable isotopes, tooth wear (mesowear and microwear) and compare them to other taxon-specific ecometric paleoecological reconstructions.

Tooth wear of ungulates point to a low level of grass in the diet of ungulates with increase perception compared to today. However, surprisingly, stable isotope results of cervids point to a C₄ vegetation diet or a mixed C₃ vegetation diet under higher water stress level compared to today. Reconciling these discordances are interpreted through the different spatial and temporal resolution of each proxy; the dietary flexibility of each taxon, migration, and the season animals died. The incongruent results may be explained by the unique taphonomy of each study population. Indeed, the tooth wear results were obtained on well-preserved unbroken teeth probably derived from individuals who died in or near the vicinity of paleolake 'Ubeidiya suggesting a low abrasive diet. In contrast, the stable isotope samples came from well-rounded and abraded specimens that may have been transported long distances from their native ecology to the shores of lake reflecting a dryer environment. Overall, cross continent taxon-specific comparisons suggest that 'Ubeidiya African taxa incorporate less grass in their diet compared to their East African penecontemporaneous counterparts, but Eurasian taxa incorporate a similar amount of grass in their diet as Eurasian species.

The ecology of early *Homo* in the Levant shortly after the dispersal from Africa present a region with low levels of herbaceous vegetation and a high proportion of browse vegetation, suggesting environmental conditions that would have provided novel selective pressures on early *Homo* population.

The upper age limit of feldspar luminescence dating: a comparison of natural and laboratory dose response curves

Jan-pieter Buylaert^{1,2}, Andrew Murray², Shuangwen Yi³, Huayu Lu³

¹Center for Nuclear Technologies, Technical University of Denmark, Roskilde, Denmark. ²Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Roskilde, Denmark. ³School of Geography and Ocean Science, Nanjing University, Nanjing, China

Abstract

In the luminescence dating of old and/or high dose rate samples (i.e. with absorbed doses >200 Gy) feldspar is usually preferred over quartz because of the extended dose response curve; with a typical D_0 of ~400 Gy, feldspar laboratory signals are usually within 3% of saturation by ~1.4 kGy. Especially since the identification of a more stable feldspar post-IR IRSL signal by Thomsen et al. (2008), several post-IR IRSL measurement protocols have been proposed and tested (e.g. Buylaert et al., 2012; Li and Li, 2012; Li et al., 2013). Although these different protocols have proved successful in dating different sedimentary environments, a number of studies have reported a dependence of the laboratory dose response curve shape on test dose size (Colarossi et al., 2018; Yi et al., 2016). This is of concern, because a prerequisite for accurate dose determination in luminescence dating is that the laboratory dose response curve matches the natural dose response curve. Several studies have investigated this for quartz signals (e.g. Chapot et al., 2012; Timar-Gabor and Wintle, 2013) but such a dataset for feldspar is limited to a single study by Li and Li (2012) with relatively few samples in true field saturation.

Here we investigate the form of both natural and laboratory dose response curves for different feldspar signals (IRSL, post-IR IRSL, IRPL,...), measurement protocols (SAR, MAAD) and normalization procedures using a set of 30 samples with independent age control from Luochuan (central Chinese Loess Plateau). Our samples range in age from mid-Holocene to the Tertiary-Quaternary boundary at 2.6 Ma with several samples presumably in full field saturation (absorbed doses >2 kGy); this ensures that the saturation level of the natural dose response curve is clearly defined. Our first results suggest that for a standard SAR post-IR IRSL₂₉₀ protocol the practical upper dose limit for these feldspar samples is 800-900 Gy; beyond this natural and laboratory response curves begin to deviate significantly. Thus although it may be possible to determine a dose above 900 Gy, this dose is unlikely to be an accurate measurement of the burial dose. At least for this signal and protocol it appears that the upper age limit in Chinese loess is ~250 ka. Ages beyond this limit should be interpreted with caution.

Luminescence dating of Quartzite and Granite Cobbles from wadi terraces in the Eastern Desert, Egypt

Lucas Ageby, Dominik Brill, Helmut Brückner, Nicole Klasen
Cologne Luminescence Lab, Institute of Geography, University of Cologne, Cologne, Germany

Abstract

Optically stimulated luminescence (OSL) dating of rock surfaces has developed into a useful method for providing chronological context to archaeological sites and features. OSL-dating of rock surfaces can be applied in settings where other dating methods are not suitable (e.g., high-erosion environments without finer sediments, deposits where bleaching is limited, direct dating of stone structures). In our study, we apply rock surface dating to cobbles and a boulder which were collected from terraces in Wadi Sodmein in the Eastern Desert, Egypt. Artefacts of different ages (Middle Stone Age to Neolithic) have been discovered on the surfaces of several of these terraces (Kindermann et al., 2018). No artefacts have so far been found interbedded in the terrace sediments; therefore, the terraces pre-date the oldest artefacts. Our goal is to investigate the possibility of using OSL dating techniques to determine burial ages for quartzite and granite cobbles and boulders from the terrace surfaces and bodies, which would provide a maximum age for our ancestors' footprint on these terraces. The collected samples were either interbedded in the desert pavements or buried in the terrace bodies. Cores from quartzite and granite cobbles were extracted and cut into approximately 0.7 mm thin slices. Measurements of normalized, natural luminescence intensity (L_n/T_n) were used to investigate the bleaching profiles of the cobbles. The quartzite cobbles have been bleached throughout during the exposure at the terrace surfaces. The translucent mineralogy of the quartzite appears to transmit light through the entire cobbles. The larger boulder has been bleached to approximately 40 mm of depth from the exposed side. In Wadi Sodmein, we observe a difference in light attenuation between translucent and more opaque lithologies, since the buried surface of a granite cobble is near saturation and no difference in L_n/T_n is observable in the depth profile. We exposed quartzite and granite cobbles that had been buried in the terrace bodies, on a rooftop in a village near Wadi Sodmein, to further investigate their luminescence characteristics. The cobbles will be collected and their luminescence characteristics will be investigated after one year of exposure. Future investigations will also focus on investigating more granite cobbles and on sampling cobbles that are buried in the wadi terraces.

A new single grain luminescence chronology for a key late Quaternary terrestrial archive: Voordrag, KwaZulu-Natal, eastern South Africa

Debra Colarossi^{1,2}, Geoff A.T. Duller², Helen M. Roberts², Stephen Tooth², Greg A. Botha³

¹Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany. ²Aberystwyth University, Aberystwyth, United Kingdom. ³Council for Geoscience, Durban, South Africa

Abstract

Donga (gully) incision at Voordrag, located at ~945 m elevation in the Drakensberg, eastern South Africa, has exposed a near-continuous succession (~18 m composite thickness) of colluvium and interbedded palaeosols. This succession represents a key Quaternary terrestrial archive for this part of southern Africa, having preserved a semi-continuous record of depositional and pedogenetic phases with little evidence of erosive events until the late Holocene. The intercalated nature of the colluvial sediments and palaeosols enables the use of both luminescence dating techniques and radiocarbon dating, respectively, to constrain the sedimentary record at Voordrag. The availability of multiple chronometers at this site, offers a valuable opportunity for cross-corroboration of the dating techniques employed.

This study compares new luminescence ages for the colluvial sediments from the Voordrag sequence, determined using the optically stimulated luminescence (OSL) signal from single grains of quartz and the post-infrared infrared stimulated luminescence (post-IR IRSL) signal from single grains of K-rich feldspar. These quartz and feldspar luminescence ages are compared to each other, and to the bulk radiocarbon dating of the palaeosol horizons from the previous chronology of Clarke et al. (2003). Key findings include the ability of the post-IR IRSL signal from single grains of K-feldspar to accurately date the heterogeneously-bleached colluvial sediments throughout the sedimentary sequence at Voordrag. Agreement between the single grain quartz OSL ages, the single grain K-feldspar post-IR IRSL ages, and the previously published radiocarbon ages is also noteworthy. The oldest single grain quartz OSL ages are also shown to increasingly underestimate the true depositional age of the sediments; unusually, the age constraint for these saturated OSL ages ($\geq \sim 24$ ka) can be provided by radiocarbon dating due to the high environmental dose rate at the site. The new luminescence ages generated in this study, combine with the previous radiocarbon-based chronology of Clarke et al. (2003), to provide a new age model for the Voordrag sequence, facilitating a revised interpretation of this important South African terrestrial archive.

Geomolecular dating: integrating OSL chronology and Molecular dating of the Late Quaternary paleorecords from South East Coast of India

Bhavatharini Shanmuganathan¹, Shan Thomas¹, Raman Gurusamy², Kartika Goswami³, Maha Dev³, Manoj Kumar Jaiswal³, Anbarasu Kumaresan¹, Senthil Kumar Sadasivam¹

¹National College, Trichy, India. ²Yeungnam University, Gyeongsan, Korea, Republic of. ³IISER, Kolkata, India

Abstract

A transdisciplinary “Geomolecular” approach had been attempted to construct a temporal scale for bacterial evolution by tying the paleoecological events that took place at known geological past to specific branch points in the genealogical tree relating the 16S ribosomal RNAs of eubacteria. Optically Stimulated Luminescence (OSL) dating was carried out in 25m core sediments at 1.5m resolution in two paleobeach ridges namely Vettaikaraniruppu (VKI: 10.572514 N, 79.835111 E) and Korukkai (KUI: 10.535717 N, 79.711936 E) located 2.6Km and 16.6Km inland respectively, along the Cauvery Delta, Tamil Nadu, South East Coast of India. OSL dating revealed the age of the VKI sediments from 3.36 ± 0.42 (VKI-2: 2.8m) to 146.64 ± 36.81 kaBP (VKI-14: 24.5m). VKI sediments formed during Middle Holocene Transgression of 9.27 ± 1.22 and 6.45 ± 1.32 kaBP started from 12.0m and lasted till 5.6m depth respectively. The rate of sedimentation during 9.27 ± 1.22 (VKI-7: 12.0m) and 3.36 ± 0.42 kaBP was found to be higher than the rate of sedimentation between 58.25 ± 12.81 (VKI-8: 14.0m) and 9.27 ± 1.22 kaBP. The VKI sediments formed between 14.0m and 12.0m depths denoted a hiatus period. The age of the KUI sediments ranged from 19.22 ± 8.65 (KUI-3: 3.2m) to 145.51 ± 27.92 kaBP (KUI-16: 22.7m). A hiatus of sedimentation was observed in the age range of 76.4 ± 40.59 (KUI-12a: 16.6m) and 125.00 ± 5.26 ka BP (KUI-12F: 17.2m). VKI-12 (21.0m) and KUI-12 (17.2m) sediments were dated to 122.10 ± 39.00 and 125.00 ± 5.26 ka BP which coincided with Last Interglacial Transgression. Further, VKI and KUI sediments were also dated to Marine Isotopic Stages (MIS). Molecular clocks of these stratigraphically estimated paleoecological sediments VKI-2 (2.8m), VKI-5 (7.2m), VKI-8 (13.6m), VKI-10 (16.9m), VKI-12 (21.0m) and VKI-14 (24.5m); KUI-3 (3.2m), KUI-7 (9.0m), KUI-11 (14.5m), KUI-12 (17.2m) and KUI-16 (24.2m) was constructed based on the Operational Taxonomic Units (OTUs) obtained by 16S rDNA Next Generation Sequencing using Bayesian Evolutionary Analysis Sampling Trees (BEAST) software program. The mean age estimates (in millions of years) of these Late Quaternary sediments depicted the molecular evolution of bacteria to be falling under Paleogene, Cretaceous period and extended till the origin of heterotrophic bacteria i.e. about 3×10^9 years. In modern evolutionary divergence analysis, the role of geological information extends beyond providing a timescale, for informing molecular rate variation across the tree. Geological information which formerly gave a temporal scale to molecular branch lengths, now substantially tells how rates of molecular evolution of bacteria varies across the genealogical trees through Geomolecular dating.

Feasibility study of ^{210}Pb -chronology in distinct marine ecosystems of coral reefs, seagrass, mangrove, and coastal sea

Wuhui Lin^{1,2}, Kefu Yu^{1,2}, Yinghui Wang^{1,2}, Xingming Liu³

¹Coral Reef Research Center of China and School of Marine Sciences, Guangxi University, Nanning, China. ²Guangxi Laboratory on the study of Coral Reefs in the South China Sea, Nanning, China. ³Guangxi Academy of Oceanography, Nanning, China

Abstract

The ^{210}Pb -chronology has been successfully applied in marine sediments to reconstruct past environmental change. However, the physical settings of marine sediments significantly vary among different marine ecosystems, greatly affecting the excess ^{210}Pb patterns and its application in sediment geochronology. A comparative study of excess ^{210}Pb patterns in marine sediments collected from distinct marine ecosystems is rarely investigated. In the present study, six sediment cores collected from typical marine ecosystems of coral reefs, seagrass, mangrove, and coastal sea were measured using High Purity Germanium γ spectrometry to validate and extend the availability of ^{210}Pb -chronology in distinct marine ecosystems.

As for coral reefs (Fig. 1a), the activities of ^{210}Pb and ^{226}Ra ranged from 3~11 Bq/kg and 2~7 Bq/kg. A slight excess of ^{210}Pb was also observed relative to ^{226}Ra . It was noted that the ^{210}Pb and ^{226}Ra activities in coral reefs were the lowest relative to that in other sediment cores due to the carbonate component and large grain size for these sediments in coral reefs. The activities of ^{210}Pb and ^{226}Ra were in the range of 22~89 Bq/kg and 22~31 Bq/kg in seagrass ecosystem (Fig. 1b). The excess ^{210}Pb was exponentially decreased along with the depth of sediment, benefiting construction of sedimentary chronology. In the mangrove ecosystem (Fig. 1c), the activities of ^{210}Pb and ^{226}Ra in sediment varied within the ranges of 10~52 Bq/kg and 13~24 Bq/kg. A reversible pattern of excess ^{210}Pb was observed. The excess ^{210}Pb was observed in the deep layer rather than the surface layer of sediment, indicating high intensification of human/biological disturbance in the easily accessible mangrove ecosystems. Three sediment cores including sandy (Fig. 1d and Fig. 1e) and muddy sediment (Fig. 1f) were collected in coastal sea. In muddy sediment, the activities of ^{210}Pb and ^{226}Ra ranged from 80~110 Bq/kg and 35~42 Bq/kg. A significant excess ^{210}Pb was observed in the bottom layer sediment (35 cm) and destroy the availability of ^{210}Pb -chronology. In sandy sediment, ^{210}Pb and ^{226}Ra activities ranged from 16~47 Bq/kg and 12~21 Bq/kg. The mixing layer was also observed in the upper zone of sediment (0~13cm) due to biological disturbance. The sediment chronology could be constructed based on the exponential curve of excess ^{210}Pb in the sublayer sediment (depth >13 cm).

Overall, the typical patterns of excess ^{210}Pb were simultaneously displayed for distinct marine ecosystems of coral reefs, seagrass, mangrove, and coastal sea. Our results would also benefit our comprehensive understanding of the variable behaviors of $^{210}\text{Pb}/^{226}\text{Ra}$ in distinct marine ecosystems for tracking specific marine processes and extending the availability of ^{210}Pb -chronology.

Testing the uncertainties of age-depth models based on coupled ^{14}C and ^{210}Pb data

Natalia Piotrowska, Jarosław Sikorski

Silesian University of Technology, Institute of Physics-CSE, Division of Radioisotopes, Gliwice, Poland

Abstract

^{14}C and ^{210}Pb methods are regularly used to determine ages and accumulation rates of peat, fen and lake sediments. The overall aim is to estimate the age of discrete layers, which were analysed for environmental proxies. Ideally, the age-depth models should fit the investigated proxy in terms of resolution and give precise results. Nevertheless, the differences in the nature of dating methods and statistical treatment of data need to be considered.

Both ^{14}C and ^{210}Pb signals are integrated over a considerable period. Moreover, they originate from different sources. ^{210}Pb is bound to aerosols and trapped by peat while ^{14}C is bound from atmospheric CO_2 by photosynthesis. Hence, ^{210}Pb gives the time span during which the aerosol has been buried, whereas the ^{14}C date gives the time of death of a plant.

After the analysis, the results are usually combined into an age-depth model. This process involves statistical treatment of data during which specific assumptions and simplifications are made. Depending on the algorithm, they lead to alterations in modelled ages compared to unmodelled data. Principally it is a desired result—increasing the robustness and decreasing the uncertainty of the age-depth model. In worse cases models alter the modelled ages to an unacceptable extent, which may be overlooked if the results are treated automatically.

We test the performance of various age-depth modelling algorithms (OxCal P_Sequence, Bacon, clam, MOD-AGE) on a few selected true datasets where ^{14}C and ^{210}Pb data overlap and are used simultaneously. Afterwards, a point estimate is selected and used for proxy analysis on a time scale and for calculation of the accumulation rates. Together with the thickness of analysed samples they provide an information about the time resolution of proxy analysis. While the age-depth curves, except outstanding circumstances, give relatively similar answers within 95% uncertainty ranges, the differences are observed in point estimates and accumulation rate, and they may be relevant for the palaeoenvironmental studies. With this exercise we attempt to assess the uncertainty beyond simple age errors reported from the measurements and age-depth modelling.

Constructing age-depth models in long terrestrial records across the Mediterranean; the importance of philosophical analysis

Mark Hardiman, Rob Inkpen
University of Portsmouth, Portsmouth, United Kingdom

Abstract

Constructing chronologies is a fundamental component of Quaternary research, and a constellation of different techniques have been both developed and employed in undertaking this critical task. Often dating methods are separated as either being 'independent' (e.g. radiometric methods) or alignment-based (e.g. where ages from target records such as the Greenland ice-core record, are imported via proxy-stratigraphic correlations). Ideally all chronologies would be formed from several lines of dating evidence with the production of a single, agreed chronology as the end goal of such research. Indeed, the "final" or "finished" chronology is a refrain often heard from Quaternary scientists, but does this really exist and what does this really mean?

Of course different lines of chronological evidence are often in marked disagreement, and the process in which one chronology is 'picked' or developed over another is often not fully explored, or worse contradictory data may never be published (or swept under the carpet with '*Occam's broom*'). Recent developments in historical sciences (Currie, 2018) concerning the nature of traces, over and under determination of the past and the value of investigative scaffolding in assessing hypotheses, may throw some light on how different chronologies continue to exist despite the range of dating techniques and evidence that continue to drive debate. These ideas may also help to understand the nature of evidence and the importance of the existing explanatory frameworks for refining competing hypotheses and discriminating between them.

Here using several case studies from the Mediterranean terrestrial record we explore these issues, highlight age-model offsets on the order of $10^{4\sim5}$ years, which arise depending on which chronological information is accepted or rejected. We argue that all conflicting data should be published, thus helping prevent against the formation and persistence of 'coherent myths' (*sensu* Oldfield, 2001) and increase our understanding of the kind of chronological offsets feasible and fully allows multiple working hypotheses to exist and be considered.

Sedimentary structure and composition of sand blows and sand dikes formed by the 2018 Iburi-Tobu Earthquake, Hokkaido, Japan

Yuichi Nishimura¹, Takashi Chiba²

¹Institute of Seismology and Volcanology, Hokkaido University, Sapporo, Japan. ²Faculty of Bioresource Sciences, Akita Prefectural University, Akita, Japan

Abstract

The M6.7 Hokkaido Iburi-Tobu Earthquake of September 6th, 2018, left sand blows and sand dikes result from liquefaction at Tomakomai, Atsuma, and Mukawa, where the distance from the epicenter is less than 20 km and Japanese seismic intensity scale is more than 6. We investigated distribution, shape, sedimentary structure and composition of the new deposits. Sand blows are mainly observed in flat areas on coast and estuaries that have undergone artificial modification. Size of the sand blows varies from several tens of centimeters to several meters in diameter. Each sand blow has a vent or vent system that aligned along a fissure. Sand blows are composed by fine to coast sand, mud, pebbles and various size of pumice. A layered structure is commonly seen in the cross-section. In most of the case, mud, pumice, and sand are deposited in order from the bottom to the top of the deposit. There is little evidence that blowing sand has eroded and involved the surrounding topsoil as it rises, as a composition including diatom assemblage is significantly different between them. It seems that the mixed layer of sand and pumice in the landfill soil liquefied and sand and pumice separated in the layer. Then they ejected with mud from the accumulated light particles near to the vent. The sand dikes are observed by trenching or by using a handy geoslicer. Most of the dikes are not straight, they are curved or bent along the boundary of the inhomogeneous medium around them. The width of the dikes vary from 1 mm to 10 cm, and they are filled with sand or pebbles that are the same materials as those came out at the final stage of the ejection. There are dikes that are clogged from the bottom with pumice and coarse sand. In those dikes, the size of the particle filling the dike decreased upward with the clogged location as the boundary. Thus, a feature of sand blow and sand dike can be complicated reflecting the size and density characteristics of the particles constituting the liquefaction layer. The precise description of the new sand blows and sand dikes can provide a better understanding of the liquefaction process and also can be useful for the identification and evaluation of paleo liquefaction deposits.

Earthquake damage recorded along the Roman Eifel Aqueduct (Lower Rhine Embayment, Germany)

Gösta Hoffmann^{1,2}, Sabine Kummer¹, Rosa Enrique¹, Mario Valdivia Manchego¹

¹Bonn University, Bonn, Germany. ²RWTH Aachen University, Aachen, Germany

Abstract

The Lower Rhine Embayment and adjacent areas are characterised by neotectonic deformation resulting in differential crustal movement. Slip rates along the fault systems are very low ($< 0.1\text{mm/a}$). Significant earthquakes are known to have occurred in the past but the faulting behaviour is not adequately known which hampers the risks assessment. We analysed the archaeological record of the largest Roman aqueduct north of the Alps. This so called Eifel Aqueduct is 95.4 km long, has its source in the Eifel mountains and supplied the ancient city of Cologne with calcareous fresh water. The aqueduct crosses major faults of the Lower Rhine Embayment perpendicular.

Analyses of the aqueduct's gradient gives weak evidence for creep along the Kirspenich Fault resulting in differential movement of hanging and foot wall in the order of a few centimetres. Vertical offsets of 15 and 35 cm are documented exactly where the aqueduct crosses the Holzheim Fault system close to the city of Mechernich. Here, also structural damage of the aqueduct is recorded and archaeological evidence exists for repair works on the aqueduct. We interpret these observations as well as the construction of a 4 km long deviation as necessary measures to keep the aqueduct operational after earthquake damage. The timing of the event falls within the period of aqueduct operation which is reconstructed to be between 80 ± 10 CE to 270 ± 10 CE. Supporting evidence for earthquake activity within this period is seen in the roof collapse of the nearby Kakus cave.

Post-seismic deformation evaluated from logarithmic and exponential transients in GNSS trajectory models

Franco Sebastian Sobrero¹, Michael Bevis², Fei Wang²

¹Universidad Nacional del Litoral, Santa Fe, Argentina. ²The Ohio State University, Columbus, USA

Abstract

For the past few decades, modern geodetic techniques have allowed us to detect and measure post-seismic deformation occurring at the surface. However, the overall interaction between the viscous upper mantle and the much stiffer elastic lithosphere in the aftermath of an earthquake, which drives such deformation, is not yet fully understood. We know that we can model GNSS time series manifesting postseismic transient displacements almost equally well using trajectory models constructed with single or double logarithmic or exponential transients. The logarithmic form is associated with rate and state friction theory and afterslip, while the exponential form is associated with bulk viscoelastic relaxation. It is believed that afterslip is the dominant driver of post-seismic displacement transients immediately after an earthquake, but eventually, it is superseded by viscoelastic relaxation of co-seismic stresses. We assess the relative explanatory value of double logarithmic, double exponential and hybrid transient forms when used in GNSS station trajectory models, focusing on GNSS time series with strong post-seismic transient signals and better than typical signal-to-noise ratios. We also look into the spatial distribution of the accumulated post-seismic displacements. We find that the double logarithmic transient typically provides slightly better fits than the hybrid transient model in which the logarithmic component is assigned shorter decay time scale parameters than the exponential component, and both models provided much better fits than the double exponential form. Therefore, the hypothesis that short-term transient behavior associated with afterslip is eventually dominated by longer time scale transient behavior associated with viscous relaxation receives no support from this study. The observations can be explained just as well – and even slightly better – by the hypothesis that the entire post-seismic transient (7 years of post-seismic measurements) was driven by afterslip. Finally, we found that while the largest observed coseismic displacements occurred at coastal GNSS stations, the largest accumulated postseismic displacements occurred well inland, suggesting if postseismic deformation is driven by afterslip, then much of that afterslip occurred below (i.e. inland of) the seismic rupture zone.

Figure 1. Coseismic jump magnitude showing maximum values at southeastern coastal stations, and approximately symmetrical about the slip vector corresponding to the Centroid Moment Tensor.

Figure 2. Accumulated postseismic displacements (7 years after the main shock). Maximum values located further inland.

Post-glacial deformation of the eastern Magallanes-Fagnano transform fault system, Tierra del Fuego, Argentina

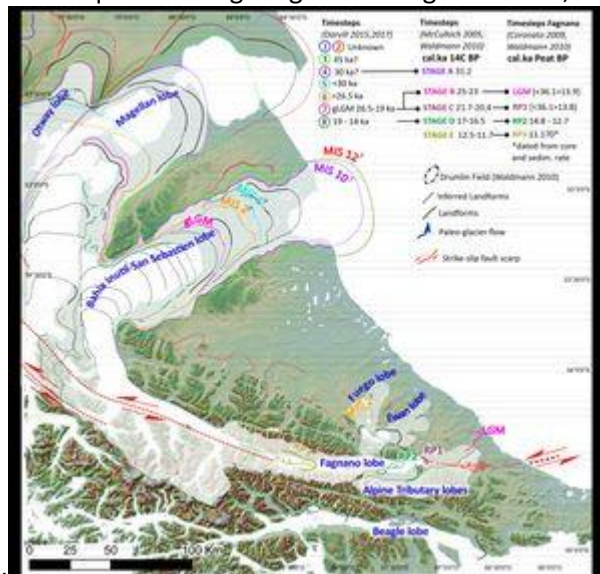

Sandrine Roy¹, Riccardo Vassallo¹, Joseph Martinod¹, Matías Ghiglione², Christian Sue³, Pascal Allemand⁴

¹ISTerre, Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, IRD, IFSTTAR, Grenoble, France. ²IDEAN-CONICET Universidad de Buenos Aires, Buenos Aires, Argentina. ³Université Bourgogne Franche-Comté, CNRS UMR6249, Besancon, France. ⁴Université Claude Bernard Lyon 1, Laboratoire de Géologie, Lyon, France

Abstract

Tierra del Fuego is crosscut by a major transform fault, the Magallanes-Fagnano Fault that accommodates sinistral strike-slip motion between Scotia and South America plates. The present-day relative velocity between these plates estimated using GPS measurements is 5.9 ± 0.2 mm.yr⁻¹. Major events occurred along this fault in 1879 and 1949. The 1949 magnitude was $M_w \sim 7.5-7.8$ with several aftershocks of similar magnitude, but the precise localization of corresponding rupture zones is not possible using seismological data. Since the onset of strike-slip, suggested at the Late-Miocene, glacial advances have rejuvenated most of the rupture markers (figure 1). Until now, the Quaternary slip rate remained unknown and investigations regarding the last 1949 ruptures were scarce. In this work, we focus on the fault behavior associated with the post-glacial stress regime over its 80-km inland eastern section, using beryllium cosmogenic-nuclide dating, combined with high-resolution Pleiades imagery and fieldwork analyses of geomorphological markers. We identified a dead valley in which the drainage network has been abandoned following the retreat of a Würmian glacier. We dated the abandoned drainage within the valley at $< 18 \pm 2$ ky, which fixes the beginning of the tectonic deformation record. We quantified the sinistral offset accommodated by the fault across this valley of 115 ± 5 m. These results yield a minimum 6.4 ± 0.9 mm.yr⁻¹ slip-rate since 18 ky. Our study shows that in this context geomorphic and instantaneous fault slip rates are mostly the same, suggesting a steady fault behavior since glaciers retreat. On the other hand, we mapped the superficial ruptures that resulted from the 1949 earthquake and its aftershocks. We measured several man-made features left-laterally shifted. Two fences are crosscut with horizontal displacements of respectively $4 \text{ m} \pm 0.2 \text{ m}$ and $6.5 \text{ m} \pm 0.5 \text{ m}$. A third sinistral offset of $6.2 \pm 1 \text{ m}$ has been measured in the foundation of an abandoned broken bridge that spanned over the fault line. Therefore, we suggest that surface-ruptures length associated with the 1949 earthquake are greater than previously

estimated. If these offsets are characteristic for main earthquakes along Magallanes-Fagnano Fault, their recurrence

period should be in the order of one thousand years.

Figure1:Glacial records of Tierra del Fuego and Magallanes-Fagnano strike-slip fault, after Darvill et al. 2015, 2017, McCulloch et al. 2005, Coronato et al. 2009, Waldmann et al. 2010.

First evidence of Holocene surface rupture at the Carboneras fault (Southeastern Iberia)

Robert López¹, Eulalia Masana¹, Giorgi Khazaradze¹, Octavi Gomez-Novell¹, Raimon Pallàs¹, Maria Ortuño¹, Stephane Baize², Thomas Rockwell³

¹ RISKMAT Group, GEOMODELS Research Institute, Departament de Dinàmica de la Terra i de l'Oceà, Facultat de Ciències de la Terra, Universitat de Barcelona, Barcelona, Spain. ² Institut de Radioprotection et Sûreté Nucléaire - Seismic Hazard Division (BERSSIN), Fontenay-aux-Roses, France. ³ Department of Geological Sciences, San Diego State University, San Diego, USA

Abstract

The Carboneras Fault belongs to the Eastern Betics Shear Zone in southeastern Iberia. Due to the scarcity of instrumental seismicity and moderate to large earthquakes in the historical record, paleoseismic studies are needed to better assess the seismic hazard of this fault. This study aims to refine the paleoseismic parameters (slip-rate, recurrence, slip per event, ...) analyzing, for the first time, the southeastern trace of the La Serrata duplex. The Carboneras Fault is a 150 km long left-lateral strike-slip fault. La Serrata Range, is a 12 km contractional duplex, defined as one of the four on-shore segments, that has been the subject of another paleoseismic study in the northwestern trace. This analyzed site area is located on the apex of a Late Pleistocene alluvial fan. The paleoseismic survey consisted in 13 trenches and 12 slices, performed in two different phases. The stratigraphy of the fan consists of two large and wide channel systems that incise into an older fan surface that has a carbonate caliche crust on top. An alternation of loose gravel channels, and wide layers of debris and mud flows forms the filling of those large channels. In the trenches dug perpendicular to the fault evidence for 4 to 5 events were found defined by capped faults, with the youngest fault trace affecting the top soil layer. The trenches dug parallel to the fault evidenced up to 16 channels. Eight of these channels were used as piercing lines for offset measurements. The incremental offsets of the different channels suggest a continuous fault activity throughout the Late Pleistocene. The preliminary radiocarbon dating from the first phase yielded slip-rates approximately ranging between 0.2 and 0.5 mm/yr for the southeastern trace of La Serrata. The youngest affected channel is offset about 2 to 3 meters, which probably corresponds to a maximum slip per event as it is the last event recorded. This would scale with a Mw 7.0-7.2 earthquake and to a rupture length of about 46 to 58 km, implying a review of the actual segmentation model of the fault. This last event could correspond to the Almeria's 1522 (EMS IX) earthquake. New radiocarbon and OSL datings are in progress to test this hypothesis.

Geological and seismotectonic investigations at a site of a planned NPP in the region of moderate seismicity

Miloš Bavec¹, K. Michael Cline², Jure Atanackov¹, Petra Jamšek Rupnik¹, Michael Logan Cline², Igor Rižnar³, Mladen Živčić⁴, Richard Quittmeyer²

¹Geological Survey of Slovenia, Ljubljana, Slovenia. ²Rizzo International, Pittsburgh, USA. ³Geološke ekspertize, Ljubljana, Slovenia. ⁴ARSO, Ljubljana, Slovenia

Abstract

The Krško Basin (SE Slovenia) is the site of an existing nuclear power plant (NPP) and a new unit is being considered. In support of an assessment of site suitability, new geologic and seismotectonic investigations were performed from 2013 through 2018. Seismic safety is the focus of the investigations with one emphasis on fault capability and another on seismic source characterization for a probabilistic analysis of ground motion hazard. The recent project (2015 – 2018) was performed by a team composed of RIZZO International and the Geological Survey of Slovenia (GeoZS).

The basin has a relatively complex geological history attributed to its geotectonic position at the junction of the Alps, Dinarides and the Pannonian Basin. The geological, in particular the structural, interpretation is further complicated by the succession of Quaternary and Neogene (soft) sediments and overlying pre-Neogene (hard) rocks. Regardless of the complexity, an in-depth understanding of the geology, especially the neotectonic setting, is essential.

The recent field and laboratory investigations comprised an integrated suite of geomorphological, geophysical, geological, geochronological, and paleoseismological studies. Special focus was given to the potentially active faults nearest to the site; the Orlica and Artiče faults.

Previously available geological, seismological, geophysical and geomorphological data compiled by a consortium of organizations in 2008 – 2013 have now been refined by data collected during subsequent investigations, including those of the most recent project. The refinements are based on work performed within the 25-km radius of the proposed second NPP sites between 2013 and 2018, including: geomorphological analyses and reconnaissance field mapping, 8.8 km of high resolution, shallow P- and S-wave reflection seismic profiles, and 3.1 km of shallow SRT and ERT profiles. This work led to the selection of three paleoseismological trench sites where trench walls were logged, and 62 samples of Quaternary sediment samples were dated.

This work provides a relevant case study in which complex geological problems are being addressed using state-of-the-art and state-of-the-practice methods. Given the complexity of the region, the multi-methodological approach is important for reducing uncertainty and providing important insights to the tectonic setting.

3-D analysis of shear-deformation bands in unconsolidated Pleistocene sands with ground-penetrating radar: Implications for paleoseismological studies

Christian Brandes¹, Jan Igel², Markus Loewer³, David Tanner², Jörg Lang¹, Katharina Müller¹, Jutta Winsemann¹
¹Leibniz Universität Hannover, Hannover, Germany. ²Leibniz Institut für Angewandte Geophysik, Hannover, Germany. ³Technische Universität München, München, Germany

Abstract

Deformation bands developed in unconsolidated sediments are of great value for paleoseismological studies, because they can indicate tectonic activity that occurs along blind faults. With ground-penetrating radar (GPR), we analysed an array of shear-deformation bands that occur in Pleistocene glacial fluvial Gilbert-type delta sediments in northern Germany. A dense grid of GPR profiles with a spacing of 0.6 m was measured on top of a 20 m-long outcrop that exposes shear-deformation bands. This allowed to directly tie features in the radargram to the exposure. The shear-deformation bands exposed in the 2-D outcrop have a normal sense of displacement in a range of 1 to 24 cm and the bands form a northeastwardly-dipping array. The array consists of seven major shear-deformation bands with a spacing of 1 to 2 m. Individual bands have dip-angles between 30° and 58° and the thicknesses vary between 1 and 3 centimetres. Two shorter antithetic bands are developed in the array and have higher dip angles. The shear-deformation bands can be clearly imaged in the radargrams, where they are partly represented by inclined reflectors and partly by the offset of reflectors. Thin sections of sediment samples show that the analysed shear-deformation bands have a denser grain packing than the host sediment. Thus, they have a lower porosity and smaller pore sizes and therefore, in the vadose zone, the shear-deformation bands have a higher water content due to enhanced capillary forces. This, together with a partially-developed weak calcite cementation and the distinct offset along the bands, are the main reasons for the clear and unambiguous expression of the shear-deformation bands in the radar survey. For a 3-D interpretation of the 2-D radargrams, a 3-D geometrical model was reconstructed. The 3-D model shows that the bands have near-planar geometries that can be traced throughout the entire sediment volume. With the 3-D analysis, it is further possible to derive the orientation and geometry of the bands and allows a correlation of the bands with the regional fault pattern. The shear-deformation bands in this study follow the trend of the regional faults, thus indicating a direct relationship of the deformation bands to the deep-seated faults. We therefore conclude that the analysed shear-deformation bands formed in the process zone above the fault tip-lines, as near-surface expression of fault movement at depth. The results imply that deformation bands can serve as indicators of deeper fault movement and thus are important structural elements that can help to better estimate the seismic hazard potential of a region.

Interactions between landslides and glacier advances during the Alpine Lateglacial of the Eastern Alps

Jürgen M. Reitner¹, Mathias G. Steinbichler¹, Marc Ostermann¹, Susan Ivy-Ochs²

¹Geological Survey of Austria, Vienna, Austria. ²ETH Zürich, Zürich, Switzerland

Abstract

Glacial erosion during the Alpine Last Glacial Maximum (AlpLGM) resulted in an enhanced relief with oversteepened slopes. The classical textbook view of mass movements starting after ice-decay during the Alpine Lateglacial (ALG, c. 19-11.7 ka) has been challenged by the increased number of numerical dates of rockslides and rock avalanches. Most of the dated catastrophic rock slope failures occurred during the Holocene and only a minority are of ALG age. However, systematic geological fieldwork accompanied by several dating techniques showed complex, direct and indirect links between glacial and gravitational processes during the ALG. Paraglacial rock slope failures had in some cases a considerable impact on glacier dynamics during the stadials. This includes (1) landslide-dammed lakes and their influence on glacier advances and (2) debris-covered (or mantled) glacier systems due to rock avalanche activity during glacier advances resulting in the formation of huge moraines and in large palaeoglacier extents. In addition, such an impact results in (3) changes of the valley topography and, hence, in very different conditions for following glacier advances compared to previous ones.

Based on recent geochronological data, especially results of surface exposure dating with cosmogenic nuclides, this contribution demonstrates the impact of various paraglacial mass movement-types (deep-seated gravitational slope deformations, rockslides and rock avalanches) on the landscape and on glacier advances. The record of gravitational processes covers the period from the onset of deglaciation during the phase of ice-decay (20-19 ka), the Gschnitz stadial (17-16 ka) and the Egesen stadial (Younger Dryas, 12.8-11.7 ka).

The examples also show that gravitational deposits could serve as an excellent marker to improve the stratigraphy of the ALG considering the whole landscape evolution since the AlpLGM.

Contribution of glacial and debris flow agents in Holocene landscape transformation of mountainous valleys, Kola Peninsula, NW Russia

Ekaterina Garankina, Vladimir Belyaev, Yuri Belyaev, Maxim Ivanov, Fedor Romanenko, Anna Rudinskaya, Elena Sheremetskaya, Egor Voroshilov
Faculty of Geography, Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

Actual landscapes of the Kola Peninsula Mountains are regarded as products of the expansive Late Pleistocene glaciations followed by an intensive erosion those caused deep troughs and valleys networks. At present, specific slushflow process appears to be one of the essential agents of valley sediment transport alongside the normal fluvial erosion. Despite widespread hazardous manifestations, only the latter is considered when reconstructing the Holocene evolution of initial glacial valley topography. However, detailed study of a series of mountain river basins and adjoining piedmonts revealed a significant role of debris flows and slushflows in their transformation. To reliably distinguish landforms and deposits of different origin we applied a combination of remote sensing data interpretation, small-scale mapping, and field investigation of geomorphic patterns and textural-structural properties of stratigraphic sequences. Grain size analysis, ^{232}Th fingerprinting, and ^{14}C dating of buried organic-rich lenses allowed revealing the age, succession and magnitude of paleogeographical events and factors of valley lithodynamics changes since the Late Pleistocene-Holocene transition.

Western and southern parts of the mountains substantially penetrated by the continental ice are filled with corresponding deposits up to 700 m a.s.l. those subsequently became the main source of debris flows. Large (10-20 m high, 4 km²) coarse debris fans are found downstream the deep cuts in glaciolacustrine and glaciofluvial bodies. In contrast, middle reaches of some smaller valleys are completely devoid of any sediment removed by the recent extreme slushflows. In some valleys, initially lacking continental drifts, the position of ice front accumulations at piedmonts controlled the local base levels, distance and lateral distribution of debris flows. Discrete bodies in their middle reaches prove to be ancient tributary debris flow fans.

Thus, during the late deglaciation and the Early Holocene, debris flows played a leading role in sediment transport leaving large geomorphic footprints inconsistent with modern runoff conditions. Asynchronous melting of continental and mountain glaciers caused moraine-dammed lakes those breaches led to the largest of debris flow events. Later, distinct decrease of their transportation capacity and frequency occurred due to reduction of both water and sediment sources. They were broadly succumbed by slushflows with much lower clastic content (<12%), which explains smaller (<1-2 m high, 0.1-0.2 km²) actual accumulations. However, higher erosional potential of those phenomena causes direct incising of glacial and debris flow landforms. Integrated 40 ^{14}C dates for peats or primitive soils in fans and taluses, attributed to landscape stability periods, indicate several stages of increased slushflow and slope activity over the second part of Holocene. Even low-magnitude but high frequency slushflow episodes almost paralyze normal fluvial process. Disregarding such intensive landscape transformation agents through the Holocene causes difficulties in regional correlations of the postglacial mountain basins development.

Paraglacial relaxation and postglacial landscape change in Great Britain

Jasper Knight¹, Stephan Harrison²

¹University of the Witwatersrand, Johannesburg, South Africa. ²University of Exeter, Penryn, United Kingdom

Abstract

Great Britain was strongly affected by multiple glaciations during the Quaternary, and these have left a clear erosional and depositional signature in the physical geography of today's landscape, and in both terrestrial and offshore (shelf) environments. This signature is manifested in patterns of landscape topography and relief; the distribution and properties of surficial sediments; soil types; and the geography of rivers and coasts. Further, the inheritance of past glacial action has strongly affected postglacial (lateglacial and Holocene) patterns of ecosystem development; patterns and processes of human occupation and landscape change from the Mesolithic onwards; and the physical and ecological properties and processes taking place in today's landscape. As such, Great Britain can be considered to have a significant but not widely discussed paraglacial inheritance. This study examines evidence for this inheritance, describing case studies from upland (mountain), lowland (river) and coastal settings across Great Britain. This comparison highlights that fact that different environments have been imprinted in different ways by paraglacial landscape responses during the postglacial period – termed paraglacial landscape relaxation – and that different physical settings exhibit different levels of sensitivity to be affected by paraglacial processes. Examining the dynamics of these different settings to past climatic events (continental-scale deglaciation) can be used as a proxy for landscape sensitivity under future climate change (global warming).

Rock glaciers climatic and dynamic monitoring in the subtropical Andes of northwestern Argentina

Mateo Martini, Eliseo Flores

Centro de Investigaciones en Ciencias de la Tierra (CONICET-UNC), Cordoba, Argentina

Abstract

The subtropical Andes of northwestern Argentina have ranges that reach more than 6000 m a.s.l. At high-altitudes, arid and cold conditions prevail, and rock glaciers are one of the most widespread features. Active rock glaciers exist above 4500 m a.s.l. where precipitation is less than 500 mm/yr. In this contribution we present the results of the geomorphological mapping, and climatic and dynamic monitoring of two active rock glaciers: the Varas rock glacier (VRG) and Lizoite rock glacier (LRG).

We used differential GPS to accurately measure the position of a network of boulders once a year to establish the rock glaciers superficial flow. In order to know the climatic conditions affecting both rock glaciers, we installed a weather station on their surface to record hourly air and soil temperature, global solar radiation and relative humidity.

The VRG is situated above 4500 m a.s.l (23° 12' 9.12"S, 65° 3' 43.31"W) in the Cordillera Oriental. Based on the position, it is classified as a talus-derived rock glacier, indicating a periglacial origin. A network of 24 boulders was monitored every year between 2012 and 2016 using a differential GPS. During the entire period of measurement, the VRG registered movements between 125 and 5 cm/yr, except for four boulders which did not move. Over the five years of monitoring, the mean annual air temperature remained above 0 °C (between 2.6 and 3.5 °C), and only for four months the mean temperature was negative. Mean annual temperatures at 5 and 50 cm depth range between 4.7-6.1 and 4.6-5.0, respectively.

The LRG is located in a glacial cirque in the Sierra de Santa Victoria of the Cordillera Oriental (22°11'41.70"S, 65°11'29.95"W). It is located above 4552 m a.s.l. and presents morphological characteristics that denote activity. Two years of thermal monitoring show positive air and soil temperature. The mean annual air temperature ranges between 3.1-4.1°C; the soil temperature at 5 cm depth ranges between 5.8-7.2°C; and the soil temperature at 50 cm ranges between 5-6.1°C. The superficial flow of the rock glacier, based on the measurement of 20 boulders, ranges from 3.5 to 14.7 cm/yr. In the front of the glacier there is a small lake, from which sediment cores were taken for paleoclimatic studies.

Both rock glaciers are under positive air temperatures and bellow the regional 0° C isotherm altitude (5000 m a.s.l.). 106 years of temperature instrumental record located at La Quiaca station (3459 m a.s.l.) reveals a warming trend of 0.8 °C during the last century. Therefore, it is possible that the Cordillera Oriental rock glaciers (i.e., VRG and LRG) are not in equilibrium or fully adapted to the current climatic conditions.

Slope instability driven by permafrost degradation in the Central Andes of Argentina

Jeanneret Pilar, Moreiras Stella Maris
IANIGLA, Mendoza, Argentina

Abstract

Landslides in the Central Andes of Argentina is a poorly studied but important topic, as these events could affect local streamflow system and water resources (Hermanns et al., 2011). As the study area has an arid to semi-arid climate, the only available source of drinking water for the neighboring settlements such as San Juan city, is melt-water from winter snow accumulation, high altitude glaciers and periglacial landforms. This means that, in the case of medium to large volume landslide, it could seriously affect the water quality, or even completely impound drainage system by natural dams. The basins fed by the Mercedario's Peak (around 32°S and 70°W) have a high local relief caused by glacial erosion and straining tectonic activity, which makes the area prone to landsliding (Costa and Schuster, 1988). After a thorough mass removal inventory carried out with remote sensing technics and field work it was noted that almost 30% of the studied 68.300Ha is affected by diverse types of gravitational processes including slowly creeping permafrost. Rock falls are the most extended events and accumulate in talus slopes and debris cones under outcrop with steeply dipping slopes (>50°) placed over 3500m asl (coincident with the lower limit of the periglacial environment). These slopes are normally densely fractured by regional structures and/or freeze-thaw action. Debris flows accumulate in alluvial cones and fans and are the second most extensive landforms, originating above the 3500m asl limit, while earth flows are more frequent but less extensive and its source area is directly associated with rock glaciers. Deep gravitational events are extensive but infrequent, being derived from lateral moraines. Rock avalanches are more frequent but smaller in size and there is no direct correlation with the type of lithology. The rest are represented by complex events and moraine collapses. Regarding the triggering and/or slope debilitating factors, it was noted that rock falls and small rock avalanches are frequent in glacial slopes with intense freeze-thaw action. Deep gravitational events on moraines could be a consequence of ice-core melting and debutressing action (Fischer et al., 2013). The first effect could also explain other irregular moraine collapses. The source area of flow type events such as debris and earth flows also indicate a strong periglacial correlation. These results show that large landslides, debris and earth flows are directly linked to the release of melt water of periglacial landforms. As the lower landforms within the basins have suffered from these phenomena, it is estimated that, in a global warming context, the ascent of the 0°C isotherm will affect periglacial landforms placed on the upper catchments increasing the frequency of water saturated debris or earth flow events.

The phasing of hydroclimatic, environmental, and geomorphic changes during the Last Glacial-Interglacial Transition in the Vale of Pickering, Northeast England.

Paul Lincoln, Ian Matthews, Adrian Palmer, Simon Blockley
Royal Holloway, University of London, Egham, United Kingdom

Abstract

It has been suggested that during the Last Glacial-Interglacial Transition (LGIT; c. 18-8 ka BP), shifts in hydrological, ecological and geomorphic systems (collectively termed as landscape changes here) occurred out of phase with abrupt climatic changes as observed in the Greenland ice-cores. These phase differences have been attributed to several variables including paraglacial readjustment, isostatic rebound, effective precipitation, soil development, and anthropogenic activity. At present however, the lack of holistic reconstructions of hydrological, ecological and geomorphic change precludes confident assessments into the driving mechanisms of landscape changes, and their phasing with abrupt climatic transitions.

The Vale of Pickering (VoP) in NE England has great potential to address this issue because it contains internationally important archives of: (1) the retreat of the BIIS during the last deglaciation (at c. 17.3 ka BP); (2) fluvial processes operating in the River Derwent catchment; (3) high-resolution palaeoenvironmental/palaeoclimatic records; (4) evidence of human occupation phases through the LGIT. This poster will present holistic palaeoenvironmental reconstructions through the two major warming phases of the LGIT, with the aims of synthesising the timing and phasing of changes in hydroclimatic, ecological, and fluvial systems in association with phases of human occupation in the valley.

Reconstructions show that landscape changes in the VoP lagged the major warming intervals in the LGIT by multiple centuries. In the Lateglacial Interstadial, low ecological activity and groundwater availability, coupled with ephemeral fluvial activity persisted in the valley for c. 700 years after climatic amelioration (and c. 3300 years after deglaciation), reflecting the roles of paraglacial and isostatic readjustment in limiting biogenic productivity and hydrological stability. At the start of the Holocene, the lag in landscape response was significantly shorter (c. 250 years) with more rapid readjustments in biogenic productivity and the hydrological system in the absence of paraglacial readjustment processes. In both instances, substantial human presence in the VoP only occurred after the step change in ecological, hydrological, and geomorphic systems towards archetypal 'interglacial' modes (i.e. stable and perennial rivers systems, high water tables, forested environs), demonstrating that local environmental conditions were not synchronous with regional climatic transitions, and were the principal factor controlling intervals of human occupation in the valley.

The last glacial Dead Sea region: vegetation history, fire activity, and biome modeling

Andrea Miebach, Sophie Stolzenberger, Lisa Wacker, Andreas Hense, Thomas Litt
University of Bonn, Bonn, Germany

Abstract

The southern Levant is a key region for studying vegetation developments in relation to climate dynamics and hominine migration processes in the past due to the sensitivity of the vegetation to climate variations and the long history of different anthropogenic occupation phases. However, paleoenvironmental conditions in the southern Levant during the Pleistocene were still insufficiently understood. Therefore, we investigated the vegetation and fire history of the Dead Sea region during the last glacial. We present a new palynological study inferred from sediments of Lake Lisan, the last glacial precursor of the Dead Sea. The sediments were recovered within an ICDP campaign from the center of the modern Dead Sea. The palynological results suggest that Irano-Turanian steppe and Saharo-Arabian desert vegetation prevailed in the Dead Sea region during the investigated period (ca. 88,000–14,000 years BP). Nevertheless, Mediterranean woodland elements significantly contributed to the vegetation composition suggesting moderate amounts of available water for plants. The early last glacial was characterized by dynamic climate conditions with pronounced dry phases and a high but unstable fire activity. Anatomically modern humans entered the southern Levant during a climatically stable phase (late MIS 4–MIS 3) with diverse habitats, constant moisture availability, and low fire activity. MIS 2 was the coldest phase of the investigated timeframe causing changes in woodland composition and a widespread occurrence of steppe. We used a biome modeling approach to access regional vegetation pattern under changing climate conditions and to evaluate different climate scenarios for the last glacial Levant. The study gains new insights into environmental responses of the Dead Sea region to climate variations through time. It contributes towards our understanding of paleoenvironmental conditions in the southern Levant, which functioned as an important corridor for human migration processes.

O-4198

Was human dispersal out of Africa limited to Pleistocene wet periods across the arid and hyper-arid Levantine Corridor?

Yoav Avni

Geological Survey of Israel, Jerusalem, Israel

Abstract

During the last decades, a debate developed among scholars regarding the geographical distribution, environmental conditions and climatic context of human dispersal routes connecting East Africa and Asia via the Southern Levant. Most scholars stressed the necessity of wet climatic periods for overcoming the hyper-arid zone of the Eastern Sahara or the Arabian Desert, together serving as a major physical barrier along these potential routes.

In light of this long debate, a re-evaluation of the physical conditions along the Levantine Corridor was carried out, focusing on the natural water availability in its most arid and hyper-arid zone. Based on high-resolution mapping of present natural water resources along a 400 km north to south transect located between the Mediterranean coast and the southern tip of the Sinai Peninsula, the following conclusions were reached, offering new insight on the subject:

1. The river Nile and its most eastern branch – the historical Pelusian arm – provided the perfect green and wet link between eastern Africa and the southern Levant via the Mediterranean coastal plain of the Sinai Peninsula, during the Pleistocene. The constant availability of fresh water on the surface and at a shallow depth along this route characterize it as the main dispersal corridor across the Saharan desert, with no need to synchronize the utilization of this route with “wet” climate periods.
2. The Negev and the Sinai deserts, which are located across the Levantine Corridor, form together a wide desert strip to the south of the Mediterranean coast. At present, these regions are experiencing aridity to hyper-aridity under the dry Holocene climate. Based on their geodiversity and climate, this strip demonstrates a variety of natural water resources that can presently support the transit and wandering of groups of humans, even in regions receiving only 20-30 mm of average annual precipitation.
3. Based on environmental and paleoclimate evidence, these harsh environmental conditions prevailed during most of the interglacial Holocene and, probably, during past interglacial phases. However, the large variety of archeological evidence proves that this region was almost constantly occupied by human societies, regardless of its harsh conditions.
4. Environmental reconstructions of the last late Pleistocene glacial phase indicate that the region was even more humid relative to the present hyper-dry climate. Therefore, human dispersal across the region was even easier during glacial times.
5. The utilization of the geodiversity by ancient societies was, and still is, a key factor for water availability in hyper-arid zones. Groups of hunters and gatherers could move and survive in this desert environment during past climates, covering both glacial and interglacial periods. Therefore, there is no need to attribute human dispersal across the hyper-arid zone between Africa and the Southern Levant only to “humid” climatic phases.

An Early Pleistocene lake-wetland sequence in the Levantine corridor: reconstructing the environmental conditions during initial African dispersal of *Homo*

Nicolas Waldmann¹, Juan Larrasoaña Gorosquieta², Steffen Mischke³, Hanan Ginat⁴, Yoav Avni⁵

¹University of Haifa, Haifa, Israel. ²Geological and Mining Institute of Spain, Zaragoza, Spain. ³University of Iceland, Reykjavík, Iceland. ⁴The Dead Sea and Arava Science Center, Tamar Regional Council, Israel. ⁵Geological Survey of Israel, Jerusalem, Israel

Abstract

The Saharo-Arabian desert belt has experienced significant environmental and climatic changes throughout the Pleistocene. These variations are evidenced by the presence of widespread deposits that indicate pluvial intervals (as expressed by lacustrine and wetland deposits, alluvial fans, paleosols, and speleothems) or hyper-arid periods (deserts and ergs). One of these pluvial intervals is represented by an Early Pleistocene lacustrine sequence that occupied an area of ~300 km² in the present extremely arid southern Negev desert: Lake Kuntila.

Several studies were previously carried out on this sedimentary sequence, with the aim of reconstructing the paleoenvironmental settings, mainly through methodological investigation of the microfauna assemblages. These previous studies show that the lacustrine sequence consists of chalky limestone with some banks of massive limestone alternating with marly to sandy-marly beds rich in gastropods, ostracods, fish remains, and charophytes. The fossil assemblage indicates a freshwater to hypersaline environment with salinity ranging between 0.5‰ and 70‰. Based on archeological artifacts corresponding to the Acheulean culture found on a nearby alluvial terrace, the top of the lacustrine sequence was assigned with a Lower Paleolithic age (~2.6-1.7 Ma).

The current study presents new results that expand our knowledge on the chronology and environmental settings of this lake system. Paleomagnetic measurements show a lower, normal polarity zone and a reverse interval in the upper part of the section. Considering previous exposure ages between 1.9 and 1.6 Ma measured on the pavement at the top of the columnar section, we correlate the observed polarity pattern with the top of Olduvai and the lowermost part of chron C1r. Hence, the Kuntila lacustrine sequence can be dated to approximately 1.9-1.7 Ma.

New analysis of the biological diversity show that the sequence mainly contains remains of very few species of ostracods, mostly recrystallized steinkerns of the euryhaline *Cyprideis torosa* and few shells of *Ilyocypris* (which is typical for freshwater and running water) or *Candona* (freshwater environments). The current study is further complemented by elemental analysis of the lithological sequence (μ XRF), and allows to better understand the environmental settings prevailing in the region during the Early Pleistocene and to propose several mechanisms for the expansion of humid conditions at these latitudes.

Dead Sea pollen – a key to environmental setting of early modern humans in the southern Levant

Chunzhu Chen^{1,2}, Thomas Litt²

¹Nantong University, Nantong, China. ²University of Bonn, Bonn, Germany

Abstract

The southern Levant is controlled by the Mediterranean climate in the north and the Saharo-Arabian desert climate in the south. The regional climate is linked to both mid-latitude and sub-tropical atmospheric-oceanic systems. Previous paleoclimatic studies of cave and lacustrine sediments have refined our knowledge of the last interglacial conditions. Yet, the pattern and trigger of the climatic change remain elusive due to the inconsistencies implied by different paleoenvironmental records. The Dead Sea is an invaluable archive hosting a long history of the regional environment. In 2010, Dead Sea deep drilling cores were retrieved allowing high-resolution multi-proxy analyses for the past c. 220 ka. On this basis, we present detailed palynological results from the Dead Sea, discussing past vegetation changes and climatic conditions in the southern Levant.

The glacial periods were semi-arid, characterized by dispersal of steppe and desert. The transition into the last interglacial was warm and hyper-arid, suggested by the predominance of desert components and virtual absence of Mediterranean trees. The last interglacial was marked by arboreal diversity maximum with strong seasonal contrast indicated by notable sclerophyllous expansion. Combining previous archaeological findings, our study suggests that the diverse ecosystems involving rich flora and fauna supported the survival and dispersal of anatomically modern humans in the southern Levant.

Depositional environments, pollen, phytoliths, and fauna from MIS 9 to MIS 1 in the central Azraq Basin, Jordan

Carlos Cordova^{1,2}, Christopher Ames^{3,4}, Amer Alsouliman⁵, April Nowell⁴, James Pokines⁶

¹Oklahoma State University, Stillwater, OK, USA. ²Kazan Federal University, Kazan, Russian Federation. ³University of Wollongong, Wollongong, Australia. ⁴University of Victoria, Victoria, Canada. ⁵The University of Ferrara, Ferrara, Italy. ⁶Boston University, Boston, USA

Abstract

The central part of the Azraq Basin (Eastern Jordanian Desert) represents an oasis at the crossroads between the Levant and the Syro-Arabian deserts. Such a reliable and resource-rich landscape in this arid region would have been important refugium for hominins throughout the Middle and Late Pleistocene. This paper presents the results of pollen and phytolith analysis from various soundings and excavation profiles throughout the Greater Azraq Oasis Area (GAOA).

Section NF-1, dated to the late MIS 9, is located on the highest identified lacustrine terrace. The sequence produced pollen dominated by Thymeleaceae and Leguminosae shrubs and grasses. Phytolith assemblages indicate more C₄ than C₃ grasses, which suggests a warm, but humid environment.

Shishan Marsh 1 archaeological site (SM1) comprises deposits represent a continuously drying lake dated to late MIS 8-early MIS 7. Aquatic grasses, sedges, and cattail, with large amounts of Chenopodiaceae shrubs dominate the pollen spectra. Phytolith assemblages indicate that the grasses consist mainly of *Phragmites* (reeds). The faunal remains identified from this deposit include *Panthera leo*, *Gazella* sp., *Bos* cf. primigenius, *Camelus* sp., *Equus* spp. *Stephanorhinus hemitoechus*, *Palaeoloxodon* cf. recki, and *Elephas* cf. *hysudricus* (Pokines et al. 2018, Quat. Res.). Late Acheulean material is associated with this deposit (Nowell et al. 2017, J. of Arch. Sci).

Located within a lacustrine terrace above the historic Druze Marsh, Section DV-1 is deposit dated to the late MIS 6. Pollen spectra include grasses and woody species such as Thymeleaceae and Oleaceae. Phytoliths indicate the presence of C₃ and C₄ terrestrial grasses and aquatic grasses (*Phragmites*). The deposit produced some Middle Palaeolithic-style Levallois flakes and remains of *Equus* sp.

Located in soundings into the former bed of the Druze Marsh, section DM-8 contains a sequence representing the transition from marsh to lacustrine facies dated to MIS 5b-5a. The combined pollen spectra includes terrestrial and aquatic grasses and woody species of the Leguminosae family and *Pistacia*. A few *Quercus* pollen grains, probably far-flung, appear in some of the deposits. The palustrine facies of this deposit also contained Middle Palaeolithic Levallois technology.

Located in the Shishan Marsh, section SM-6 contains a marsh deposit sequence spanning the LGM to the Holocene. Although aquatics dominate the pollen spectra, the non-aquatic pollen sequence shows a transition from Artemisia-dominated desert to a Chenopodiaceae dominated desert. The lower part of the deposit produced early Epipaleolithic material.

In summary, the combination of pollen and phytoliths at these localities complement one another to produce a more complete reconstruction of vegetation patterns from MIS 9-1. It becomes evident that during high lake stands

grasses dominate this part of the Azraq basin. During low lake levels, aquatic taxa stand out against a background of more desert-like vegetation of *Chenopodiaceae* and/or *Artemisia*.

O-4202

A multi-proxy study of late Pleistocene environmental variability in Israel's Hula Valley

Elizabeth Bunin¹, Birgit Plessen², Steffen Mischke¹, Gonen Sharon³

¹University of Iceland, Reykjavik, Iceland. ²Helmholtz-Zentrum Potsdam, Deutsches GeoForschungsZentrum, Potsdam, Germany. ³Tel Hai College, Upper Galilee, Israel

Abstract

The Epipaleolithic (c. 23 to 11.5 ka cal BP) was a period of rapid and remarkable environmental and cultural change in the southern Levant as nomadic bands of hunter-gatherers transitioned to life in sedentary communities. While climate warmed following the Last Glacial Maximum, published proxy reconstructions of late Glacial environmental conditions have produced conflicting precipitation histories for this region where water availability was likely particularly important.

Here, we have undertaken a multi-proxy examination of lacustrine sediments collected from the open-air archaeological site Jordan River Dureijat (JRD), located on the east bank of the Jordan River in the Hula Valley (northeast Israel). A three meter sedimentary sequence exposed during the archaeological excavation was sampled continuously at a vertical resolution of one centimeter and composes alternating units of homogenous dark grey silt, each approximately 10-40 cm thick, and horizons rich in mollusk remains (3-7 cm thick) dominated by freshwater mussels of the genus *Unio* and freshwater snails (genus: *Melanopsis*) and containing cultural artifacts including stone tools and carved bone fish hooks.

The shell-rich, artifact-bearing units are interpreted as being deposited nearer to the lake paleoshorelines than the shell-poor, archaeologically sterile units which likely represent deposition in a deeper, less shore-proximal environment. Extensive radiocarbon dating of the site's abundant charcoal has allowed for the creation of a robust age model using Bayesian modeling techniques (OxCal); this model has been used to constrain the timing of water level fluctuations in the basin and we estimate that the Hula Valley experienced dry periods with relatively low water level from 15.2-14.9, 12.8-12.2, 11.7-11.5 and 10.9-10.5 cal ka BP.

Subfossil ostracod remains are present in all samples, with the most abundant species being *Ilyocypris bradyi*, followed by *Candona neglecta* and *Candona angulata*. The habitat preferences of the observed species and their relative abundances are used to reconstruct environmental conditions in paleo-Lake Hula including lake water salinity, turbidity and energy level, while changing precipitation sources and amounts are examined using stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) measured from ostracod valves of the genus *Ilyocypris*. In addition to providing the site with a robust chronological framework, the age model allows the proxy data to be assessed as fluxes, simplifying interpretations of population density and species richness, and for the produced environmental reconstruction to be compared to records from nearby sites. This well-dated, robust multiproxy paleoenvironmental reconstruction of the late Pleistocene/Early Holocene Hula Valley is important both to understand living conditions at the site during periods of human occupation and to contribute to ongoing debates about the nature of water availability during the transition from glacial to interglacial conditions in this part of the Levantine corridor.

Palaeoenvironmental history from New Zealand swamp kauri (*Agathis australis*) tree ring records: Recent progress, sample collection and radiocarbon dating

Andrew Lorrey¹, Alan Hogg², Christian Turney³, Jonathan Palmer³, Gretel Boswijk⁴, John-Mark Woolley¹, Anthony Fowler⁴

¹National Institute of Water and Atmospheric Research, Auckland, New Zealand. ²University of Waikato, Hamilton, New Zealand. ³University of New South Wales, Sydney, Australia. ⁴University of Auckland, Auckland, New Zealand

Abstract

Swamp kauri (*Agathis australis*) trees are preserved in bogs across northern New Zealand. The anatomical structure of this buried wood has not been replaced with a mineral precipitate, so they are "subfossil" and can be mined and milled as workable timber. Some excavated swamp kauri have diameters in excess of 2.5m, and many trees attained great ages prior to death (>2000 years of growth). Swamp kauri can be preserved for many millennia in anoxic conditions, and Holocene, late glacial, pre-last glacial maximum, and last interglacial subfossil wood has been recovered. There are associations of the swamp kauri wood with peats, tephra and macrofossils within several types of geomorphic settings.

Recent concerns about swamp kauri extraction rates led us to define how this dendrochronology resource offers globally-unique opportunities for Quaternary science. This presentation will overview the potential of the swamp kauri, and advances made from several contemporary projects, including MIS3 kauri dendrochronology efforts and new sample collections. At present, >6000 years of chronology coverage exists for MIS3. Our expanded radiocarbon results from the last decade of analyses suggest the period 27ka to 60ka may be blanketed by swamp kauri samples. A new project underway as of July 2019 will target the development of supra-long MIS3 kauri chronologies with our collections. Our aim will be to produce higher resolution 14C calibration curves and detailed climate reconstructions to better align global palaeoevidence with ice core data.

Irish Dendrochronology: a review of new approaches in tree-ring dating

David Brown¹, Maire-Therese Barrett¹, Paula Reimer¹, Neil Loader², Michael Baillie¹

¹Queen's University Belfast, Belfast, United Kingdom. ²Swansea University, Swansea, United Kingdom

Abstract

The construction of a continuous Irish oak tree-ring chronology spanning the last 7492 years has led to a better understanding of human, ecological and climatic events. The information obtained from other environment sources can now be evaluated against this and other worldwide, precisely-dated tree-ring sequences. Examination, review and further advances of the long chronologies will provide greater clarity of the timing of past environmental and human activities. We present an overview of new approaches in Irish dendrochronology that enhance the dating and interpretation of tree-ring chronologies in Ireland, including stable and radio-isotopes that facilitate the correlation of problematic samples and floating chronologies from short-lived species. Additionally, pine chronologies provide an opportunity to replicate and extend information obtained from the oak chronologies; in particular, we consider the significance of subfossil bog timbers in the understanding of mid- to Late Holocene environmental change. These new techniques and datasets will produce, new, clear and important environmental and climatic information.

Application and evaluation of a dendroclimatic process-based model (MAIDEN) during the last century in the Northern Hemisphere

Jeanne Rezsöhazi^{1,2}, Hugues Goosse¹, Joel Guiot², Fabio Gennaretti³

¹Université catholique de Louvain, Earth and Life Institute, Louvain-la-Neuve, Belgium. ²Aix-Marseille Université, CEREGE, Aix-en-Provence, France. ³INRA Centre Grand Est, Nancy, France

Abstract

Tree-ring archives are important to reconstruct climate variations of the last millennium with annual resolution. The links between tree-ring proxies and climate have usually been estimated on the basis of statistical approaches, assuming linear and stationary relationships. Both assumptions can be inadequate but this issue can be overcome by ecophysiological modeling based on mechanistic understanding. For example the model MAIDEN (Modeling and Analysis In DENdroecology) simulates tree ring growth starting from temperature and precipitation daily inputs and considering carbon assimilation and allocation in forest stands. Currently, MAIDEN has been applied in the Mediterranean and temperate regions, in the Eastern Canadian taiga and in Argentina. In this study, we test the model sensitivity to the calibration of parameters and to the quality of the climatic inputs. Both are main sources of uncertainties. We especially want to answer the following question: Can we use MAIDEN driven by climate models outputs to reconstruct the climate of the last millennium using data assimilation? We develop a protocol to systematically calibrate the model and apply it to main extratropical tree species, based on the Bayesian procedure with Markov Chain Monte Carlo sampling developed by Gennaretti et al. (2017). MAIDEN is applied to selected sites of the Northern Hemisphere, covering a range of environmental conditions and tree species. The performance of the model at those sites is evaluated through a validation step (h-block Jack-knife and cross-validation) and compared with the VS-Lite model (a simple tree-growth process-based model). Pseudoproxy experiments help to evaluate the performance of the MAIDEN model in a flexible and controlled framework.

Gennaretti, F., Gea-Izquierdo, G., Boucher, E., Berninger, F., Arseneault, D. & Guiot, J. (2017). Ecophysiological modeling of the climate imprint on photosynthesis and carbon allocation to the tree stem in the North American boreal forest. *Biogeosciences Discuss.*, 48, 1-26.

Increased variability of Chao Phraya River peak-season flow in Thailand and associated ENSO activity: evidence from tree ring $\delta^{18}\text{O}$

Chenxi Xu

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The Chao Phraya River is central to Thailand's agricultural and economic well being, yet records of annual and seasonal flow regimes are relatively short and incomplete. A long-term record of stream flow variations would therefore be a necessary component for water management plans that take into account the historical impacts from climate variability. Here we present a statistically robust reconstruction of Chao Phraya peak-season (August-November) flow that spans the 257-year period from 1748-2005. Our reconstruction is based on tree-ring cellulose $\delta^{18}\text{O}$ series from three *Pinus merkusii* site collections from northern and central Thailand and north-central Laos, respectively. The regional $\delta^{18}\text{O}$ index accounts for 57% of the observed variance of August-November stream flow as measured at the Nakhon Sawan gauging station. Spatial correlation and 21-year running correlation analyses results reveal that Chao Phraya River peak season flow is greatly influenced by precipitation variation driven by the El Niño-Southern Oscillation (ENSO). Periods of enhanced and reduced ENSO activity are associated with strong and weak ENSO-stream flow correlation, respectively. The Pacific decadal oscillation (PDO) also modulates ENSO-streamflow correlations, hence the most extreme flood events along the Chao Phraya occur during periods of increased frequency of La Niña events during extended cold phases of the PDO. Our CPRPF reconstruction should serve as an important tool for future water management planning.

Establishing magnitudes of past debris floods events on an alluvial fan in the Julian Alps (NW Slovenia) using dendrogeomorphological method

Andrej Novak¹, Ryszard J. Kaczka^{2,3}, Tomislav Popit¹, Andrej Šmuc¹

¹University of Ljubljana, Faculty of Natural Sciences and Engineering, Department of Geology, Ljubljana, Slovenia.

²University of Silesia, Faculty of Earth Science, Sosnowiec, Poland. ³University of Hradec Kralove, Department of Biology, Hradec Kralove, Czech Republic

Abstract

The Planica Valley is a typical post-glacial Alpine valley located in the Julian Alps in NW Slovenia. Structurally it belongs to the Southern Alps. The bedrock mainly belongs to Upper Triassic carbonates. After the post-LGM glacier retreat, the Valley has been filled with various Holocene deposits among which alluvial fans and cones are the most prominent geomorphological features. The Valley has no permanent water streams and thus the sediment, composed of poorly sorted sands, gravels and boulders, is transported onto fans and cones only during (usually autumnal) episodic high precipitation torrential events in a form of debris floods. Debris floods induced by heavy precipitation affect trees by partially burying the stems up to one meter height. Such a combination of sediment transport mechanism, type of vegetation, geomorphological setting as well as the vicinity of a permanent meteorological station makes the Planica Valley a perfect study site for dendrogeomorphological research of past debris floods.

Establishing the magnitudes of past debris flood was a three-step process. In the first step, we sampled 105 trees (*Picea abies*, *Abies alba* and *Larix decidua*) on one of the most active alluvial fan in the Valley. We successfully dated thirteen debris flood events from the year 1903 onward as well as calculated the percentage of affected trees during each event. Debris floods were dated based on sudden growth suppression of buried trees expressed by sequences of narrower tree-rings. In the second step, we correlated flood events with high precipitation potential triggering events by careful analysis of meteorological data. Based on previous research and documented events we choose the minimum threshold of 50 mm of rainfall in a 24-hour period as a potential triggering meteorological event. In the third step, we established the magnitude of each debris flood event by comparing the amount of affected trees with the return period of potential triggering meteorological events. The comparison of the two data sets shows that debris floods, which affected 10 to 20 % of trees, were induced by torrential precipitation events with a 1-2 or 2-5 year return period. Debris floods, which affected 20 to 30 % of trees, were induced by torrential events with a 10- to 25- or 25- to 50-year return period, while debris floods affecting more than 30 % of trees were triggered by torrential events with a 100-year return period. Our dendrogeomorphological research, one of the few done in broader southeastern Alpine region suggests, that magnitude of past debris flood events can be indirectly determined by comparing the amount of affected trees and return period of a triggering rainfall event.

Do tree-ring records from southern Ontario, Canada track local ^{14}C releases from nuclear power plants?

Michael Pisaric¹, Carley Crann², Felix Vogel³

¹Brock University, St. Catharines, Canada. ²A.E. Lalonde AMS Laboratory, Ottawa, Canada. ³Climate Research Division, Environment and Climate Change Canada, Toronto, Canada

Abstract

Trees are natural integrators of changes in the environment. Tree-ring records can provide annually resolved information about a suite of past environmental conditions, including reconstructing past changes in climate and tracking changes in the isotopic composition of the atmosphere. Radiocarbon (^{14}C) is one such component. Naturally, ^{14}C in the atmosphere varies through time due to cosmic ray flux and ocean-atmosphere dynamics. Anthropogenic activities effect the concentration of ^{14}C in the atmosphere from global to local scales through burning of fossil fuels, nuclear bomb testing, and the operation of nuclear power plants (NPPs). Tree-ring-based ^{14}C records are ideal for examining past levels of ^{14}C because these measurements represent the ^{14}C concentration in the atmosphere and cross-dated tree-ring samples provide absolute dating control (Reimer et al., 2013). These attributes make tree-ring records an effective tool to track ^{14}C in the atmosphere from a variety of sources, including NPPs (Matsunaka et al., 2018).

Southern Ontario, Canada is home to 17 operational CANDU reactors (Bruce (8), Darlington (1) and Pickering (6)). The Bruce and Darlington facilities have been undergoing refurbishments since 2016. Monitoring of atmospheric ^{14}C in Ontario is conducted by the Centre for Atmospheric Research Experiments (44°14'N, 79°47'W), operated by Environment and Climate Change Canada (ECCC). The facility is located in Egbert, Ontario, approximately halfway between the Bruce and Darlington NPPs. Previous studies have found a noticeable influence on atmospheric $^{14}\text{CO}_2$ levels from 2008-2010 (Vogel et al. 2013) and data collected at the ECCC monitoring station indicate another period of significant increase of ^{14}C in the atmosphere, well beyond its natural variability, between July-September 2014 and May-July 2015. While the source of these emissions is unknown, refurbishment activities at the NPPs coincide with this time period.

We measured the $\Delta^{14}\text{C}$ of tree-rings from white spruce (*Picea glauca* [Moench.] Voss) trees sampled across a west-east geographic transect between the NPPs with the aim of better understanding how the atmospheric concentration of ^{14}C has varied locally in this region, while also attempting to pinpoint the source of the ^{14}C emissions. Furthermore, atmospheric transport model data was used to assess when the Egbert measurement station (and the tree sites) were downwind of the CANDU facilities. Preliminary results give insight into how the atmospheric samplers and tree-rings record ^{14}C in the atmosphere. Based on preliminary results, the tree growth period is important and overall the signature of excess ^{14}C is more diffuse in the tree-rings than in the atmospheric samples.

A new Millennial Length Reconstruction of Summer Precipitation from Stable Oxygen Isotopes in United Kingdom Oaks

Giles Young¹, Neil Loader¹, Danny McCarroll¹, Darren Davies¹, Christopher Bronk Ramsey², Dan Miles²

¹Swansea University, Swansea, United Kingdom. ²Oxford University, Oxford, United Kingdom

Abstract

We present a new reconstruction of summer precipitation for the central England region over the past millennium, based upon stable oxygen isotopes ratios ($\delta^{18}\text{O}$) from UK oak tree rings. Western European summers dominated by anti-cyclonic circulation patterns, are characterised by clear skies, warm temperatures, low precipitation totals, low air humidity and more enriched $\delta^{18}\text{O}$ precipitation. Such conditions usually result in relatively more positive (enriched) oxygen isotope ratios in tree leaf sugars and ultimately in the tree-ring cellulose formed in that year, the converse being true in cooler, wet summers dominated by westerly air flow and cyclonic conditions. In such regions, there should therefore be a strong link between tree-ring $\delta^{18}\text{O}$ and the amount of summer precipitation. Stable oxygen isotope ratios from the latewood cellulose of oak trees sampled across Great Britain produce a mean $\delta^{18}\text{O}$ chronology that correlates strongly and significantly with the amount of summer precipitation across the England and Wales region of the United Kingdom. The isotope-based rainfall signal is stronger and much more stable over time than reconstructions based upon oak ring widths.

Abstract

The Last Interglacial (LIG; 129-116 thousand years ago [ka]) was characterized in its earlier part by strong positive summer insolation and temperature anomalies at high northern latitudes, amplified by ocean, sea- and land-ice, and vegetation feedbacks. Attendant sea-level rise is estimated to have been ~6-9 m above present, with 0.6-3.5 m derived from Greenland Ice-sheet melting. Despite an abundance of LIG records, considerable ambiguity remains over the extent and nature of climate instability. This arises from the lower signal-to-noise ratio of interglacial variability compared to glacial, and the uneven resolution and poor chronological control of palaeorecords. We address these issues by analysing marine and terrestrial proxies from a deep-sea sediment sequence on the Portuguese Margin and combine results with an intensively dated Italian speleothem record and climate-model experiments. The strongest expression of climate variability occurred during the transitions into and out of the LIG. Our records also document a series of multi-centennial intra-interglacial arid events in southern Europe, coherent with cold water-mass expansions in the North Atlantic. The spatial and temporal fingerprints of these changes indicate a reorganization of ocean surface circulation, consistent with low-intensity disruptions of the Atlantic meridional overturning circulation (AMOC). The amplitude of this LIG variability is greater than that observed in our Holocene records. Episodic Greenland ice-melt and runoff as a result of excess warmth may have contributed to AMOC weakening and increased climate instability throughout the LIG.

The diachronic nature of the Saalian - Eemian boundary in Europe

Freek Busschers¹, Kim Cohen^{2,3}, Jan Peeters², Mark Sier⁴

¹TNO - Geological Survey of the Netherlands, Utrecht, Netherlands. ²Utrecht University, Department of Physical Geography, Utrecht, Netherlands. ³Deltares Research Institute, Utrecht, Netherlands. ⁴Oxford University, Department of Earth Sciences, Oxford, United Kingdom

Abstract

The Eemian is the term for the terrestrial and coastal marine Last Interglacial in Europe. The Eemian has been extensively studied from paleolandscape, sedimentary, archaeological, molluscan and botanical perspectives and its lower boundary is currently also under evaluation in light of ICS' SQS base Upper Pleistocene Subseries/Stage stratotype definition [1]. Although the duration of the Eemian in north western Europe is well known from lake sediments [2], the absolute age of onset and ending are a matter of correlation and discussion. A critical part is the debate on to what extent the Eemian pollenzone biostratigraphical correlation can be diachronic between subregions of Europe. A second matter is the correlation with the MIS 6-5e transition.

On basis of detection of the Blake paleomagnetic excursion at a site close to the original Eemian type locality in the Netherlands, Sier et al. [3] concluded that the Saalian - Eemian boundary was positioned at ~121 kyr, confirming earlier findings from a site in Germany [4]. Comparison with a marine core offshore Portugal, for which marine isotope stratigraphy, pollen biostratigraphy and paleomagnetic excursion data exists [5,6,7], shows that the onset of Eemian interglacial environmental conditions in north western Europe was delayed by ~6 kyr with respect to southern Europe (~127 kyr). The onset of the Eemian in NW Europe is thus placed well after the MIS 5e benthic $\delta^{18}\text{O}$ plateau was entered. The striking diachroneity in the onset of interglacial conditions between southern and northern parts of Atlantic Europe, implies that regional climatic conditions over Europe and the North Atlantic in the first part of MIS 5e were very much different from those in equivalent parts of MIS 2 and 1, a feature that is related to known differences between the melting history of the Greenland ice cap following Termination II and Termination I [8,9,10]. It also has implications for reading global fingerprints in the sea-level history of the period [11].

In this presentation we give an overview of the current state of insights in the age of the Saalian - Eemian boundary throughout north western Europe. We perform a cross-correlation including the above and new records, strengthening our earlier findings of diachronic registration of Saalian-Eemian boundaries throughout Europe.

Abstract

The Eemian interglacial represents a natural experiment on how past vegetation with negligible human impact responded to amplified temperature changes compared to the Holocene. In Europe, numerous records cover the Eemian or at least parts of it. To understand the spatial patterns of pollen turnover and total variation across Europe we compiled a new dataset of 47 Eemian pollen sequences from 14 different countries. Data were derived from key collaborators around Europe and from open sources such as PANGAEA. Additionally, we scanned and extracted data from publications that represented important geographical voids in our spatial coverage. We selected pollen sequences using a number of criteria that include covering the full Eemian and displaying all phases of an interglacial, namely the protocratic, mesocratic, and oligocratic/telocratic phases. We aimed to explore geographical patterns of i) total compositional turnover and total variation for each sequence and ii) stratigraphical turnover between samples within each sequence. We used detrended canonical correspondence analysis (DCCA), multivariate regression trees, and principal curves. Our results show that turnover and variation are highest in central Europe (47–55°N), low in southern Europe (south of 45°N), and lowest in the north (above 60°N). The DCCA results indicate that there is a distinct temporal pattern of compositional change within each sequence over geographical space. The observed patterns are, in part, site-specific changes, but it is also possible to identify two general patterns in turnover where the DCCA sample values show either a gradually changing linear trend or a unimodal pattern where it reaches a peak and then slowly declines. We provide several hypotheses to explain these observed patterns that encourage further research on the causes of vegetation change during the Eemian and their possible drivers.

Consequences of Saalian ice sheets on early Eemian climate and sea level

Henning A. Bauch¹, Ekaterina Taldenkova², Yaroslav Ovsepyan³, Olga Rudenko⁴, Anna Stepanova⁵

¹AWI c/o GEOMAR, Kiel, Germany. ²Moscow University, Moscow, Russian Federation. ³Geological Institute, Moscow, Russian Federation. ⁴Oryol University, Oryol, Russian Federation. ⁵Texas A&M University, Texas, USA

Abstract

It is now widely accepted that the course of Eemian climate development and sea level rise in the North Polar region after the penultimate glacial maximum (PGM) differed significantly from the Holocene climate pattern which emerged after the LGM. It has been further suggested that the cause for it must be sought in the particular volumes and maximal geographical extensions of the Saalian (pre-Eemian) and Weichselian (pre-Holocene) ice sheets, respectively. While in the mid-latitudes both interglacials show a comparable, insolation-driven climate development after each glacial maximum, this pattern deviates in Arctic and sub-Arctic realms. But, understanding the paleoenvironmental history of that important region is particularly hampered by a scarcity of continuous Eemian records, especially on land. To fill that gap we investigated a 4.5 m thick sequence of Eemian marine beds some 100 km south of Kanin Peninsula (Arctic Russia). The sequence directly overlies Saalian till and allows for a detailed evaluation of past events and their chronology vs. ocean records by using a multiproxy data set. Our record is time-coeval with the collapse of the huge Saalian shelf-based ice sheet which left a glaciostatically overdeepened Barents-Kara Sea shelf region, thereby providing a pathway for rapid inundation of the Eurasian margin during early post-Saalian sea level rise. The oldest marine sediments reflect a period of harsh, fluvially-affected environmental conditions with cold turbid waters and heavy seasonal sea-ice cover. The later occurrence of a typical Arctic shelf and deep-sea microfossil assemblage together with broad-leaved species in pollen spectra is representative of the climatic amelioration in the early Eemian. The final stage of the record is marked by regression due to regional glaciostatic adjustment. Although conditions remained largely humid and warm - these did gradually deteriorate towards the end of the record - there is no direct indication from the microfossil community for enhanced penetration of warm Atlantic waters. The rich malacofauna, however, among them plentiful *Arctica islandica*, reflect conditions akin to the early Holocene in Svalbard's fjords. At face value, U/Th ages of this species indicate that these sediments were deposited shortly after the PGM during early sea level rise.

Last-interglacial sea-level records on New Providence Island, Bahamas: A test of glacial isostatic adjustment models

Daniel Muhs, Kathleen R. Simmons, R. Randall Schumann
U.S. Geological Survey, Denver, USA

Abstract

With the prospect of rising sea level on a warming Earth, there is considerable interest in high-sea stands of the recent geologic past. One period that has received much attention is the last interglacial (LIG), corresponding to marine isotope stage (MIS) 5.5 or 5e, estimated to be ~130 ka to ~115 ka. Although there is agreement that LIG sea level stood higher than present, geologic records show differences from region to region. Some differences may be due to glacial isostatic adjustment (GIA) processes. Most sea-level GIA models agree that relative sea level during the LIG was highest in regions close to former ice sheets, such as the Laurentide Ice Sheet of North America. One modeled area includes the islands of the Bahamas in the western Atlantic Ocean. Here, LIG sea level is modeled to be as much as 11-12 m higher than present. We tested this using the geologic record of LIG sea level on New Providence Island, Bahamas. Two independent geologic records of LIG sea level are found in the Bahamas, emergent coral reefs and oolitic beach ridges. Both corals and ooids take up uranium from seawater when they are precipitated and therefore both can be dated by uranium-series methods. Coral patch reefs on the north shore of New Providence Island have present elevations between 3 m and 4 m above sea level. Patch reefs are dominated by the corals *Acropora cervicornis*, *Orbicella annularis*, *Siderastrea* sp., and *Diploria* sp., many in growth position. U-series ages of corals that have experienced closed-system conditions range from ~128 ka to ~118 ka. All the coral taxa have optimal growth in waters ranging from -3 m to as much as -10 m to -45 m. Their presence at 3-4 m above sea level implies, therefore, a paleo-sea level of *at least* 6-7 m above present. An independent estimate of paleo-sea level comes from beach ridges that contain oolitic beach foreshore and sub-tidal sediments. The foreshore facies sediments preserve keystone vugs, indicators of paleo-sea level. Although many oolites contain calcite cement, previous studies in the Florida Keys show that U-series analyses of such deposits still yield reliable approximate ages. Ten localities along the southern shore of New Providence Island have beach ridge exposures of vug-bearing oolitic beach sediments that have corrected U-series ages of ~124 ka to ~116 ka (one is ~105 ka), correlating these deposits to the LIG. Elevations of beach ridge vugs range from ~4 m to ~13-14 m and average ~9 m. We conclude from both records that sea level during the LIG stood at least as high as 6-7 m and possibly as high as 13-14 m, which supports GIA models for the LIG in the western Atlantic Ocean.

The last interglacial (MIS-5e) in Alpine speleothems: the Sieben Hengste record (Switzerland)

Marc Luetscher^{1,2}, Gina E. Moseley², Daniela Festi², Florian Hof³, Christoph Spötl², R. Lawrence Edwards⁴

¹SISKA, La Chaux-de-Fonds, Switzerland. ²Univ. Innsbruck, Innsbruck, Austria. ³SSS, Bern, Switzerland. ⁴Univ. Minnesota, Minneapolis, USA

Abstract

The last interglacial (MIS-5e) represents the closest opportunity to characterize ecological adaptation to a warmer climate. In the European Alps, evidence of thermophile vegetation is abundant (Wegmüller, 1992; deBeaulieu and Reille, 1992; Drescher-Schneider, 2000; Pini et al., 2010) but still lacks precise chronological constraints. Meanwhile, speleothems provide accurately dated paleoclimate records which do, however, only indirectly record changes in the local environment.

Here, we present a speleothem record (7H-12) from the Sieben Hengste cave system, Switzerland, encompassing the last interglacial period. The onset into the interglacial is dated at 129.8 ± 0.8 ka, consistent within error with recently published records of Termination II for the European Alps (Häuselmann et al., 2015; Moseley et al., 2015). However, in marked contrast to these speleothem records, 7H-12 shows a rapid increase in $\delta^{18}\text{O}$, which reaches a climax at 128.4 ± 0.8 ka and is followed by a gradual depletion until 117.5 ka. This distinct pattern, characterized by low interannual variability, correlates well with the Greenland synthetic record suggesting that 7H-12 was little affected by local processes and, thus, may represent a robust archive for the last interglacial at a regional scale. Pollen extraction from the speleothem calcite reveals maximum concentrations of ca. 20 palynomorphs per gram with assemblages dominated by *Alnus*, *Hedera*, *Corylus* and *Picea*. Several of these species are presently absent from the cave's hydrological catchment area, but are clearly identified in regional pollen assemblage zones of the last interglacial. Although statistically weak, these results support warmer conditions consistent with the stalagmite $\delta^{18}\text{O}$ record. Overall, our sample offers a unique opportunity to link higher resolved palynological sequences with a precisely dated paleoclimate record.

Climatic and oceanographic conditions in the Santa Barbara Basin (southern California) during the Last Interglacial (MIS 5e)

Jin-Si R. Over , [Vera Pospelova](#)
University of Victoria, Victoria, Canada

Abstract

The dinoflagellate cyst record from Ocean Drilling Program (ODP) Hole 893A in Santa Barbara Basin (SBB), southern California, is examined at sub-millennial scale resolution ~150-110 kyr. A qualitative and quantitative (modern analogue technique) approach utilizing dinoflagellate cyst abundance and assemblage composition is used to reconstruct changes in marine primary productivity and sea-surface temperature. Throughout the sequence, dinoflagellate cyst assemblages are dominated by the coastal upwelling related heterotrophic cysts of *Brigantedinium* spp., while changes in the relative abundances and concentrations of thermophilic taxon *Spiniferites mirabilis*, cold water taxon *Selenopemphix undulata*, and oceanic taxa such as *Impagidinium* spp. and *Operculodinium centrocarpum* indicate the development of at least four distinct intervals in the hydrological regime from MIS 6 into MIS 5e and MIS 5d. The overall dinoflagellate cyst assemblage of MIS 5e is notably different from the Holocene and the modern in the SBB, particularly by abundances of *Spiniferites mirabilis* that reach up to ~10% in MIS 5e and the low abundances of *Echinidinium* spp. and *Lingulodinium machaerophorum*. This suggests SST's were higher but the basin did not undergo or record strong seasonal surface stratification.

Quaternary Mars?

Frances E. G. Butcher¹, Matthew R. Balme¹, Colman Gallagher^{2,3}, Susan J. Conway⁴, Stephen R. Lewis¹, Lauren Mc Keown⁵

¹School of Physical Sciences, The Open University, Milton Keynes, United Kingdom. ²UCD School of Geography, University College Dublin, Dublin, Ireland. ³UCD Earth Institute, University College Dublin, Dublin, Ireland. ⁴CNRS, UMR6122, LPG Université de Nantes, Nantes, France. ⁵Department of Geography, Trinity College Dublin, Dublin, Ireland

Abstract

On Earth, the Quaternary period, extending from ~ 2.6 Ma to the present day, is defined by the most recent periods of widespread northern hemisphere glaciation, and its deposits are generally very-well studied. On Mars, the concept of an analogous 'Quaternary' is harder to apply and study, as in situ data from 'fieldwork' is rare: only at a few locations has the local stratigraphy been observed using instrumented, robotic explorers. Thus, much of what we know about Mars chronology has been revealed by remote-sensing surface geomorphology studies, meaning that Mars' geological periods are far simpler, less sub-divided, and have greater uncertainties in their bounds than Earth's.

Mars' main geological periods (the Noachian, >3.7 Ga; the Hesperian, 3–3.7 Ga; and the Amazonian, <3.0 Ga) are defined by impact crater size-frequency statistics and global-scale morphostratigraphic mapping. Amazonian Mars has undergone little geological activity compared to Earth, so many ancient morphologies are preserved. Coupled with mounting evidence that the Noachian environment was more suitable for life than Mars today, the focus of Mars exploration has mainly been on the more ancient landscapes and rocks. Yet the most recent period of Mars' history is fascinating: there is growing geomorphic evidence for recent shifts in environmental conditions, and many questions to answer.

For example, Mars' polar ice caps host numerous layers of ice and dust. What can they tell us about recent climate cycles on Mars? Mars' mid-latitudes host older, debris-covered glaciers. What environmental conditions permitted glaciation of Mars' mid-latitudes, where exposed ice is currently unstable? Huge swathes of the high latitudes are draped in a smooth (at m-scale) ice-rich mantle that appears to be actively degrading. When did mantle modification processes change from deposition to degradation? Very young landforms in the northern latitudes appear to have formed by solifluction or freeze-thaw processes, yet Mars' climate is currently too dry and cold, and the atmosphere too thin, for water-ice to melt or liquid water to be stable at the surface. Do these landforms demonstrate a recent climatic excursion, or extreme micro-environments?

Additionally, 10m-scale aeolian mega-ripples known as Transverse Aeolian Ridges are abundant, appear to have pristine morphologies, yet must be relics of palaeoenvironmental conditions because larger dunes migrate by ~1 m per year under present-day winds, yet TARs remain immobile. Did global mean wind strengths change recently?

Theoretical studies suggest that Mars' obliquity (currently similar to the Earth's at $\sim 25^\circ$) varies cyclically by up to tens of degrees on ~ 100 ka timescales, with orbital eccentricity having similar cycles. Additionally, mean obliquity shifted from $\sim 35^\circ$ to the present level around 5 Ma.

In this presentation we will describe Mars' 'Quaternary' landscapes, and discuss how they fit into the current understanding of Mars' recent palaeoclimate.

Building high resolution Holocene palaeoenvironmental chronologies: A case study from Lough Cullin, southeast Ireland

Susan Hegarty¹, Benjamin Gearey², Suzi Richer³, Kevin Kearney²

¹DCU, Dublin, Ireland. ²UCC, Cork, Ireland. ³University of York, York, United Kingdom

Abstract

The construction of robust, high resolution chronologies is a critical aspect of palaeoenvironmental study. Accurate interpretation of ecological patterns and processes and the integration of palaeoenvironmental data with the archaeological record requires precise chronologies, with the interpretative value of detailed sub-fossil proxy analyses impacted by poor or flawed chronological control. Radiocarbon is the predominant method for dating organic material such as peat and lake sediments which form the source material for most sub-fossil proxy records of environmental change. However, there are certain problems and issues in terms of 'best practice' approaches to the dating and chronological modelling of palaeoenvironmental records, including optimal sample selection in terms of different organic fractions (macrofossils, humin and humic fractions), the relative density of dates required in terms of individual sequences as well as with reference to particular sections of the radiocarbon calibration curve, and overall strategies in terms of maximising return from investment of effort and financial resources.

In this paper we present a case study of a near complete Holocene sequence from a small lake basin in southeast Ireland, with high-resolution radiocarbon dating, to constrain the environmental reconstruction of the area. The use of a multi-proxy approach, using pollen data, loss on ignition and XRF geochemical signatures constrained by this high-resolution dating reveal a palaeoclimatic history spanning the Holocene for the south-east of Ireland - an area which has been mostly overlooked on the island of Ireland, and where the influence of the Atlantic ocean is not as marked as it is on the west coast, where many of the palaeoclimatic studies have taken place to date. The sequence includes evidence of anthropogenic influences on the lake from early the Mesolithic to early Medieval times. Potential evidence of the 8.2k event affecting the environmental conditions of south-east Ireland is also seen within the sequence.

Abstract

Human impacts to lake ecosystems are well documented, typically driven by land-use changes, increased nutrient loading and warming temperatures. Increased primary production and bottom-water anoxia are globally recognized as significant environmental problems. However, long-term records of eutrophication and meromixis are needed to understand the natural range of variability in lake systems and to be able to detect and quantify anthropogenic disturbances. Additionally, we can better understand the dynamics of lake ecosystems by studying the interactions between forcings such as climate and land-cover change and the response of lake ecosystems over long timescales.

Hyperspectral Imaging (HSI) is a recently developed, rapid, non-destructive, and cost-effective scanning method that measures the spectral signal of the sediments at very high spectral (3 nm) and spatial resolution (60 µm pixel size). Using this technique, the abundance of sedimentary pigments such as chlorophylls and Bacteriopheophytin *a* can be quantified¹. HSI data, in combination with micro X-ray Fluorescence (XRF) data, allow for unprecedented insights into lake ecosystem trajectories at subannual resolution.

In this study, we present Hyperspectral measurements of chlorophylls and Bacteriopheophytin *a* to reconstruct lake productivity and meromixis, respectively, in a ca. 11,000 year-long varved sedimentary record from Lake Żabińskie, a small (42 ha) deep (44 m) kettle-hole lake in NE Poland. These data are supported by XRF, Carbon, Nitrogen and Sulphur elemental datasets. The record has been dated using varve counting (most recent 6,500 years), ¹⁴C AMS dating (91 dates), and radionuclides (Pb-210 and Cs-137) to produce a high-quality chronology. Evidence of meromixis is found from ca. 10,600-9,800, 7,500-3,000, 2,600-2,100 and 1,330-330 cal yr BP. During the Holocene, the lake was typically meromictic with strong stratification favored by warm summer temperatures and limited wind fetch on the small lake surrounded by dense forest. Beginning in 1620 CE, forest clearing and increased agriculture lead to major increases in lake productivity and soil erosion rates (Ti counts)². Prolonged meromixis (since 620 CE) was terminated at this time, with holomixis persisting until present. This is evidence of a direct link between anthropogenic land-cover modification and lake biogeochemistry. The causes of earlier shifts in mixing regime are currently under investigation, however there is evidence for erosional events causing the termination of meromixis periods, and periods of denser forest cover are likely associated with meromixis.

Establishing the 'natural' baseline and anthropogenic perturbation of phosphorus dynamics in the Shropshire Meres

Madeleine Moyle¹, John Boyle¹, Richard Chiverrell¹, Mags Cousins²

¹University of Liverpool, Liverpool, United Kingdom. ²Natural England, Telford, United Kingdom

Abstract

Excess nutrient loading and the cultural eutrophication of aquatic ecosystems is a global problem. In many catchments mitigation practices to reduce loading and tackle the impact of excess nutrients have been met with varying success. Disentangling nutrient cycle and climate impacts on the lake ecology is challenging, particularly where the legacy phosphorus (P) contained in the sediments critically undermines catchment management practices to remediate impacts of P loading. The longer perspective from sedimentary records can be used to examine whether there is a history of nutrient loading and quantify the 'natural' baseline of a catchment. Palaeo-records provide a methodology for examining these long-term nutrient dynamics, however previous studies have tended to focus on measured element concentrations (or diatom-inferred P) rather than calculating loading.

Here a combination of sediment records and limnological monitoring from Crose Mere (Shropshire, UK) are used to show the benefits of a loading approach. The inclusion of sediment mass accumulation rates enables quantification of the P load from the catchment and allows the anthropogenic impact on the nutrient budget and the present-day lake status to be examined.

Twenty-four months of monitoring at Crose Mere found P levels which exceed EU water quality targets. Elevated P has persisted at the site since at least the 1970s, when the lake was previously monitored, and historical evidence suggests an even longer nutrient rich legacy. To understand the context of the present lake status, a longer-term approach is critical to determine both the onset and explore the causes of eutrophication. Here, sediment accumulation and geochemical records have determined the phosphorus and detrital erosion fluxes for the last ~12,000 years at Crose Mere. A transect of cores across the lake reveals repeatable basin-wide episodes that show increased flux of erosional indicators (soil-derived Ti, K, Zr, Rb) and these are accompanied by in-wash of particulate-bound P. The earliest of these episodes is attributed to Neolithic farming, with the subsequent pattern of loading increasing step-wise towards the present day. Pollen inferred episodes of human impact coincide with these rate increases in particulate and nutrient fluxes, and correspond to the timing of major (pre)historic periods. Fossil pigments record parallel changes in algal communities and show the in-lake ecological responses to changes in nutrient flux. Thus, Crose Mere has experienced a long legacy of human impact from low-level pre-historic perturbation of the landscape, introduction of agriculture and large-scale and permanent woodland clearances. Linking the monitoring of P dynamics with the sedimentary record suggests an initial onset to declining nutrient status ~800 years ago and crossing reconstructed EU thresholds for poor nutrient status ~60 years ago, highlighting the importance of legacy P in the management of lowland farmed catchments.

Abstract

Humans have changed European ecosystems since the beginning of agriculture in the early Neolithic. Anthropogenic activities around lakes increased soil erosion and changed terrestrial nutrient cycles in the course of agriculture and domestication of animals, causing a release of additional nutrients into lakes and consequently leading to lake eutrophication. The information about human-induced changes in aquatic ecosystems and their surroundings can be extracted from lake sediments. Areas with a long history of human occupation are particularly attractive for studying the effects of early human impacts on lakes, since in these repeated phases of impact and recovery should be expected.

Burgäschisee is a small (21 ha), deep (31 m) and eutrophic lake on the Swiss Plateau with well-studied pile-dwellings and other archaeological findings indicating human presence and activities around the lake since the early Neolithic (ca. 4500 BCE). Burgäschisee is of particular interest because of its annually laminated sediments which allow the development of records with exceptional high temporal resolution and chronological precision. We applied multi-proxy palaeoecological (pollen, diatoms, non-pollen palynomorphs, microcharcoal) analyses to reconstruct human-induced eutrophication in Burgäschisee during the last 6500 years.

Our results show remarkable changes in diatom assemblages along with the first appearance of cultural indicator pollen, such as *Cerealia*-, *Hordeum*- and *Triticum*-type, as well as increased concentrations of microscopic charcoal in the sediments of Burgäschisee (3830-3620 BCE). Rapid increases of *Staurosira construens* and *S. venter* indicate a turbid environment as a result of landscape opening and soil erosion due to agricultural activities. Planktonic *Pantocsekiella pseudocomensis*, *P. costei* and *C. radiosa* are replaced by periphytic diatoms, such as *Gomphonema parvulum* and *Navicula vulpina*, indicating eutrophication due to anthropogenic impact. Additionally, the occurrence of akinetes of cyanobacteria (e.g. *Anabaena*, *Aphanizomenon*) supports our diatom and pollen-based interpretation that local human impact led to significant nutrient enrichment in the lake. The subsequent increase of planktonic diatoms, such as *P. pseudocomensis* and *C. radiosa*, indicate ecosystem recovery. The lake ecosystem recovered from human induced disturbances relatively quickly (probably promoted by the water level rise) but did not return completely to the pre-disturbance state.

According to the diatom data, the second remarkable regime shift occurred along with intensification of agricultural activities around Burgäschisee in the early Medieval period (ca. 700 CE). Small planktonic *Stephanodiscus binatus* indicate increased nutrient concentrations. Increases by *Tabularia flocculosa* and *Centronella reicheltii*, indicators of pH lowering, are more difficult to explain but may be caused by paludification of shores and/or by hemp retting, which had a direct impact on the lake ecosystem.

The obtained information is relevant for the understanding of lake ecosystem response to climatic change and human impact. Our study provides valuable information on the resilience of lake ecosystems to repeated human induced disturbance.

How severe was the impact of human activity on the landscape of Late Holocene Orkney? Evidence from Tuquoy, Westray.

Tim Mighall¹, Scott Timpany², Antonio Martinez Cortizas³, Ian Foster⁴, Olwyn Owen²

¹University of Aberdeen, Aberdeen, United Kingdom. ²UHI, Kirkwall, United Kingdom. ³University of Santiago de Compostela, Santiago de Compostela, Spain. ⁴University of Northampton, Northampton, United Kingdom

Abstract

Since prehistoric times, human activities have played, directly or indirectly, an increasing role in the evolution of terrestrial ecosystems, generating significant changes in biotic communities, soil erosion and atmospheric pollution. In order to ascertain the severity of human impacts on the landscape, it is important to use a variety of different biogeostatigraphic proxies to identify and separate the contribution of different causal factors, such as climate, and to assess the importance of each through time. A palaeoenvironmental investigation of sediments from the infilled Loch of Tuquoy, located within 500m of the high-status Norse farmstead and Crosskirk at Tuquoy on Westray, Orkney, provided an opportunity to assess the role of humans in landscape change. Orkney is an important location in the Viking/Norse world, containing a wealth of Norse archaeological remains, but little is known about the impact Norse communities had on the landscape and it is also located on the western seaboard of the North Atlantic so should be sensitive to changes in climate. Pollen, non-pollen palynomorphs, microscopic charcoal, sediment geochemistry and mineral magnetics were performed on a 2.2 metre-deep core to assess the severity of human activity. Two major periods of human activity occurred: the first from c. 900 to 150 cal BC and then between cal AD 700 and 1750, which encompasses the Norse occupation of the farmstead at Tuquoy. Pollen evidence suggests that land was cultivated for barley and oats/wheat and used for pasture during both periods as part of a mixed agrarian economy. While the landscape was largely treeless from 850 cal BC onwards, minor woodland clearance occurred in both periods. A cultural landscape seems to have been created before the Loch of Tuquoy record commenced and development of vegetation thereafter appears largely unchanged by human activity from the Late Bronze Age onwards. The palaeoeconomy of the Norse seems to have been a continuation of earlier practices. Switches in sediment source to the loch and changing intensity of non-pollen palynomorphs indicative of nutrient-poor water appear to be linked to human presence, but the loch shifts back to an earlier state when human activity appears to be less intense.

A late-Holocene proxy record of eutrophication in a small kettle lake (Ontario, Canada): Indigenous settlement or climate change?

Rebecca Doyle, Zijun Liu, Jacob Walker, Ryan Hladyniuk, Katrina Moser, Fred Longstaffe
The University of Western Ontario, London, Canada

Abstract

Globally, the period of AD 1000 to present was characterized by three climatic regimes: the Medieval Warm Period (AD 1000- 1300), the Little Ice Age (AD 1450- 1850) and the modern period (AD 1850- present). Many studies have invoked these intervals when interpreting shifts in sedimentary proxy signals during the late-Holocene. Previous research in Ontario (Canada), however, has suggested that bush burning and early agriculture undertaken by Indigenous peoples also influenced the eutrophication of lakes during this period. To understand the relative roles of climate change and Indigenous activities during the late-Holocene, we have analyzed recent sediments from Barry Lake, a kettle lake in southern Ontario which is located near the remnants of an Indigenous village (the Richardson Site), an important portage route (the Percy Portage), and an archaeologically-significant lake (Rice Lake). Interpreting proxies derived from the sediment organic matter allows us to trace the lake's productivity, indicating when cultural eutrophication may have occurred. Moreover, proxies from the inorganic record, such as the oxygen isotope compositions of marl ($\delta^{18}\text{O}_{\text{marl}}$), offer information about historical temperature or hydrologic changes, indicating how climate affected the lake.

Thus, for two ~950-yr sediment core records tightly constrained by radiocarbon and lead-210 dates, we present (i) carbon ($\delta^{13}\text{C}_{\text{org}}$) and nitrogen ($\delta^{15}\text{N}_{\text{total}}$) isotope ratios of sedimentary organic matter; (ii) total organic carbon (TOC), total nitrogen (TN) and C:N ratios; (iii) $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of marl and shelly fauna; (iv) macrofossil analysis; (v) grain size analysis; (vi) mineralogy; and (vii) magnetic susceptibility. Both cores show synchronous changes in organic proxies that are indicative of eutrophication from AD ~1300 to AD ~1600. This period is characterized by increasing TOC, TN and $\delta^{13}\text{C}_{\text{org}}$ and decreasing or unchanging C:N ratios. Our finding of eutrophication from AD ~1300 to AD ~1600 corresponds with similar trends at Crawford Lake (213 km distant), which were attributed to the population growth of Indigenous peoples. We have also determined, however, that $\delta^{13}\text{C}_{\text{marl}}$ and $\delta^{18}\text{O}_{\text{marl}}$ increase rapidly in one core from AD 1247 to AD 1307 (and increase in the other core from AD 1337 to AD 1446) and remain relatively high in both cores until AD ~1600, indicating that the changes in organic proxies may be driven by climatic change rather than (or in addition to) human activity. This research demonstrates that analyzing the isotope compositions of organic and inorganic sedimentary fractions can offer insights into the drivers of eutrophication.

A New Zealand perspective on the Anthropocene: how successive waves of human land use shaped Lake Pounui's current condition

Andrew Rees¹, Leise Cochrane², Marcus Vandergoes³, Susie Wood⁴

¹Victoria University of Wellington, Wellington, New Zealand. ²Open Polytechnic, Wellington, New Zealand. ³GNS Science, Lower Hutt, New Zealand. ⁴Cawthron Institute, Nelson, New Zealand

Abstract

Despite New Zealand (NZ)'s "clean and green" image, which underlies its strong touristic appeal, 44% of the country's monitored lakes are categorised as eutrophic or worse. If one likens ecosystem health to human health and the ecologist's impact assessment to the physician's exam, the dearth of medical history readily becomes apparent. Most lake monitoring programmes are of too short a duration and only start after a system has already begun deteriorating, so that the ecologist cannot answer those fundamental questions analogous to the physician's "When did you begin feeling ill? How quickly did you become ill? What symptoms prompted you to seek medical attention?". Lake Pounui, located in NZ's lower North Island, is an all-to-common case – throughout its spotty four-decade monitoring history, the lake transitioned from oligotrophic to eutrophic states currently characterised by fortnightly episodes of anoxic bottom water during summer months. Interestingly, Lake Pounui's catchment comprises 90% native bush with marginal pastureland on the northeastern flank, and the lake is one of the few North Island bastions of declining *Isoetes kirkii*, an endemic aquatic macrophyte that indicates good health. In conjunction with the landowners, we developed null and alternative hypotheses directed at Lake Pounui's medical history: phytoplankton blooms have always occurred in Lake Pounui (H_0), and the introduction of exotic fish species prompted a trophic cascade, resulting in the contemporary algal proliferations (H_1). Results from a 3-kyr, multiproxy sediment record reveal eutrophic diatom abundances as prevalent 3-2 kyr BP as today, supporting H_0 . Māori occupation was detected through an abrupt increase in macro-charcoal fragments concurrent with an opening forest canopy and the appearance of bracken fern. Together, these suggest people used the landscape for food staples roughly 400 yr BP. Whether intentionally or not, these catchment modifications clarified the water column, supported by the first appearance of *I. kirkii* and an increased abundance of epiphytic diatoms. Prokaryotic DNA from the most recent sediments exposes a fascinating sequence: bacteria typical of perch and trout gut contents precede denitrifying bacteria which in turn pre-empt cyanobacteria, a major constituent of the contemporary blooming flora. Collectively, these data suggest the introduction of pest species triggered a chain of events resulting in Lake Pounui's annual algal proliferation and that any restoration plan should consider exotic fish removal. This test case highlights the importance of long-term baselines, which are often only supplied by "paleo" techniques, to create evidence-based recovery programmes.

Abstract

Terrestrial ecosystems play an important role in Earth systems processes, yet we still do not fully understand the feedbacks between these ecosystems and Earth's climate. These ecosystem processes operate at multiple timescales; fast processes occur at sub-annual timescales, and slow processes, driven by changes in forest composition and structure, occur over decadal and longer timescales. Slow processes are rarely directly observed from instrumental data, yet are critical to understanding the stability of the terrestrial biosphere over the coming decades. Networks of paleoecological data, particularly sedimentary pollen data, offer our strongest observational constraint on long-term vegetation dynamics and underlying processes and feedbacks.

We reconstruct land-cover for the Holocene for the Northern Hemisphere. To do this, we use: (i) networks of fossil pollen records - the most reliable paleoecological proxy for land-cover; (ii) estimates of pollen productivity and fall speed, and (iii) a model of pollen-vegetation relationships, REVEALS (Sugita, 2007). For the Northern Hemisphere, we estimate the fraction of summergreen trees, evergreen trees, and open land.

To determine the differences between these pollen-based reconstructions and land-use scenarios that are more commonly used land-use models, we compare the fraction of open land with estimates of deforestation from the anthropogenic land-cover change (ALCC) scenarios generated by KK10 (Kaplan et al., 2009). Identifying cause to these differences provides an opportunity for improvement in ALCCs used to inform both global earth system and dynamic vegetation models.

This work results in improved understanding of the history of Holocene land-use change over a large spatial extent and slow ecosystem processes, the biogeochemical and physical forcings from past anthropogenic land-cover change on climate, and the long-term carbon dioxide budget. It is a contribution to PAGES LandCover6k.

Abstract

The PAGES LandCover6K group is concerned with whether prehistoric human impacts on land cover were sufficiently large to have had a major impact on regional and global climates. This is usually done via modelling land cover using different scenarios. However, there are major differences between the current available land-use scenarios, between these scenarios and reconstructions based on pollen analysis. The only way to provide a useful assessment of the potential for land-use changes to affect past climate is to input land-use models with more realistic land cover and land-use changes based on palaeovegetation (land cover) and archaeological evidence (land-use). Here, we present efforts to reconstruct land use for the European continent at 6000 cal BP, using a synthesis of land-use data derived primarily from radiocarbon dates, site based distribution maps, the environmental archaeological record of animals and plants recovered, alongside expert, contextual data.

We discuss some of the methodological challenges of developing generalised land-use categories within a European context and how these reflect the diversity of agricultural and hunter-gatherer land-use at this time; identify regions for which we have good datasets and major gaps in our understanding and how we move from point data to wider understandings of land-use activity. We present a top-level land-use map for Europe at 6000 cal BP and summarise key land-use activities and the variability of land-use for selected regions and potential per capita usage. Finally, we compare these data to preliminary land-use maps for periods before and after 6000 cal BP and to modelled outputs of land-use. We show that large areas of Europe were already occupied by 6000 cal BP and subjected to land-use change, although the intensity of land usage at this time varied significantly between regions, likely the consequence of both gaps in archaeological knowledge and differences in land-use practice. Incorporating this variability in land-use intensity will produce a considerable improvement in existing land-use scenarios.

Abstract

Understanding land use and land cover (LULC) change through time is an important aspect when attempting to interpret human-environment interactions through time. Palaeoenvironmental techniques have been crucial in bridging this gap by providing information that has been used to estimate climate change, vegetation change, sea level change etc. through time using a variety of proxies. Producing quantitative land-cover reconstructions has been an aim and a challenge with several methods attempted during the decades. In this project, we use the REVEALS model has been tested and validated in several regions of the world.

We use REVEALS-based quantitative reconstructions of vegetation change to investigate the biogeochemical and biogeophysical forcings of land-cover change on climate. In the first phase of this project, LandClim I, quantitative vegetation reconstructions were produced for Europe (Mediterranean area excluded) focusing on five time windows of the Holocene between 6ka BP and present. The results from a regional climate model showed that the impact of the reconstructed LULC between 6 ka and 0.2 ka BP via biogeophysical forcing varied geographically and seasonally.

We present the REVEALS quantitative pollen-based vegetation reconstruction from the ongoing second phase of the project LandClim II "Quantification of the biogeophysical and biogeochemical forcings from anthropogenic deforestation on regional Holocene climate in Europe". This reconstruction covers entire Europe and is transient over the Holocene with a time resolution of 500 years between 11.2 and 0.7ka BP, and 100 to 300 years from 0.7ka BP to modern time.

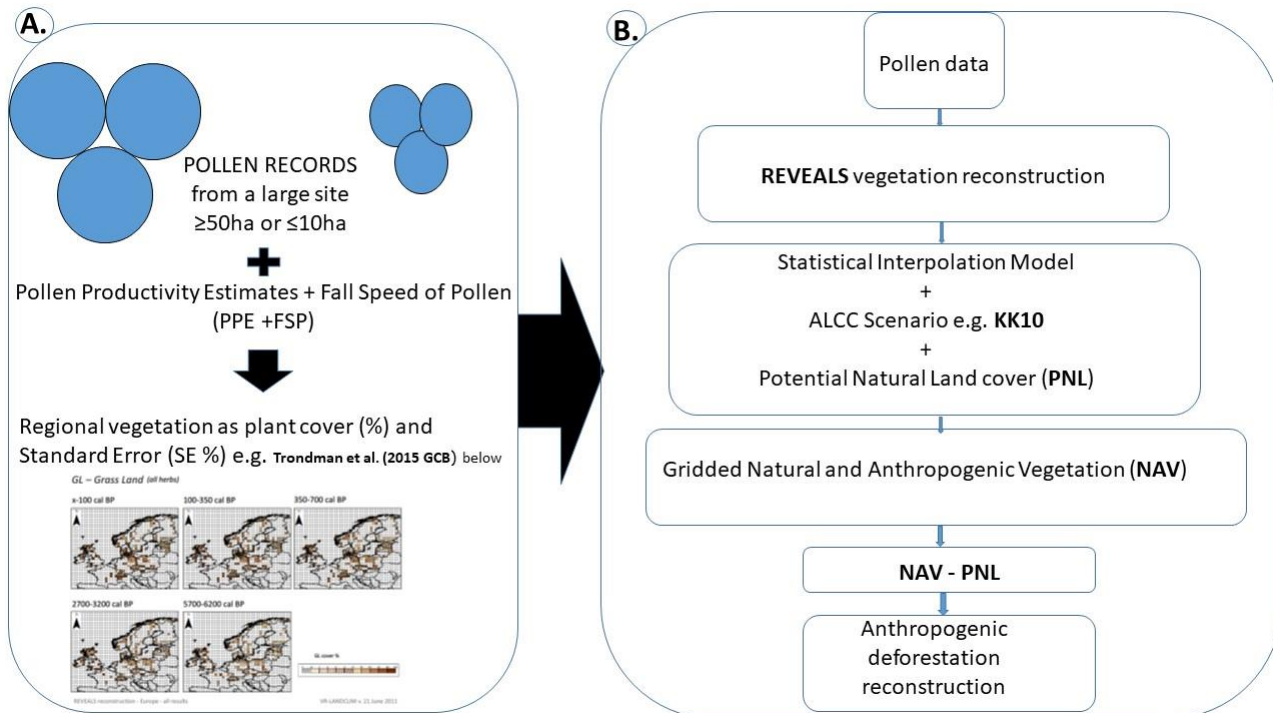

Figure 1: Schematic representation of the quantitative vegetation reconstruction process. **A.** Requirements and results of the REVEALS process while **B.** highlights the steps that we undertake to elucidate the anthropogenic impact from the natural land cover

Spatiotemporal changes of Holocene cultivated land use in China based on archaeological data

Yanyan Yu¹, Haibin Wu^{1,2,3}, Zhengtang Guo^{1,2,3}

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China. ³University of Chinese Academy of Sciences, Beijing, China

Abstract

With the spread of agriculture during the Holocene, human cultivated land use has begun to alter the earth surface for thousands of years, however, the amounts and spatial patterns of land use are unclear due to lack of corresponding records in prehistoric period. PLUM (Prehistoric Land Use Model), which is developed based on the relationship between environmental variables and archaeological sites distributions, has been successfully validated and applied in several typical river valleys in northern China. In recent years, we have established an archaeological sites database across the whole China according to the systematic second national culture survey, and it provides an opportunity to reconstruct the spatiotemporal changes of cultivated land use during the Holocene in China.

The results reveal that the most significant relative and absolute increases of cultivated land use amounts occurred during 7-6 ka BP (about 174%) and 3-2 ka BP (about 136591 km²), respectively. The percentage of cultivated land use area to the whole country has increased from about 0.2% to 2.6% during 8-2 ka BP, which indicates that about 20.3% of modern land clearance levels occurred 2000-3000 years ago on average. In spatial sense, the Yellow River valley in northern China has been the most important human activity center until 5 ka BP, but the center has moved southwards and eastwards since then. Around 3 ka BP, the intensities of human activity in northern and southern China have even turned to the similar levels.

In comparison above results with the reconstructed vegetation evolution by pollen records in China, we could conclude that the impact of human activity on vegetation has intensified from regional to country scale during the Holocene, and the decrease of forest cover since 5 ka BP in eastern China is significantly accelerated by the coupled effects of drier climate conditions and spread of human cultivation.

REVEALS -based reconstruction of Holocene vegetation abundance in temperate China: new insights on past human-induced land-cover change for climate modelling

Furong Li¹, Marie-José Gaillard¹, Qinghai Xu², Shinya Sugita³, Xianyong Cao⁴, Ulrike Herzschuh⁴, Yan Zhao⁵, Jian Ni⁶
¹Department of Biology and Environmental Science, Linnaeus University, Kalmar, Sweden. ²College of Resources and Environment Science, Hebei Normal University, Shijiazhuang, China. ³Institute of Ecology, University of Tallinn, Tallinn, Estonia. ⁴Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Research Unit Potsdam, Potsdam, Germany. ⁵Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China. ⁶College of Chemistry and Life Sciences, Zhejiang Normal University, Jinhua, China

Abstract

Quantification of the effects of human-induced vegetation-cover change on past (present and future) climate is still a subject of debate. Our understanding of these effects greatly depends on the availability of empirical reconstructions of past anthropogenic vegetation cover. In this context, China is an important region given that agriculture started already in early Holocene, and expanded rapidly over large areas throughout the eastern part of the country. Quantitative reconstructions of plant cover based on pollen data has long been a challenge. In recent years, approaches were developed to correct biases due to inter-taxonomic differences in pollen productivity, dispersal and deposition, and between-site differences in size and type of accumulation basin (lake or bog). The REVEALS model (Sugita, 2007) is the approach for quantitative reconstruction that has been most tested, validated, and applied over the last years. The model estimates regional vegetation cover using pollen records from large lakes or multiple small sites (lakes and bogs). The spatial scale of REVEALS reconstructions is ca. 10⁴ km², which is adequate for climate modelling. Relative pollen productivity (RPP) of plant taxa is a key parameter required for REVEALS applications. RPP estimates are available from earlier studies in temperate China for plant taxa characteristic of steppes, meadows, and woodlands.

In this study, we estimated RPPs for plant taxa of traditional agricultural landscapes in central-eastern China, as a complement to earlier RPP studies (Li et al., 2017). We then established a synthesized RPP dataset by assessing all available RPPs (Li et al., 2018) and used it with pollen records from lakes and bogs to produce REVEALS-based estimates of Holocene regional vegetation-cover change in temperate China. We compared the REVEALS reconstructions with existing data on past climate and human history in order to interpret our results in terms of anthropogenic land-cover change. The study is a contribution to PAGES LandCover6k.

The REVEALS-based estimates of regional plant cover differ significantly from the pollen percentages. Pollen percentages mainly underestimate landscape openness in comparison to REVEALS based estimates of open-land cover, except when *Artemisia* (high RPP) is dominant. Timing and magnitude of change often differ between REVEALS-based plant cover and pollen percentages. There is general agreement between periods of increased REVEALS-based landscape openness and times of human activity as inferred from archaeological data. Human-induced deforestation is highest in eastern China with 3 major phases at ca. 5500, 3000 and 2000 calibrated years before present. The cover of trees was highest during mid Holocene from ca. 8000 BP in some regions, mainly between ca. 7000–5000 BP and until ca. 3000 years BP.

¹Laboratory of Palynology and Paleoecology, Department of Ecology, French Institute of Pondicherry,, Pondicherry, India. ²Laboratory of Palynology and Paleoecology, Department of Ecology, French Institute of Pondicherry,, 11, St. Louis Street, Pondicherry, 605001, India. ³Department of Biology and Environmental Science, Linnaeus University,, Kalmar,, Sweden. ⁴CNRS GEODE UMR 5602, Toulouse University Le Mirail,, Toulouse, France. ⁵Institute of Ecology, Tallinn University,, Tallinn, Estonia

Abstract

Reconstructing the past vegetation conventionally uses pollen percentages (PPs) or pollen accumulation rates (PARs). Qualitative interpretation of PPs and PARs is based on insights gained from modern analogues of the pollen-vegetation relationship or on the comparative approach that compares past and modern pollen assemblages. Quantifying past vegetation/ land cover using pollen data requires other approaches that can correct the non-linear relationship with vegetation and biases due to inter-taxonomic differences in pollen productivity, dispersion and deposition. Relative Pollen Productivity (RPP) can be estimated using the Extended R-Value (ERV) model (Prentice and Parsons, 1983), provided modern pollen assemblages and distance weighted vegetation abundance (DWPA) around the pollen sampling point are available from actual field measurements (e.g. Li et al., 2017).

We present for the first time RPPs of some of the key pollen taxa retrieved from the fossil pollen sequences located within the broader *Acacia–Albizia* biogeographic zone in the drier parts of south-east India along the Coromandel coast, falling in the rain shadow of the southwest or summer monsoon. To achieve this, surface soil samples for pollen analysis and distance-weighted vegetation data were collected from 14 sites in the current mosaic landscape of this biogeographic zone using the Crackles Vegetation Survey protocol (Bunting *et al.*, 2013). RPPs of 6 key pollen taxa, viz., Poaceae, *Acacia/Albizia*, *Dodonaea*, *Justicia*, Melastomataceae/ Combretaceae, and *Randia* were estimated with the ERV model (sub-model 3) for which the best likelihood function curve was obtained using the Prentice Bog (dispersion) model. Results indicate a Relevant Source Area of Pollen (sensu Sugita, 1994) of 164 m radius for the modern pollen samples. The estimated RPPs relative to Poaceae (RPP set to 1) are highest for *Acacia/Albizia*, *Dodonaea*, and *Justicia* (>10), and are <5 for the three remaining taxa. Ecologically, taxa such as *Acacia/Albizia*, *Dodonaea*, Melastomataceae/ Combretaceae, and *Randia* are considered as markers of the Tropical Dry Evergreen forests of the Coromandel Coast.

Abstract

Pollen-based quantitative reconstruction of regional land cover is an essential step to infer past landscape dynamics and to produce vegetation descriptions useful in Earth-system modelling. In this study, we test the REVEALS (Regional Estimates of VEgetation Abundance from Large Sites) model (Sugita, 2007a) for the first time tropical south east India to reconstruct Holocene regional land-cover change. We use three fossil pollen records from the Coromandel coast, falling in the rain shadow of the southwest or summer monsoon and characterized by Tropical Dry Evergreen Forests (TDEFs). One of the pollen records is from a site located in the same region as sites used to estimate Relative Pollen Productivity (RPP) needed for the application of the REVEALS model. The two other pollen records are from the same biogeographic zone, ~150 km south of the primary site. The REVEALS reconstructions are achieved for consecutive 500-year time windows up to 0.7 ka BP and time windows of decreasing length up to present following the protocol of PAGES LandCover6k (Gaillard et al. 2018).

In addition to RPPs estimated for six key taxa of SE India, *Poaceae*, *Acacia/Albizia*, *Dodonaea*, *Justicia*, *Melastomataceae/Combretaceae*, and *Randia*, we applied RPPs from China (Li, et al., 2017) for *Aster/Anthemis-t.* (known as Compositae Echinata in India), *Amaranthaceae/Chenopodiaceae*, and *Cyperaceae*, assuming that RPPs in temperate China and SE India are comparable. The REVEALS reconstructions suggest that, except for *Cyperaceae*, all other taxa are over-represented in the pollen record. Fluctuations in the quantitative estimates of key pollen markers of the TDEF vegetation through time indicate that the present mosaic vegetation of the region may have existed for a long time, and that the land cover of SE India was a scrubland with grasses and patches of TDEFs through most of the Holocene.

Microfacies analysis of Lateglacial Swedish clay varves

Rachel Devine¹, Adrian Palmer¹, Alison MacLeod², Stefan Wastegård³, Ian Matthews¹

¹Royal Holloway, University of London, Egham, United Kingdom. ²University of Reading, Reading, United Kingdom.

³Stockholm University, Stockholm, Sweden

Abstract

One of the most renowned varve chronologies is the Swedish Timescale (STS). This is generated through the analysis of annual layers deposited in the Baltic Ice Lake (BIL), which was ice-dammed by the Fennoscandian Ice Sheet during the Lateglacial Interstadial and Younger Dryas periods. The STS is based on correlation between numerous clastic varve thickness series, which generates an annually resolved record of Fennoscandian Ice Sheet retreat. However, the total number of varves in the STS is contested with some researchers suggesting there are “missing varves”, in particular 700-900 years are missing during the Younger Dryas - Pre-Boreal period (12.9-11.35 ka BP). These errors may be caused by the practice of linking varve series between sites based on either macroscale varve thickness patterns and/or distinct sedimentological features, observed at the macroscale that are considered to reflect regional processes. However, to date, there have been few studies that have examined the microfacies of the glaciolacustrine varves from this time period and that test whether sedimentological features identified at the macroscale are corroborated by common features at the microscale across sites.

We present the results of microfacies analysis from three Lateglacial/early Holocene varve records from Östergötland. Microfacies analysis has enabled an understanding of the evolution of local proglacial lake processes through the construction of site-specific varve deposition models. Several distinct varve microfacies ranging in thickness, texture and structure were identified at each site. Melt season characteristics vary from complex microfacies that are typically >10 mm thickness with multiple sediment inputs (proximal varves) to simple single-layered melt seasons in the thinner, <1 mm thickness varves (distal and ultra-distal varves). However, whilst there are common microfacies at each site, differences exist and these changes occur over temporal scales. In addition, across all three sites, deformation structures such as faults, folds and inverted varves were identified, but the frequency and complexity of deformation zones is site-specific. We suggest that the observed differences in varve microfacies and frequency of deformation zones likely reflect a combination of a) local lake processes and b) differences in local slope instability; verified by basin topographical surveys.

These results have implications for the robustness of the existing Lateglacial STS and potentially the timing of deglaciation in Sweden. We conclude by making a series of recommendations for correlating regional varve thickness chronologies and to test existing correlations.

Abstract

Recent research in Svalbard has provided compelling evidence for early Holocene glacier advances during a time when marine bivalves indicate that the surrounding seas were warm. The overall aim of this project is to reconstruct the Holocene climate and glacial history of northeast Spitsbergen, using a holistic approach that includes collection and integration of marine, terrestrial and lacustrine data. The area of main interest is the 8 km long lake Femmilsjøen in NE Spitsbergen, one of the largest and deepest lakes in Svalbard, its surroundings, as well as the adjacent, outer parts of the fjord Wijdefjorden. The surge-type glacier Longstaffbreen terminates in the eastern end of the lake.

Marine sediment cores, swath bathymetry data, as well as sub-bottom profiler data were collected just off Femmilsjøen in the summer of 2017. Lacustrine sediment cores, sub-bottom profiles and swath-bathymetry from the lake were collected in 2018. The surrounding area of Femmilsjøen, between the coast of Wijdefjorden and Longstaffbreen/Midtgarsbreen, were mapped during the field campaign in 2018, and ridges with shells deposited by re-advances during Late glacial - early Holocene were identified. The acoustic data reveal numerous transverse ridges across the lake floor. Acoustically stratified deposits fill the depressions between these ridges.

On-going analyses of the sediment cores from the two archives are: lithostratigraphic logging, organo-geochemical analyses, biomarker and granulometric analyses, as well as XRF core scanning. The multiproxy approach enables inter-archive comparison.

This study will help to clarify the timing of glacier advances in the region in relation to the timing of incursion of warm marine waters in the early Holocene. On our poster, we present preliminary results of the on-going analyses of the data set and we discuss potential and draw first implications about the development of the environmental conditions during the Holocene on northeast Svalbard based on our terrestrial-marine records.

Formation and deformation of an ice-contact sub-lacustrine fan, Blessington, Ireland

Michael Philcox

Geology Department, Trinity College,, Dublin, Ireland

Abstract

A Late Midlandian/Devensian ice-contact delta with foresets >60 m high developed during ice retreat from its LGM position against the Wicklow Mountains. The delta complex includes a zone of sub-lacustrine fan sediments <200 m wide, which built up a ridge >20 m high, and leeside bottomset sands extending several hundred metres further. Successive faces in an active gravel pit, cut perpendicular to ice movement towards the SE, revealed the geometry and sedimentary architecture of the fan.

The following features are present: 1) an early fan ridge with common flat thrusts; 2) a thin diamict drape over this ridge; 3) backsets <15 m high including gravel cross-beds prograding up slope; 4) local W-dipping erosion/non-deposition surfaces on the ice side of the fan ridge, time-equivalent to highly asymmetrical growth of foresets on the lee side; 5) rare larger-scale W-dipping erosion surfaces truncating <15 m of section; immediately below these surfaces are localized gravel fans <8 m thick, indicating that these are effectively ice-contact surfaces; 6) diamict "intrusions" <6 m high penetrating and deforming adjacent fan sediments; 7) occasional W-dipping thrust sheets >5 m thick with diamict at base, overlain by bedded sediment; some emerged on lake floor, to be partially eroded before burial; 8) back-slope collapse features on various scales, including coherent rotated blocks of sand and gravel >5 m thick; 9) steep gravity-faulted back-slope surfaces displaced by subsequent low-angle thrusts; 10) a free-standing vertical cliff >5 m high cut through undisturbed horizontal sediments; 11) sand and silt diapirs on various scales, some due to sediment loading, some probably responding to ice push.

The faces show a complex history of ice retreat and re-advance on a local scale, during overall retreat prior to growth of the delta itself. Distance between the ice and the fan ridge varied: when close, erosion surfaces and asymmetrical leeside foresets developed, or cross-bedded sediments prograded up the backslope; with ice retreat the backslope often collapsed, sometimes to be followed by re-advance and thrusting of the remaining ridge. Prolonged melting of buried ice blocks was responsible for some deformation.

Environmental reconstruction based on lake sediments: implications for proglacial lakes distribution in central Russian Plain during the last glaciation

Olga Borisova

Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation

Abstract

Lake Galich (58°24'N, 42°17'E, 101 m above sea level) is one of the largest natural lakes in the middle part of the Volga River basin. Although it is situated outside the area of the Late Valdai/Weichselian ice-sheet, it is believed that during the Last Glacial Maximum (LGM) it was a part of the vast Kostroma proglacial lake connected with other similar lakes. According to this hypothesis, during the LGM the shoreline of the Kostroma proglacial lake was at about 145 m a.s.l., and the present-day Lake Galich formed a narrow bay over 60 m deep. According to the age model based on radiocarbon dating, 69 m of Lake Galich sediments penetrated by coring accumulated for almost 60 thousand years. This sediment thickness provides a continuous archive of the Valdai Glaciation environment and climate history, from the end of the Marine Isotope Stage (MIS) 4 to the beginning of the Holocene, which is unique for the region. The studies of Lake Galich sediments are of great importance for resolving the question of the existence of large proglacial lakes in the central part of the Russian Plain during the LGM. Palynological data indicate that during the Early and Middle Valdai (MIS 4 and 3) the vegetation in the area was of a periglacial forest-steppe type, with open woodlands of spruce, pine and birch. Grain-size analyses of lake sediments indicate very stable sedimentation conditions during MIS 3, with particle size gradually increasing from clay to medium loam and an average accumulation rate of 1.4 mm per year. At the boundary of MIS 3 and 2 the sediment accumulation rate did not change, but the fraction of coarse silt, the main component of loess deposits, reached its maximum content (60%). At the LGM, the periglacial-steppe communities with *Artemisia* prevailed in the area due to increasing aridity of climate. Development of erosion on the slopes poorly protected by sparse vegetation is marked by presence of spores reworked from the Jurassic and Early Cretaceous deposits. After the LGM, the mean accumulation rate of lake sediments decreased to 0.8 mm per year, in spite of the considerable increase in particle size. Therefore, the studies of bottom sediments of Lake Galich showed no traces of a manifold increase in the depth of the lake during the proposed damming up to 145 m a.s.l. at the LGM, which casts doubt on the very possibility of such proglacial lakes existence in the region at the time.

The research was carried out with support of the Russian Science Foundation project 17-17-01289 «Runoff rerouting and migration of the Main Divide of the Russian Plain during the last glaciation».

Abstract

Seismostratigraphic studies of the 11.8 km² and ~140 m deep Lake Bolshoye Shchuchye, Polar Urals, reveal that the lake basin contains up to 160 m thick acoustically laminated sediments. The spatial and temporal distribution of the lake sediments have been mapped with the aid of 100 seismic profiles and 2 well-dated long sediment cores retrieved from the lake basin. Time slice maps constructed from the seismic reflection data allows the sediment volume and sediment flux to be quantified through four periods. Hemipelagic processes dominated the sedimentation in Lake Bolshoye Shchuchye during at least the last 24 cal. ka BP, with only local variations from delta progradation and slope gravity processes. The sedimentation rate during Last Glacial Maximum was high and characterized by varved deposits. A major shift in the sediment accumulation, dated to c. 18.7 cal. ka BP, is interpreted to mark the end of the local glacial maximum and the initiation of glacial retreat in the area. At this time the sedimentation flux was greatly reduced, indicating fast retreat and possible disappearance of the glaciers. The shift at the Younger Dryas - Holocene boundary is very pronounced in the seismic signature, marked by a further reduction in sedimentation rate. The denudation rate in the accumulation area during the Holocene is only a eighth of the LGM denudation rate. The age of the oldest stratified sediments in Lake Bolshoye Shchuchye is not well constrained, but estimated to c. 50-60 ka.

The development of proglacial lake within the Izborsk-Malskaya paleovalley (Pskov region, Russia) in the Late glacial time.

Natalia Karpukhina¹, Evgeny Konstantinov¹, Inessa Karevskaya², Elya Zazovskaya¹, Svetlana Bricheva²

¹Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation. ²Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

Some fingerprints of lacustrine conditions (varves and ancient shorelines) were found into the Izborsk-Malskaya paleovalley (Pskov region, Russia). It gave us a possibility to suggest the existence of unknown earlier proglacial lake which was forming during the deglaciation of paleovalley. The semi-buried erosion form (Izborsk-Malskaya paleovalley) is located at the base of the eastern slopes of the Haanja Upland. The paleo-incision is narrow, straight and deep (the modern depth is 40-50 m, while the depth of paleovalley - about 100 m). The thickness of the Late Pleistocene glacial deposits filling the paleovalley reaches 50 m.

During the fieldwork in the southern part of paleovalley were found varves. The depth of their top varies from 6,40 to 8,20 m (probably more). There is a decrease in depth of varves towards modern lakes located at the bottom of paleovalley. Near the northern shoreline of Lake Malskoye was observed hummock moraines and other landforms originated under a condition of melting dead ice which could dam the runoff from the proglacial lake. The position of the former ice-dam and structure of terraces of the valley right side helps us to reconstruct sizes of the proglacial lake. AMS 14C dates combined with results of pollen analysis support that the proglacial lake was existing during the Allerød. The proglacial lake was rapidly drained at the end of the Allerød. This event reflects in the sediment sequence. Grain size and microstructure analysis of varves obtained to suggest that the key borehole penetrated into proximal and distal varves formed in different ways of sedimentation.

Investigations of geomorphology and sediments filling the paleovalley allow us to reconstruct the proglacial lake development within the Izborsk-Malskaya paleovalley and also deglaciation features of the paleo-incision.

The reported study was funded by RFBR according to the research project № 18-35-00700.

Palaeoenvironmental history of proglacial lakes in eastern Siberia.

Bernhard Diekmann^{1,2}, Boris Biskaborn¹, Luidmilla Pestryakova³, Larisa Nazarova², Dmitry Subetto⁴

¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Potsdam, Germany. ²University of Potsdam, Potsdam, Germany. ³North-Eastern Federal University, Yakutsk, Russian Federation. ⁴Herzen State Pedagogical University of Russia, Potsdam, Germany

Abstract

Sedimentary records from glacial lakes of eastern Siberia provide insight into palaeoenvironmental changes over the late Quaternary. One key site represents the Bol'shoe Toko lake system in southeastern Yakutia, Russia (56°15'N, 130°30'E). It is situated at 903 m a.s.l. at the northern foot of the Stanovoi Mountains. Surrounded by three sets of moraine arcs and an ancient lake terrace, the hydrologically open fresh-water lake basin is 83 km² large and extends over 15 km in length and 7 km in width, with a maximum water depth of 80 m. The central part of the lake includes a subaquatic ridge. Isolated smaller kettle-like lakes cover the surrounding moraines and terrace. The geomorphological features point to a former proglacial setting, though the mountainous catchment (up to 2200 m a.s.l.) today is unglaciated. The area is occupied by taiga vegetation and situated within the continental temperate climate zone.

The lake system represents a natural laboratory of hydrology and palaeolimnological changes in the past, unaffected by direct anthropogenic influence. Modern hydrochemistry (ions and stable isotopes) displays differences between the open and closed water bodies, which tend to higher and heavier element concentrations. These lake systems also differ with oligotrophic conditions in the large and deep lake and mesotrophic conditions in the smaller and shallower lakes. This contrast is also reflected in limnoecology by bioindicators of preserved modern remains of diatoms and chironomids and the composition of organic matter in modern lake-bottom sediments. Water depth is another important habitat factor for limnoecology. Mineralogy and grain size of the minerogenic sediment fraction helps to unravel sediment supply from the mountain river versus shore erosion.

Modern depositional environments support the interpretation of sediment cores, spanning the last 30 kyr, according to radiocarbon dating. A glacial advance during the last glacial maximum, did not affect the whole lake, as former glaciations did. Postglacial development was characterized by a lake-level lowering of around six metres around 4.5 ka BP after the early to mid-Holocene climate optimum, demonstrated by the deflooding and isolation of a small lake on the lower lake terrace. Diatom remains in short sediment cores, dated by Cs and Lead activity, point to ecological changes during the last century, possibly related to the onset of global warming.

Restricted glaciation during the last glacial maximum compared to former glacial advances is consistent with geomorphological and limnogeological findings from the central Verkhoyansk Mountains some 1000 km farther to the north. The sequence of mountain glaciation thus is out of phase with the global ice-volume pattern, possibly because of complex atmospheric moisture routing effects, which so far are poorly understood for eastern Siberia. The postglacial lake history matches the northern-hemispheric pattern of Holocene climate history.

Defining the 'generalist specialist': Exploring the ecological and cultural plasticity of Middle and Late Pleistocene *Homo sapiens*

Patrick Roberts¹, Brian A. Stewart²

¹Max Planck Institute for the Science of Human History, Jena, Germany. ²University of Michigan, Ann Arbor, USA

Abstract

Attempts to define our species as unique amongst all other hominins have tended to focus on differences in capacity for symbolism, language, social networking, technological competence, and cognitive development. More recently, however, a series of researchers, drawing on previous discussions of 'variability selection', have highlighted the unique *ecological* characteristics of *Homo sapiens*. Here, we critically review the current archaeological, palaeoecological, and palaeoenvironmental datasets associated with the Middle to Late Pleistocene (300-12 ka) evolution and dispersal of our species within and beyond Africa. We argue that evidence for the occupation of diverse 'extreme' environments, including deserts, high altitude environments, the palaeoarctic, and tropical forests characterize our species as a 'generalist specialist'. Not only could *H. sapiens* occupy and use a variety of environments, but local human populations could also develop specialized, culturally mediated adaptations in particular environments over the course of millennia. Testing and evaluating this ecological niche represents a framework for discussing what it means to be human, and reveals new priorities in archaeological and palaeoanthropological research. It also represents a potential point of intersection for discussions of human neurological, cultural, and ecological 'plasticity'.

Abstract

The Aterian is crucial to understanding the dispersal of early modern *Homo sapiens* and the development of behavioral complexity in North Africa. A currently unresolved question relates to the environments and climates that these early *Homo sapiens* occupied. Here we report a new Aterian site in Southern Tunisia that shows occupation of a humid Sahara. It is found within shoreline deposits of a megalake which developed within the Chott el Djerid basin during past humid periods. The geomorphology, sedimentology, molluscan/fish/ostracod assemblage and OSL ages indicates a fresh water lake existed between 80 and 90 ka. The Aterian lithics recovered from the site occur in association with an extensive assemblage of vertebrate remains consisting of 25 different taxa that indicates an open savanna environment. Analysis of the fauna suggests a natural death assemblage, yet some faunal remains bear witness to human butchery, indicating active scavenging of carcasses by Aterian populations. This evidence of Aterian occupation of a humid Sahara contrasts with evidence from other sites for occupation of arid and coastal environments, thus indicating that these archaic *Homo sapiens* could occupy a diverse array of environments, from the benign to the extreme.

Coping methods – how Western Mediterranean hunter-gatherers dealt with climate change

Taylor Otto^{1,2}, Gerd-Christian Weniger^{2,1}, Viviane Bolin³, Yvonne Tafelmaier⁴, Alessandro Poti¹, Martin Kehl⁵, María de Andrés Herrero¹

¹CRC 806, Institute of Prehistoric Archaeology, University of Cologne, Cologne, Germany. ²Neanderthal Museum, Mettmann, Germany. ³Institute of Prehistoric Archaeology, University of Cologne, Cologne, Germany. ⁴Institute of Prehistoric Archaeology, University of Tübingen, Tübingen, Germany. ⁵Institute of Geography, University of Cologne, Cologne, Germany

Abstract

Throughout the Late Glacial in the Western Mediterranean, there are multiple evidences of rapid climate change that likely affected the hunter-gatherer inhabitants of the region. A particularly significant example was Heinrich Event 1, a short-term climate event 18 to 15 thousand years ago. Paleoclimate models (Ludwig et al. 2018) show an increase in arid areas throughout the Southern parts of the Western Mediterranean, which are expected to have significantly influenced human settlement dynamics. To this day, however, the exact impact and nature of such changes is poorly understood.

Working with a comprehensive archaeological database, this contribution analyzes the influence such rapid climate changes had on the hunter-gatherer societies of the Western Mediterranean. With a rich research history and a detailed archaeological and climatological dataset to work with, the prehistoric societies inhabiting Late Glacial Northwest Africa and Iberia are an ideal test case to examine human–climate interactions. Focusing on the Late Pleistocene societies of Morocco and comparing them to contemporaneous groups on the Southern Iberian Peninsula, we drafted a multi-proxy approach to characterize and compare different land use strategies. We applied a number of spatial analytical methods to our dataset of Iberomaurusian and Magdalenian sites of Heinrich 1 and Greenland Interstadial 1 (18-13ka). With this approach, we aimed not only to examine direct reactions to the environmental changes of Heinrich 1, but also the aftermath during the subsequent phase of climate amelioration.

We were able to identify different land use strategies employed by both societies during as well as after Heinrich 1. These we interpret as different coping strategies used to deal with phases of increased aridity, leaving unique, detectible marks on the archaeological record. Importantly, we also show that the reactions to short-term climate events have long-term impacts on societies, these remaining in place even after the climate event itself has passed. These observations not only expand our knowledge of Western Mediterranean prehistory, but also hint at the wide range of methods prehistoric communities employed to cope with extreme environments.

Abstract

The *Homo sapiens*-related Middle Stone Age occupation of Eastern Morocco is well-known from cave or rockshelter long sequences (ie. Station Météo, Rhafas, Ifri N'ammur, Taforalt). Notwithstanding, little or nothing is known about open-air dynamics, where the only information so far came from disperse and unstratified lithic scatters.

For the last ten years, we have undertaken systematics surveys and excavations in the Aïn Beni Mathar – Guéfaït basin, Jerada province, which has allowed the discovery of different stratified open-air locations and provide new data about the *Homo sapiens* management of wider environments. The paleoecological reconstructions show open semidesert environments with vegetation concentrations related to water points and lakes, very similar to the actual landscape. The sites documented are mostly located on slopes and exposed surfaces of riverbanks, around springs, and appear to be associated with areas rich in both biotic and abiotic resources, namely lithic raw materials outcrops. Technologically these sites are characterized by homogeneous sets of flake assemblages with important Levallois components (preferential and recurrent) but also discoidal and opportunistic strategies. Retouched tools are abundant, mainly denticulates and scrapers, and at some locations “Aterian” assemblages with tanged pieces and bifacial foliates have been documented.

In this paper we present data about different surface locations discovered in the Sahb el Gahr – Swiwina plain, including the systematic excavations at SBG1-1 & SBG2-1 and Oued Charef sites. Our interdisciplinary results will provide an overview of this MSA dynamics open air contexts in a semidesertic area, focusing on the subsistence strategies and comparing them with the information provided by cave and rockshelter occupations.

This work will contribute to providing a broader perspective of the *Homo sapiens* technological evolution and adapting during the North African Middle Stone Age.

Abstract

The interior Kalahari of southern Africa is an archaeological enigma: a desert that is not quite a desert; lacking surface water yet with evidence of multiple Lake highstands during the last 250ka; and long regarded as an archaeological backwater. It is home to the world-renowned MSA sites at Tsodilo Hills but despite the wider landscape being noted 70 years ago for its rich lithic legacy, systematic archaeological analyses have been few and far between, especially in the context of extensive open-air sites. This huge region remains a significant knowledge gap in African Stone Age archaeology.

From 2016-19 a major landscape archaeology project has been conducting the first systematic analysis of the extensive Stone Age archaeology of the Kalahari's 90,000km² Makgadikgadi basin, framed around the question of how Late Quaternary hydrological changes, relating to mega-lake waxing and waning, affected human mobility, resource use and the distribution of archaeological sites in the landscape.

We have mapped 38 archaeological sites and 44 scatters/minor sites (mainly MSA, also LSA and Pastoralist) on the floor and perimeter of Makgadikgadi; excavated six sites using *décapage* methodology; conducted sedimentological and landform including sampling for chronometric (OSL, ¹⁴C), geochemical and bio-proxy analyses; and mapped and sampled >300 silcrete outcrops for geochemical provenancing of lithic source areas. Together, these methods provide an unprecedented approach to reconstructing MSA interactions with, and movement in, a hydrologically dynamic environment, with implications for wider theories of early human interactions with changing environments.

Preliminary findings indicate extensive MSA use of Makgadikgadi during lowstands or at seasonally dry times. Basin floor occupation sites have been preserved through burial during lake highstands and subsequent deflation exposure. Raw materials are dominated by black silcrete that arrived from a range of source areas, often many tens of km distant, in different stages of preparation. While the degree of post-depositional artefact disturbance varies from site to site, *chaîne opératoire* analyses show that some sites are surprisingly well preserved. In these cases flakes and tools have been refitted to cores over distances of a few metres, allowing documentation of technological approaches and knapping sequences, with further reconstruction of site specific behaviour patterns. Excavated sites fall in the 90-70ka age range. Overall, the Makgadikgadi MSA has greater affinities to areas to the north and east rather than South Africa, suggesting that hydrological networks connecting the basin to more tropical source regions have played a key role in Late Quaternary societal dynamics.

Social network mapping in southern African highlands and drylands using strontium isotope geochemistry

Brian Stewart¹, Yuchao Zhao¹, Peter Mitchell², Genevieve Dewar³, James Gleason¹, Joel Blum¹

¹University of Michigan, Ann Arbor, USA. ²University of Oxford, Oxford, United Kingdom. ³University of Toronto Scarborough, Scarborough, Canada

Abstract

Today's social media platforms are the outermost branches of an evolutionary tree whose roots run deep. At some point in the Pleistocene, hunter-gatherers began exchanging non-utilitarian artifacts like beads and other ornaments over hundreds, and sometimes thousands of kilometers. Among ethnographically documented foragers these networks symbolically link distant groups, acting as social adhesives that enhance fallback opportunities, information availability, and reproductive potential, among other benefits. Charting the evolution of long-distance social networks can thus help determine when, why and how our species began harnessing material culture to mitigate risk, particularly when strategizing life in extreme environments. This paper presents the results of strontium isotope analyses of ostrich eggshell beads recovered from late Pleistocene and Holocene contexts in two contrasting habitats of southern Africa: the Namaqualand Desert (South Africa) and Maloti-Drakensberg Mountains (Lesotho). Our data demonstrate the existence and persistence of highland and dryland exchange networks, and hold implications for tracing the development of social strategies for long-term survival in the southern African interior.

Assessing variations in the habitability of deserts during humid episodes: defining extreme.

Paul Breeze, Nick Drake, Katie Manning
King's College London, London, United Kingdom

Abstract

Hyper-arid deserts are some of the most hostile environments on the planet for humans. Nonetheless, archaeological evidence demonstrates repeated occupations of the Sahara and Arabia during the Pleistocene and Early Holocene, correlating temporally with orbitally mediated periods when these areas were relatively wetter and greener. During such 'greening' episodes, however, environmental amelioration would have been spatiotemporally variable, dependent upon diverse geomorphological, hydrological, and topographic conditions and the interaction of these local variables with large-scale climatic conditions, such as the movement of the ITCZ and monsoon belt. It thus cannot be assumed that amelioration of these deserts was uniform, and a spectrum of environments likely existed, some more extreme than others. However, this dynamism and its expression at different spatial scales remain relatively poorly understood. Understanding the spatiotemporal patterns of habitability within these deserts is crucial both for understanding the observed distribution of archaeological sites, and for assessing the important roles these areas may have played in relation to key events in human history through the removal, or reinstatement of barriers created by hyper-aridity and absence of surface water.

Here we discuss how syntheses of palaeohydrological mapping and palaeoenvironmental proxy data can elucidate where seasonally or permanently activated drainage, lakes, and wetlands may have recurrently formed in these deserts during different humid periods, and where the density and distribution of these water sources may have produced relatively contiguous 'corridors' of surface water. We discuss high spatial resolution (90m) data we have now produced for the Saharan and Arabian deserts. These data allow more nuanced discussion of when and where relatively more hospitable and inhospitable environments persisted during humid episodes, permitting hypotheses to be proposed regarding where different regions within deserts lay upon an 'extremity spectrum'. At a larger scale, the patterns of when and where habitable environs connected at different times are providing new insights into potential environmental controls upon routes for hominin dispersals and population interactions, in particular, new data regarding likely routes for early expansions of our own species within Africa and across southwest Asia.

Abstract

Reconstructing the Holocene hydroclimate of southern Alaska is important for understanding the evolution of North Pacific ocean-atmosphere circulation. Previous research suggests a shift in the climate of the Northeast Pacific continental margin occurred at ~ 4 ka. This shift is characterized in part by a strengthened Aleutian Low (AL) associated with mean conditions resembling a positive phase of the Pacific Decadal Oscillation (PDO). Oxygen isotope data from endogenic materials formed in lakes and subsequently stored in sediments can be used to infer the isotope composition of lake water ($\delta^{18}\text{O}_{\text{lake}}$), which is sensitive to hydroclimatic variables such as the $\delta^{18}\text{O}$ of meteoric water and precipitation-evaporation balance (P-E). While the $\delta^{18}\text{O}$ of calcites is most often analyzed, in Alaska carbonate-bearing lakes are relatively rare; in such cases, the $\delta^{18}\text{O}$ of diatoms can be studied alongside diatom flora analysis to further elucidate paleoenvironmental change. We present a new Holocene $\delta^{18}\text{O}_{\text{diatom}}$ and diatom flora record from Sunken Island Lake, a hydrologically-closed kettle lake in the Kenai Peninsula lowlands, where the local evaporation line indicates $\delta^{18}\text{O}_{\text{lake}}$ is influenced by changes in P-E.

The $\delta^{18}\text{O}_{\text{diatom}}$ data show a Holocene range of 5.7‰ (+26.5 to +32.2‰ VSMOW, $n = 98$). Mean $\delta^{18}\text{O}_{\text{diatom}}$ prior to 4 ka was +29.5‰ ($n = 49$), which increased to a mean of +30.5‰ ($n = 20$) between 4 and 1 ka, then decreased to a mean of +28.4‰ ($n = 29$) over the past 1 ka. Increased $\delta^{18}\text{O}_{\text{lake}}$ at Sunken Island might reflect either drier conditions (decreased P-E) or increased $\delta^{18}\text{O}_{\text{precipitation}}$. Increased $\delta^{18}\text{O}_{\text{precipitation}}$ in this region implies positive PDO-like conditions and a strengthened AL, which promote moisture transport from the relatively ^{18}O -enriched North Pacific Ocean through the Gulf of Alaska to the Kenai Peninsula. Shifts in $\delta^{18}\text{O}_{\text{diatom}}$ during the instrumental period are broadly consistent with changes in annual precipitation at Kenai airport as well as with shifts in the PDO and AL. This suggests that $\delta^{18}\text{O}_{\text{diatom}}$ reflects both changes in source water and P-E, which are opposing influences on $\delta^{18}\text{O}_{\text{lake}}$. Although higher values from 4 to 1 ka might indicate decreased P-E, a regional study of lake-level fluctuations suggests water levels rose progressively following their lowest levels in the early Holocene. Therefore, our observed shift to higher $\delta^{18}\text{O}_{\text{diatom}}$ at 4 ka suggests a change in meteoric source water, which dominated the $\delta^{18}\text{O}_{\text{lake}}$ signal rather than decreased P-E. This increase in $\delta^{18}\text{O}_{\text{diatom}}$ at 4 ka adds to evidence for an ocean-basin-scale shift involving the PDO and AL. The origin of the decrease in $\delta^{18}\text{O}_{\text{diatom}}$ at 1 ka is uncertain. In absence of regional evidence for a change in moisture source, we ascribe it to local factors that increased P-E at this site. Major shifts in diatom flora will be used to further contextualize these changes in $\delta^{18}\text{O}_{\text{diatom}}$.

Palaeohydrological changes in Yellowstone Lake (Wyoming, USA) for the last 11 000 years inferred from oxygen isotopes in diatoms

Rosine Cartier¹, Daniel J. Conley¹, Melanie J. Leng^{2,3}, Jack H. Lacey², Petra Zahajská¹, Sherilyn C. Fritz⁴

¹Lund University, Lund, Sweden. ²British Geological Survey, Nottingham, United Kingdom. ³University of Nottingham, Nottingham, United Kingdom. ⁴University of Nebraska-Lincoln, Lincoln, USA

Abstract

The hydrothermal system of Yellowstone is located on one of the World's most active volcanic plateaus (Wyoming, 2357 m a.s.l.) and comprises more than 10,000 thermal features, which influence geochemical cycling through fluid-rock exchanges (Cl, Si, Li, Na) and gas formation. Springs host unique groups of microorganisms living in extreme environmental conditions and using diverse inorganic sources for their development.

Several large hydrothermal explosions (creating craters of more than 1 km in diameter) occurred during the Holocene, raising the question of how climate and associated changes in lake level and hydrostatic pressure have affected the hydrothermal system and the lake ecosystem at a multi-millennial timescale. For this purpose, sediment cores (c. 12 m-long) were taken in the northern part of Yellowstone Lake in 2016 as part of the "Hydrothermal Dynamics of Yellowstone Lake (HD-YLake)" research program. The lake sediments are highly rich in diatom fossils, enabling hydrological changes to be inferred using oxygen isotope ratios ($\delta^{18}\text{O}$) of the biogenic silica. $\delta^{18}\text{O}$ reflects the isotopic composition of the lake water during diatom growth. The ratio varies according to changes in lake water temperature, lake water balance, and precipitations sources. The current functioning of Yellowstone Lake and its influence on $\delta^{18}\text{O}$ in the lake waters were investigated using modern water samples from the lake and its main tributaries. To avoid possible influences of vital effects, we extracted only one diatom species, *Stephanodiscus yellowstonensis*.

A major hydrothermal explosion about 8000 years ago was identified from geochemical and sedimentological evidence near the base of the sediment core, lying just below a tephra layer, dated ca. 7700 years ago, from the explosion of the Mount Mazama. A long-term decrease in $\delta^{18}\text{O}_{\text{diatom}}$ (samples becoming depleted in heavy isotopes) through the record is interpreted as a gradual change in lake surface area and lake water evaporation. Short-term variations and an abrupt decrease in $\delta^{18}\text{O}_{\text{diatom}}$ 3000 years ago reflect periods of rapid change in the lake water balance. These isotopic results will be compared with lake-level changes inferred from terraces and diatom assemblages to study the response of the lake ecosystem to hydrological changes. Comparison with regional paleoclimatic records and shoreline and stratigraphic evidence of hydrothermal explosions will allow an examination of the potential influence of climate on the hydrothermal system.

Biogeochemical cycling in the North Pacific Ocean through the Mid Pleistocene Transition

Andrea Snelling¹, George Swann¹, Vanessa Pashley²

¹University of Nottingham, Nottingham, United Kingdom. ²British Geological Survey, Nottingham, United Kingdom

Abstract

The subarctic North Pacific Ocean has been a relatively understudied region in terms of palaeoclimate, limiting our understanding of how the region has both driven and responded to palaeoenvironmental events. Today, the subarctic North Pacific Ocean is marked by a year round stratified water column with a halocline at c. 300 m water depth. Previous studies at ODP Site 882 in the Northwest Pacific (Fig. 1) have suggested this system developed at the onset of major Northern Hemisphere Glaciation (2.73 Ma). In addition to limiting the upwelling of carbon rich deep waters and associated ventilation of CO₂ to the atmosphere, the shift to a stratified state fundamentally altered oceanographic conditions and biogeochemical cycling across the region. Key questions remain over whether the region remained permanently stratified for all of the Quaternary, or whether the changes in stratification/biogeochemical cycling altered over major climatic transitions such as the Mid Pleistocene Transition (MPT), a process that would alter regional ocean-atmospheric carbon exchanges.

Diatom isotope records from IODP Site U1341 at Bowers Ridge in the Bering Sea (Fig. 1) indicate that the development of the stratified system at ODP Site 882 in the subarctic Pacific led to a nutrient leakage from the deep North Pacific Ocean through the Kamchatka Strait and into the Bering Sea, fuelling an opal bloom at IODP Site U1341 and indicating a strong linkage between the two regions that may have impacted regional carbon cycling. It is not known whether this nutrient leakage and the link between the two regions continued after 2.5 Ma and whether these changes alter over the evolution of the MPT or are concordant with changes in south Bering Sea productivity. This has important implications for assessing whether changes in biogeochemical cycling and associated impacts on the Bering Sea carbon cycle could have contributed towards lowering atmospheric CO₂ and the climate transitions at the MPT.

We present here silicon isotope data from diatoms ($\delta^{30}\text{Si}_{\text{diatom}}$) from both sites, constrained using records of opal biogenic silica in order to test the mechanisms of biogeochemical cycling and the hypothesis of nutrient leakage from the subarctic North Pacific Ocean to the Bering Sea between 2.52 Ma and 0.5 Ma encompassing the MPT. This has enabled us to reconstruct temporal changes in photic zone nutrient utilisation and silicic acid supply in the northwest subarctic Pacific Ocean and south Bering Sea through the progressive intensification of glacial-interglacials through the early Quaternary and over the MPT. We will use these data to identify whether changes in biogeochemical cycling and oceanographic conditions (stratification) at ODP Site 882 are concurrent with biogeochemical cycling in the south Bering Sea, advocating potential linkages between the two sites.

⁷CSIRO Agriculture and food, Adelaide, Australia. ⁸University of Tokyo, Tokyo, Japan

Abstract

Records of terrestrial environmental and climatic variability that extend beyond the Last Glacial Maximum (LGM) in Australia are rare. This paucity of terrestrial archives is further hampered by poor age constraints and low sample resolution. Such records are critical to debates about the relative roles of people, climate and the extinction of megafauna in shaping Australia's environment. Here we present a high-resolution, well-dated, multi-proxy record of climate, vegetation and fire history covering the past ca. 80,000 years from Welsby Lagoon, North Stradbroke Island, subtropical eastern Australia. The Welsby Lagoon chronology has been developed from 21 OSL ages and 20 ¹⁴C dates and spans the regionally significant periods of Marine Isotope Stage (MIS) 4, MIS3 and the LGM.

To reconstruct the evolution of the wetland and document environmental and hydrological change we utilise a variety of proxies reflecting within-wetland change (plant macrofossils, $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, $\delta^{18}\text{O}$, aquatic pollen, plant lignin, photosynthetic pigments). Since its formation, Welsby Lagoon has undergone an ecosystem state shift from an open-water lacustrine system to a macrophyte-dominated palustrine swamp after ca. 40 ka. A thorough understanding of the development of this site permits robust interpretations of aquatic, terrestrial and climatic changes. For example, the $\delta^{13}\text{C}$ composition of the Welsby Lagoon sediments during MIS4 and MIS3 reflect variations in lacustrine primary productivity, corresponding to multi-millennial scale changes in nutrient input and insolation. Hydroclimate variability, inferred from $\delta^{18}\text{O}$ of aquatic cellulose, drives centennial scale lacustrine and terrestrial environmental changes. $\delta^{13}\text{C}$ -inferred lake productivity declines during wet periods, while terrestrial pollen composition displays greatest response to rapid drying events. This high-resolution, independently dated record extending to the beginning of MIS4 has the potential to advance our understanding of millennial to centennial scale climate and ecological variability during significant time periods in subtropical Australia.

Monsoonal-driven terrestrial subsidies controls lake-atmosphere carbon exchange since the LGM

Qian Wang, Xiangdong Yang

State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

Secondary production in lakes and associated emission of CO₂ are heavily subsidized by terrestrial carbon but the role of climate forcing remains unclear. The carbon stable isotope composition of zooplankton in a sediment core from a sub-tropical alpine lake in SW China tracked atmospheric CO₂ and δ¹⁸O records of monsoonal strength over the last ~26 ky. Both terrestrial and aquatic ecosystems were carbon limited during the Last Glacial Maximum when C₄ vegetation dominated the catchment. Zooplankton production and lake CO₂ (inferred from *Bosmina* δ¹³C) increased from 10 k y B.P. with strengthening of the SW Asian monsoon and forest expansion, indicating a strong but indirect climatic control on lake-carbon dynamics. These results highlight the importance of land-cover and hydrology in controlling terrestrial organic matter subsidies of secondary aquatic production and greenhouse gas emission at 10²-10³ years timescales.

Nitrogen isotopes in lake sediments of Tiefer See (NE Germany) from monitoring to the sedimentary record

Birgit Plessen¹, Sylvia Pinkerneil¹, Ulrike Kienel², Nadine Dräger¹, Achim Brauer¹

¹GFZ German Research Centre for Geosciences, Section Climate Dynamics and Landscape Evolution, Potsdam, Germany. ²privat, Berlin, Germany

Abstract

Nitrogen is an important element reflecting nutrient input and recycling in lake sediments. Lacustrine paleorecords of nitrogen and their isotope composition $\delta^{15}\text{N}$ may reveal human impact by extensive land use, manure, fertilizer, and atmospheric pollution and can be used to reconstruct the eutrophication history under consideration of lake setting, surrounding catchment and internal processes.

To understand the $\delta^{15}\text{N}$ signature of paleorecords and to distinguish the natural variability and anthropogenic forcing from nitrogen cycle and lake productivity, we compared the recent input and productivity, monthly monitored in sediment traps since 2012, with annually laminated lake sediments from NE Germany. The studied lake Tiefer See is located on the southern rim of the Pomeranian terminal moraine at the border of temperate oceanic to continental climate. The region is sparsely populated and used for agriculture and affected by manure and synthetic fertilizer.

Today the trapped material in lake Tiefer See is mainly autochthonous produced and signed by significant high $\delta^{15}\text{N}$ values ranging between +7 and +14‰, reflecting seasonal variations with lower values during the spring and higher values during the autumn and winter time. High $\delta^{15}\text{N}_{\text{NO}_3^-}$ and low $\delta^{18}\text{O}_{\text{NO}_3^-}$ in lake water clearly indicate influence of manure (Kendall et al. 2007). Comparing the mean $\delta^{15}\text{N}$ values of the trapped material to the isotope composition of the recent annual layers, a good accordance were found with $\delta^{15}\text{N}$ values of around +9‰. Our results allow the transmission into the past and the high resolution seasonally reconstruction of nutrient input and eutrophication. The $\delta^{15}\text{N}$ record testify the anthropogenic nitrogen input over the past 2000 years with largest changes since the last 200 years. With the agricultural reform at the beginning of the 19th century, $\delta^{15}\text{N}$ start to rise from around 3‰ to recent 9‰ due to intensified land use and fertilization and with this nutrient input and enhanced lake productivity and eutrophication.

Kendall, C., E. M. Elliott, and S. D. T. Wankel, 2007, Tracing anthropogenic inputs of nitrogen to ecosystems, in R. H. M. a. K. Lajtha, ed., *Stable Isotopes in Ecology and Environmental Science*, Blackwell Publishing, p. 375-449.

Comparison of paleotemperature reconstructions based on the assemblage composition and oxygen isotope ratios of sedimentary diatoms

Biljana Narancic¹, Émilie Saulnier-Talbot¹, Reinhard Pienitz¹, Hanno Meyer², Bernhard Chaplignin², Guillaume St-Onge³
¹Laboratoire de Paléocéologie Aquatique, Centre d'études nordiques (CEN) & Département de géographie, Université Laval, Québec, Canada. ²Alfred Wegener Institute (AWI) Helmholtz Centre for Polar and Marine Research, Potsdam, Germany. ³Institut des sciences de la mer de Rimouski (ISMER), Canada Research Chair in Marine Geology, Université du Québec à Rimouski & GEOTOP, Rimouski, Canada

Abstract

Sedimentary diatoms have been successfully used to quantitatively reconstruct diverse limnological variables, including temperature, at various timescales. Even though temperature is often less of a key driver of diatom ecology than other environmental parameters (such as water chemistry), inference models based on diatom assemblage composition have been shown to be reliable in deriving past air and lake water temperature trends. The oxygen isotope composition ($\delta^{18}\text{O}$) preserved in the biogenic silica of sedimentary diatoms have also demonstrated the potential to reliably reflect water temperature at the time of frustule formation.

This study aims to compare the two approaches in identical samples from one sediment core (Ni2-B) and to explore if and how the results differ, and how their combination can contribute to more reliable paleotemperature inferences. We used as our case study a large Arctic lake (Nettilling Lake, Baffin Island, Canada) from a region where paleoenvironmental reconstructions remain sparse. Results revealed a rather weak correlation ($r^2=0.4$, $p < 0.1$) between inferences from the two approaches, with significant differences in the inferred values. These discrepancies could in part be due to the complex hydrology of the study system which is also recorded in the $\delta^{18}\text{O}$ signal.

Despite these results, we believe that this combination of proxies has the potential to provide new and exciting insights for paleotemperature reconstructions and future studies of postglacial environmental change in well-mixed lakes. To our knowledge, this is the first study to simultaneously present temperature inferences from both lacustrine sedimentary diatom assemblage composition and the isotopic signal extracted from their siliceous structure.

SEQS-DATESTRA a Geographic Database of terrestrial Quaternary stratigraphical sites of Europe (IFG 1620F-SACCOM)

Pierluigi Pieruccini¹, Davide Susini², Pier Lorenzo Fantozzi², Silvia Marchese², Guzel Danukalova³, Markus Fiebig⁴
¹Dipartimento di Scienze della Terra, Università degli Studi di Torino, Torino, Italy. ²Dipartimento di Scienze Fisiche, della Terra e dell'Ambiente, Università degli Studi di Siena, Siena, Italy. ³Institute of Geology of the Ufimian Federal Research Centre, Russian Academy of Sciences, Ufa, Russian Federation. ⁴University of Natural Resources and Life Sciences, Wien, Austria

Abstract

INQUA-SEQS during the 2016-2019 Intercongress period aimed to build a Database of Quaternary Terrestrial European Stratigraphic Sites (DATESTRA). DATESTRA follows the need for stratigraphic Quaternary correlations across Europe and a concise, informative and easy to use system to share as many information as possible about the most important Quaternary sites. Across Europe stratigraphical schemes were developed in the past using complex litho-, chrono-, and bio-stratigraphical criteria due to the fragmentary nature of the records and to the problems related to reliable dating techniques covering the full range of Quaternary time. The terminology used for defining the chronostratigraphical setting is often based on local or old-fashioned schemes and the need for a common language/terminology/methodology is strongly necessary in order to share among European Quaternary scientists basic geoscientific information. The main goal of SEQS-DATESTRA is therefore to create a Database that summarize the litho-, bio-, pedo-, morpho and chrono-stratigraphical data from the main Quaternary sites of Europe and therefore provide a tool for cross-border correlations of the main Quaternary subdivisions, combining existing knowledge and expertise of regional specialists. The main outcome is a shared Database available to all the Quaternary audience on open GIS based Web platforms to give to the wider audience as possible, also at informative level, the chance to have an overview of the European Terrestrial Quaternary setting. The Database principles are that it must be: a) concise, containing very basic information as starting point for further refined search; b) easy to compile, allowing with few and clear rules its compilation from people with different scientific backgrounds; c) easy to query, this is the crucial point for consultation and correlation across Europe. The Database should serve to the end-user as a starting point for further and more detailed information. At first, DATESTRA should contain only key sites, such as historically known sites or the better stratigraphically significant and constrained sites from every country of Europe. The structure of the Database is therefore conceived considering these objectives. Each point (site) holds values of domains that provide the knowledge applicable to the Database and each site has a number of attributes (and related domains) and each attribute has a limited number of values, in order to make the Database as simpler as possible.

Signatures of the pre-Eemian interglacial in northern Russia

Valery Astakhov^{1,2}, Ludmila Semenova¹

¹A.P. Karpinsky Russian Geological Research Institute, St. Petersburg, Russian Federation. ²St. Petersburg State University, St. Petersburg, Russian Federation

Abstract

This issue has been discussed since 1940-s when two different marine formations were described in the subtil position. In the 1960-s geologists firmly believed in two interglacial invasions of Atlantic saline water into the Russian Arctic. The first such transgression named Kazantsevo and related to the late Quaternary by V. Sachs imported boreal fauna including extinct *Cyrtodaria jenseae*=*C. angusta* as far east as the Taimyr Peninsula. Later investigators related *Cyrtodaria* strata to much older events and therefore adopted for the late Quaternary only one interglacial transgression correlated with the Eemian (Larsen et al., 2006). However, in the thickest Quaternary of West Siberia and the Pechora Basin *Cyrtodaria* strata are separated from the uppermost boreal marine formation only by one glacial complex. This complex, covered by Eemian sediments and commonly related to the final Middle Pleistocene, extends far beyond the limit of the last Early Weichselian ice sheet (Svendsen et al., 2004).

The late middle Pleistocene age of the marine formation with *Cyrtodaria* shells and arboreal pollen commonly inferred from its second from the surface stratigraphic position has lately been confirmed by ESR ages from 200 to 290 ka. The dates are obtained in VSEGEI on a *Cyrtodaria* sequence on river Yangarei in present tundra, 68°44'N. The sequence is overlain by marine sands with OSL dates 115 and 122 ka.

The warm marine incursion of the late Middle Pleistocene into the Arctic seems strange considering the cool interglacial of MIS 7 elsewhere in northern Europe. However, there is independent evidence of very warm conditions provided by peat layers in the Pechora Basin which occur between two thick diamict formations conventionally mapped as youngest Middle Pleistocene tills. The Seyda peat in tundra at 67.5°N has yielded pollen spectra of southern taiga and the age ca 200 by 10 OSL measurements and by uranium-series dating (Astakhov, 2004; Murray et al., 2008). The Rodionovo peat 3.5 m thick yielded U/Th dates ca 250 ka at its stratotype on 65.5°N (Arslanov et al., 2006). These results confirm a MIS 7 age for the penultimate interglaciation identified as `the Rodionovo thermochron` in northeastern European Russia.

The data obtained so far in northern Russia suggests a MIS 7 interglacial at least as warm as the Eemian. If corroborated the described interglacial formations would provide an important stratigraphic landmark for the Eurasian Quaternary.

O-5038

Weichselian ice dynamics in the SW sector of the Baltic Sea

Margot Böse¹, Jacob Hardt¹, Christopher Lüthgens²

¹Freie Universität Berlin, Institute of Geographical Sciences, Berlin, Germany. ²BOKU, University of Natural Resources and Life Sciences, Vienna, Institute of Applied Geology, Vienna, Austria

Abstract

Dating of Weichselian sediments in the south-western sector of the Scandinavian Ice Sheet (SIS) in Sweden, Denmark and Germany, mainly by luminescence dating of glaciofluvial and glaciolacustrine sediments, and cosmogenic nuclide exposure dating of boulders give new insights into the timing of various glacial, glaciofluvial and glaciallimnic processes (Hughes et al., 2016). In Germany, the traditional names of ice advances like Brandenburg, Frankfurt and Pomeranian advance pretend a synchronous formation of ice marginal positions over some distance. The existing data are reviewed and a revised model of Weichselian ice dynamics in the SW sector of the SIS is presented.

During the early MIS3, the lithostratigraphically documented Ellund-Warnow advance marks the first expansion of glaciers during the Weichselian into the SW Baltic Sea area. Related tills were found in western Mecklenburg and in parts of Schleswig-Holstein.

During late MIS 3, the ice attained the maximum extent within the Oder lobe (Brandenburg advance) and reached into Denmark (Klintholm advance) (Hardt et al., 2016). Nevertheless, there is no evidence that Bornholm, the Rønne Bank as well as Rügen were overridden by ice at that time; instead, glaciofluvial and glaciolacustrine sediments were deposited. The area shaped by the maximum ice advance of the Oder lobe, dated to 32-28 ka, is mainly characterized by meltwater sediments and erosional channels, which are in accordance with the assumption of a fast flowing ice of an outlet glacier. Distinct terminal moraines are missing. Thus, various sedimentary environments existed in close neighborhood in the southwestern Baltic Sea basin and the surrounding areas.

The ice advance in correspondence with the global LGM at about 22-20ka, named Pomeranian advance in NE Germany, (Lüthgens & Böse 2011, Lüthgens et al. 2011), was likely characterized by slower moving ice, forming boulder-rich, distinct end moraines in northern Brandenburg, Mecklenburg-Vorpommern and in Schleswig-Holstein. Isochronic ice cover is also documented in the Baltic Sea basin and Denmark.

The configuration and dynamics of the SIS in its southwestern part was therefore very different during the MIS 3 and MIS 2 ice advances, influenced by climatic parameters, and the topography of the Baltic Sea basin and adjacent areas.

Molluscs from the Singil deposits (late Middle Pleistocene) of the Lower Volga region, Russia: a new stratigraphical approach

Guzel Danukalova^{1,2}, Eugenija Osipova¹, Andrey Zastrozhnov³

¹Institute of Geology, Ufa Federal Research Centre Russian Academy of Sciences, Ufa, Russian Federation. ²Kazan Federal University, Kazan, Russian Federation. ³All-Russian Geological Research Institute (VSEGEI), Saint Petersburg, Russian Federation

Abstract

According to the traditional point of view, the Singil deposits were located between the Baku and Khazar Horizons and were correlated with the Likhvin Horizon of the Quaternary Stratigraphical scale of Russia, or with the Holsteinian (MIS 11). The Upper part of the Singil deposits is visible at the basis of the riverside cliffs, and their lower part goes below the level of the Volga River water and can be opened only by boreholes. Researchers usually analyzed only the surface part of the Singil clays.

New core materials indicate the occurrence of the Singil deposits between the Lower and Upper Khazar, which suggests that the Singil is much younger (the end of the Middle Pleistocene, Late Saalian, MIS 7-6) than previously stated. New data changes the history of the Caspian region geological development.

We have studied two mollusc complexes from Singil deposits – from the lower dark gray clay and from the upper yellowish-gray clay. Malacocomplexes of these parts differ from each other.

The first mollusc complex is represented by 2856 shells of bivalves and gastropods from the sediments of Borehole 2 Kosika and six localities in the riverside cliffs – Zaimiszhe, Tsagan-Aman, Vostok, Kosika, Kopanovka, Vladimirovka. In total, 28 taxa, 15 genera, 11 families were identified. Freshwater molluscs include *Lymnaea*, *Bithynia*, *Valvata*, *Lithoglyphus*, *Viviparus*, *Sphaerium* and *Corbicula* genera. Brackish-water molluscs include *Pyrgula*, *Adacna*, *Monodacna* and *Hypanis*, which are able to tolerate significant desalination. Representatives of the genus *Dreissena* could inhabit both fresh and brackish-water bodies. Thus, freshwater species, Caspian gastropods and cardiids were encountered in the complex, which is probably due to the proximity of the seashore. The presence of a *Corbicula* indicates a relatively warm climate. The association of molluscs from the Zaimiszhe locality differs from other by the presence of *Didacna*, which indicates a more seaward conditions of sedimentation.

The second mollusc complex is represented by 574 specimens of bivalves and gastropods from the same localities. In total, 19 taxa, 11 genera, 8 families were identified. The difference in the species composition of this complex from the first molluscs complex is in a smaller number of specimens and species diversity, the presence of few *Didacna* and molluscs living in rivers (*Unio*), which indicates the development of a regressive stage.

The studied material showed that the conditions of the Singil sediments accumulation were not homogeneous – there were freshwater reservoirs with periodic flooding by seawater. Up section, the depletion of the malacological complex indicates the regressive stage of development. Our results were compared with findings on mammals, amphibians, reptiles, palaeocarpological and palynological analyzes. The main conclusion of the research is that the formation of the Singil sediments took place at the final regressive stage of development of the Early Khazar basin

EQUATE – Building a European Quaternary Aminostratigraphic Timescale

Kirsty Penkman¹, Richard Preece², Simon Parfitt^{3,4}, Tom Meijer⁵, Nicole Limondon-Lozouet⁶, Pavel Frolov⁷, Vadim Titov⁸, Alexey Tesakov⁷

¹University of York, York, United Kingdom. ²University of Cambridge, Cambridge, United Kingdom. ³Natural History Museum, London, United Kingdom. ⁴University College London, London, United Kingdom. ⁵Netherlands Centre for Biodiversity, Leiden, Netherlands. ⁶CNRS, Meudon, France. ⁷Geological Institute of the Russian Academy of Sciences, Moscow, Russian Federation. ⁸Southern Scientific Centre RAS, Rostov-on-Don, Russian Federation

Abstract

Timing is everything: accurate dating of the archaeological record is essential to an understanding of the history of the human species, but beyond the limit of radiocarbon dating (~60 ka), sites become more difficult to date. Amino acid geochronology, which uses the time-dependent breakdown of proteins in biominerals, has the potential to date the whole of the Quaternary. Recent analyses of the intra-crystalline fraction of calcitic biominerals (*Bithynia opercula*) has enabled the development of an aminostratigraphic framework for Britain for the Pleistocene. The intra-crystalline protein decomposition (IcPD) within the opercula provides a framework for understanding the regional geological and archaeological record, and has revealed a temporal structure within the British Palaeolithic.

Correlation of Quaternary sequences, even in adjacent regions, can often be problematic, but the development of regional aminostratigraphies promises to provide robust chronologies, enabling more confident correlation. The calcitic opercula of bithyniid (or similar) gastropods occur commonly in many Quaternary sequences, offering potential for development and correlation of regional aminostratigraphies around the world.

Extending the British framework to continental Europe (and beyond) is the next step, and we present the results from analyses of a series of key archaeological and palaeontological sites from across Europe from France to Russia. In order to build the most comprehensive framework possible, we are targeting type localities for interglacial stages, sites with independent geochronology, horizons that can be related to glacial sediments, river terrace sequences, biostratigraphy and archaeology. A critical region for study is the Black Sea, since this region harbours the oldest evidence of human presence in Eurasia and is the type area for the Pleistocene small mammal biozonation applicable across Europe. These dating schemes will shed light on our human story, providing temporal context for episodes of human occupation across Europe, framed within their palaeoenvironments.

Multi-proxy analysis for reconstructing the late Quaternary sedimentary evolution and stratigraphy of a south-Alpine alluvial basin (Venetian Plain, Italy)

Arianna Marcolla¹, Alessandra Asioli², Antonella Miola³, Paolo Mozzi¹, Giovanni Monegato⁴, Cristina Stefani¹

¹Department of Geosciences, University of Padova, Padova, Italy. ²ISMAR-CNR, Bologna, Italy. ³Department of Biology, University of Padova, Padova, Italy. ⁴IGG-CNR, Padova, Italy

Abstract

The research investigates the sedimentary evolution of the Venetian Plain (NE Italy) with a focus on the Middle and lower Upper Pleistocene climatic and environmental changes. This period is still poorly known in the area, due to the few available cores reaching the relative sediments, generally found at a depth higher than 30 meters.

The Venetian Plain constitutes part of the foreland basin of the southern Eastern Alps, the Northern Apennines and the External Dinarides. Its particular position, characterized by the proximity of both the orogenic belts and the Adriatic Sea, has influenced its sedimentary evolution during the glacial-interglacial cycles occurred since the Middle Pleistocene. General aim of the research is to enhance the comprehension of the stratigraphy and prograding mechanisms of the alluvial systems (megafans) of the plain in relation to climatic fluctuations, sea - level change and active tectonics. This will allow to extrapolate the depositional history and the drainage pattern of the plain, to define the paleoenvironmental evolution and to improve the climatic proxy dataset on the southern side of the Alps needed for bio - chronostratigraphic subdivision and correlation with neighboring Mediterranean, north-Alpine and eastern European regions.

We are focusing on a 130 m deep core ("GER1") drilled in Padua, in the distal part of the megafan of the Brenta River, analyzing different environmental and sedimentological proxies and testing stratigraphic and bio - chronological correlation with others deep cores in the area.

Basing on lithofacies assemblages, the presence of paleosoils, and the micropaleontological content, we divided "GER1" into 8 depositional units, mainly constituted by fluvial sediments but with evidence of marine intercalations. In one of these units we find foraminifera such as *Ammonia beccarii tepida* and *Elphidium granosum* suggesting a shallow-marginal marine environment during an interglacial phase. Sediment provenance analysis (gross composition of both sand and gravel levels and transparent heavy mineral associations) allows us to distinguish the different supply of fluvial sediments in the area (Brenta, Adige, Bacchiglione and Piave rivers) and to infer the variation in the drainage pattern during the Middle - Upper Pleistocene.

Fundamental environmental and biostratigraphic information derive from pollen and NPP analysis, in particular for sediments older than the radiocarbon dating limit.

Along the core we identified two principal components of tree pollen types: a group of broadleaf taxa including *Quercus robur – pubescens* type and a group of conifers (*Pinus* undiff., *Larix*, *Juniperus*) with *Betula*. In the deeper part of the core we find ancient taxa such as *Zelkova*, *Buxus*, *Carya* and *Keteleeria/Abies* in association with temperate forest types. Thanks to the finding of the last two, we can hypothesize the MIS correspondence of the proximal marine unit and suppose that we are in an ecological refuge area.

Late Wolstonian Substage (c. MIS 6) glaciation in the British Isles

Sebastian M. Gibson^{1,2}, Philip L. Gibbard^{1,3}, Mark D. Bateman⁴, Julian B. Murton⁵, Steven Pawley⁶

¹Cambridge Quaternary, Department of Geography, University of Cambridge, Cambridge, United Kingdom. ²Climate and Environmental Dynamics Group, Department of Geography, University of Cambridge, Cambridge, United Kingdom. ³Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom. ⁴Department of Geography, University of Sheffield, Sheffield, United Kingdom. ⁵Permafrost Laboratory, Department of Geography, University of Sussex, Brighton, United Kingdom. ⁶Alberta Geological Survey, Government of Alberta, Edmonton, Canada

Abstract

Glaciation during Marine Isotope Stage (MIS) 6 is widely recognised around the world, with significant ice extension across continental Europe during the Saalian Stage (c. MIS 10–6). In the British Isles, understanding of the age and extent of the equivalent glaciation has been debated. The Wolstonian Stage (c. MIS 10–6) stratotype is based on a series of glacial sediments exposed at Wolston, West Midlands. Here direct evidence that the glacial sediments are underlain or overlain by Hoxnian (c. MIS 11) or Ipswichian (c. MIS 5e) interglacial stage sediments is limited. This age is further complicated since these sediments overlie fluvial deposits (Baginton-Lillington Formation Gravel) that have been attributed by some researchers to deposition in the headwaters of a pre-Anglian Stage (c. MIS 16–14) ‘Bytham River’. This attribution is based on the suggested correlation of similar lithological characteristics of the Baginton-Lillington Gravel to the Bytham Gravel in the East Midlands, and the Ingham Formation Gravels, in East Anglia, both of which are thought to be overlain by Anglian Stage (c. MIS 12) glacial sediments. Research presented here challenges this interpretation of the age the Midlands glacial sequence, since younger Middle Pleistocene glacial sequences occur in both the English Midlands and East Anglia. Glaciofluvial sediments associated with the ‘younger’ advance of the lowland late Middle Pleistocene glaciation have been sampled for optically-stimulated luminescence (OSL) and post-infra-red stimulated luminescence (pIRSL) dating. The ages obtained demonstrate that glacial ice advanced into the West Midlands as far as Moreton-in-Marsh at c.180 ka, within the Late Wolstonian Substage (correlated to MIS 6 globally). Additional work in East Anglia confirms significant glacial advance during c.170 ka at Tottenhill. Moreover, important Hoxnian Stage interglacial sequences in the West Midlands are overlain by deposits of this younger glaciation, the latter being directly correlated to that of the Wolstonian Stage sequence in the type area. These findings unequivocally date the MIS 6 ice limit for the British Isles to the Late Wolstonian Substage, allowing correlation with the equivalent Late Saalian Substage across continental Europe.

Glacial landsystems and their applications: retrospect and prospect

David Evans

Durham University, Durham, United Kingdom

Abstract

Glacial landsystems are holistic evaluations of sediment–landform associations and their genetic relationships to the processes involved in terrain development. As such they are encoded with a wealth of information on former glaciation style as dictated by physiography and ice dynamics and hence can facilitate a preliminary prediction of expected subsurface conditions using depositional surface morphology and the wider landscape setting. Since their introduction to engineering geology in the 1970s, glacial landsystems have become more sophisticated and bespoke to a wider range of glaciated terrain types. Moreover, the compilation of modern landsystem exemplars has ensured the development of an increasingly firm foundation in the understanding of process-form regimes in glacial systems. In particular, the landform-sediment assemblages that are evolving rapidly in recently deglaciated terrains provide invaluable modern analogues for paleoglaciological reconstruction. Consequently we have become more adept at deciphering the highly variable depositional record of former glaciers, ice caps, and ice fields in terms of the interrelationships between glacier type, thermal regime, climate, and topography, but because the thermal regime plays a critical role in the entrainment, transport, and final deposition of glacial debris, it is emphasized here in terms of its controls over landform and sediment genesis. The role of the basal thermal regime in the formation of moraines and subglacial tills is presented as a spatial and temporal continuum in a conceptual process-form model, which identifies active temperate and cold polythermal glacier snouts as end members and a range of polythermal scenarios inbetween. The spatial and temporal continuums inherent within this model help us to recognise and acknowledge superimposition and change in glacial landsystem evolution and signatures. A range of examples are used to demonstrate spatio-temporal change in glacial landsystems, in both modern and ancient contexts, emphasizing the role of thermal regime variability. As this variability is driven by the climate of the environment in which a glacier snout is located, we can begin to develop greater confidence in employing glacial geomorphology (i.e. landsystem imprints) as archives of temporal climate change.

O-5044

Periglacial landsystems: retrospect and prospect

Julian Murton

University of Sussex, Brighton, United Kingdom

Abstract

Periglacial landsystems provide a conceptual framework to interpret the imprint of periglacial processes on the landscape, and to predict the engineering properties of the ground. In the UK, landsystems have been distinguished according to topography, relief and the presence or absence of a sediment mantle. Four landsystems characterise both lowland and upland periglacial terrains in the UK: *plateau* landsystems, *sediment-mantled hillslope* landsystems, *rock slope* landsystems, and *slope-foot* landsystems. Two additional landsystems are also identified in lowland terrains, where thick sequences of periglacial deposits are common: *valley* landsystems and *buried* landsystems. Finally, submerged landsystems, which may contain more than one of the above, exist on the continental shelf offshore of Great Britain. Individual landsystems contain a rich variety of periglacial and permafrost landforms, sediments and sedimentary structures. Key periglacial lowland landsystems are summarised using ground models for limestone plateau-clay-vale terrain and caprock-mudstone valley terrain, and upland periglacial landsystems are synthesised through ground models of relict and active periglacial landforms, supplemented by maps of upland periglacial features developed on bedrock of different lithology. The landsystem concept can be extended to modern permafrost and periglacial regions. An example is presented of thermokarst landsystems in regions of ice-rich permafrost in Canada, Siberia and Alaska.

Quaternary Geological Ground Models for the Reduction of Engineering Risk

David Giles¹, David Evans², Julian Murton³

¹University of Portsmouth, Portsmouth, United Kingdom. ²Durham University, Durham, United Kingdom. ³University of Sussex, Brighton, United Kingdom

Abstract

The geology of the Quaternary Period is often under-appreciated in construction yet its legacy is highly significant for ground engineering. All ground projects will encounter relict Quaternary terrains, deposits and landforms and their correct identification and interpretation is key to the success of any such engineering projects. The development of Quaternary ground models will help to communicate and understand the vertical and lateral variability of these environments, defining geological hazards that may be present and understanding the risks that they potentially pose.

This presentation will highlight the report developed by the Geological Society of London Engineering Group Working Party on the Engineering Geology and Geomorphology of Glaciated and Periglaciated Terrains within a UK context. Case study examples will be presented to illustrate the hazards potentially encountered in these terrains and the diagnostic characteristics that the geoscientist should be aware of during the site investigation process in order to manage the uncertainty presented by these highly variable ground conditions. The tools and building blocks necessary for the development of Conceptual Ground Models will be addressed.

O-5046

A Landsystems Approach to Glacier-Permafrost Interactions

Richard Waller

Keele University, Stoke on Trent, United Kingdom

Abstract

Whilst glaciers and permafrost comprise the two key components of the global cryosphere, the nature, extent and wider implications of glacier-permafrost interactions have until recently received surprisingly little attention. Traditional views have assumed that such interactions are spatially restricted and that where they do occur, the cold-based and polythermal glaciers underlain by permafrost are slow moving, geomorphologically inactive and therefore of limited research interest. Recent research in both modern and ancient glacial environments has however challenged these traditional conceptions and illustrated the ability of glaciers and permafrost to actively couple and interact over larger areas and over longer timescales than previously assumed. These interactions have in turn been associated with the operation of distinctive basal and ice-marginal processes and geomorphic impacts that are diverse, complex and commonly very different to those typically associated with glaciers and ice sheets.

The adoption and utilisation of the landsystems concept by glacial geomorphologists has promoted the development of increasingly robust genetic associations between glacial processes and forms that have revealed both the diversity of glacial landsystems and the glaciological and environmental controls responsible for their formation. Previous research examining the diverse landsystems associated with Pleistocene Ice Sheets in North America, Europe and Siberia has provided an insight into the distinctive landforms and landform assemblages associated with glacier-permafrost interactions. In addition to preserving pre-glacial features, the influence of subglacial and ice-marginal permafrost has for example been attributed to the formation of thrust-block moraines and extensive tracts of hummocky moraine. It has also been connected to the development of extensive lateral meltwater channels that are commonly used to reconstruct the retreat behaviour of cold ice in high latitude settings (figure 1).

This presentation will address recent developments in landsystems research concerning the diagnostic signatures and wider implications of glacier-permafrost interactions in both ancient and modern landsystem settings. In addition to considering the remarkable ability of cold-based glaciers to preserve pre-existing land surfaces, the presentation will consider the operation of distinctive processes such as bedrock fracture, debris entrainment and the detachment of bedrock rafts and well as the associated landsystem products. It will also highlight the role of permafrost in preserving buried ice and delaying specific processes of paraglacial adjustment in polar environments. Finally, the potential implications for engineering projects in landsystems affected by glacier-permafrost interactions will also be considered.

Figure 1: Ice margin and foreland of Fountain Glacier, Bylot Island. This illustrates the boulder-dominated surfaces, incised lateral meltwater channels and large proglacial icing commonly associated with polythermal glaciers terminating in areas of continuous permafrost.

Significance of glacial landsystems and process-form regimes in permafrost terrain: the Smoking Hills region of northwestern Arctic Canada

Rod Smith¹, David Evans², John Gosse³

¹Geological Survey of Canada, Calgary, Canada. ²Durham University, Durham, United Kingdom. ³Dalhousie University, Halifax, Canada

Abstract

In northern Canada, considerations of natural resource potential include not simply identification of a resource itself, but also an understanding of aspects of engineering geology of surficial and shallow bedrock materials within formerly glaciated terrain, particularly in areas of ice-rich permafrost. Hence, understanding the landscape is not simply a surficial geology mapping exercise, but more an integrated consideration of the evolution of the landsystem and the inherent process-form regimes. As part of the Geological Survey of Canada's GEM2 research program, this study examined the Smoking Hills region of northwestern Arctic Canada (~69°N; 127°W). While parts of this area were previously reported as unglaciated during the last (Late Wisconsinan) glaciation, new glaciological models and field studies argue that the entire region was glaciated, and that the study area was situated south of the westward-flowing Amundsen Gulf Ice Stream. A unique older glacial stratigraphy (3-5 separate glaciations) is preserved in the region, for which an improved chronology based on cosmogenic nuclide burial dating and a stratigraphic reinterpretation is being undertaken.

Regionally exposed bedrock and complex Quaternary stratigraphies located in incised valleys document a range of past glacial processes, and in particular extensive glaciotectonic deformation and entrainment of poor to weakly-consolidated Cretaceous sedimentary bedrock. Glaciotectonic features include deformed intraclasts of coherent bedrock ranging from thin (<1 cm) stringers and blocks to large metre-scale boudins, cohesive bedrock rafts (metres to 10s of metres thick) and acute to overturned fold structures ≤100 m in vertical height. Extensive preglacial bedrock slumping along valleys likely contributed much of the entrained bedrock material, however, sections of deformed bedrock in valley walls also clearly demonstrate regional-scale, thin-skinned glaciotectonic deformation. Southward directed, arcuate, *en echelon* ridges on either side of the Horton River valley in an area of thin (0-2 m), discontinuous till cover expose massive ice and ice-rich debris that is interpreted as glacial thrusting of proglacial sediments, possibly buried glacial ice, and underlying bedrock. Elsewhere thick (up to 12 m) layers of buried glacial ice in valley bottoms suggests the potential for long-term preservation and re-incorporation by subsequent glaciations. The ice-thrust ridges are amongst the only regional-scale surface landforms recognized in the area (i.e. no extensive fluting or drumlin fields), suggesting that while the presence of patchy till cover indicates warm-based conditions, the thin-skinned tectonics and buried glacier ice, reflect localised basal freeze-on. Thicker tills within the complex stratigraphies of the buried valleys yield clast macrofabrics indicative of long term ice flow from the east or northeast. The evolution of this landsystem signature likely requires transitory changes in glacier basal thermal regimes possibly in association with advance and retreat of the adjacent westward-flowing Amundsen Gulf Ice Stream.

Intensification of thaw slump activity in the Keele and Redstone River watersheds, Northwest Territories, Canada

Joseph Young¹, Benjamin Stoker², Alajandro Alvarez¹, Casey Buchanan¹, Martin Margold², Duane Froese¹

¹University of Alberta, Edmonton, Canada. ²Charles Universtiy, Prague, Czech Republic

Abstract

Retrogressive thaw slumps are a dynamic climate-driven geomorphic process in ice-rich terrains that can rapidly degrade thick accumulations of permafrost into surrounding aquatic systems. We identify over 200 prominent thaw slumps largely absent from earlier inventories in the Keele and Redstone River watersheds (~ 5000 km²) west of the Mackenzie River in the western Northwest Territories, Canada. These slumps represent the southernmost concentration of widespread thermokarst disturbance in the western Canadian subarctic. High-resolution satellite imagery (2002-present) and air photography (pre-2002) show the majority of these features have initiated in the last 10-15 years. Increases in disturbance size and growth rate are consistent with regional increases in temperature and rainfall. The headwalls of several thaw slumps that we visited consist of diamicts from the late Wisconsinan Laurentide Ice Sheet that include massive, and sometimes deformed ice at their base. The largest retrogressive thaw slump documented could be termed a 'mega-slump' with a headwall height of > 35 m and total disturbance area of ~ 25 ha, displacing large amounts of thawed sediment into the river below. A thick (~ 5 m) massive to glaciotectonized ice lens at the base of this slump is driving the degradation upslope, similar to mega-slumps documented in the Peele Plateau further north. Using remotely sensed mapping techniques, in conjunction with field and lab-based permafrost characterization, we aim to provide a basis for evaluating climate-driven trajectories of ice-rich terrain in northwestern Canada.

O-5049

Using boreholes to identify and classify buried palaeovalleys in Scotland

Tim Kearsey, Jonathan Lee, Andrew Finlayson
British Geological Survey, Edinburgh, United Kingdom

Abstract

Buried palaeo-valleys have significant (and often unexpected) implications for groundwater, hydrocarbon and geothermal resources and may provide detailed archives of palaeoenvironmental and landscape change.

They have been identified widely beneath lowland parts of the UK including eastern England, central England, south Wales and the North Sea. Although it is unclear whether the features onshore were created by: (i) subaerial fluvial incision; (ii) glacial erosion forming over-deepened U-shaped valleys, which can then become partly submerged and filled by younger sediment; or (iii) incision of tunnel valleys (or tunnel channels) by subglacial meltwater beneath glaciers and ice sheets.

In the Midland Valley of Scotland palaeo-valleys have been identified yet the age and genesis of these enigmatic features remain poorly understood. This study utilized a digital data set of over 100 000 boreholes that penetrate the full thickness of Quaternary deposits in the Midland Valley of Scotland. It identified 18 buried palaeo-valleys, which range from 4 to 36 km in length and 24 to 162 m in depth.

Geometric analysis using the borehole dataset has revealed four distinct valley morphologies, which were formed by different subglacial and subaerial processes. Some palaeo-valleys cross-cut each other with the deepest features aligning east–west. These east–west features align with the reconstructed ice-flow direction under maximum ice sheet conditions. The shallower features appear more aligned to ice-flow direction during ice-sheet retreat, and were therefore probably incised under more restricted ice-sheet configurations.

The bedrock lithology influences and enhances the position and depth of palaeo-valleys in this lowland glacial terrain. Faults have juxtaposed Palaeozoic sedimentary and igneous rocks and the deepest palaeo-valleys occur immediately down-ice of knick-points in the more resistant igneous bedrock. The features are regularly reused and the fills are dominated by glaciofluvial and glaciomarine deposits. This suggests that the majority of infilling of the features happened during deglaciation and was unrelated to the processes that cut them.

O-5050

Temperature effects on carbon isotope composition in plants and soil and their relevance to paleoclimate reconstruction

Guoan Wang¹, Jia Wang¹, Jiazhu Li²

¹China Agricultural University, Beijing, China. ²Institute of Desertification Studies, Chinese Academy of Forestry, Beijing, China

Abstract

Understanding of the relations between climatic factors and carbon isotope composition ($\delta^{13}\text{C}$) in modern plants and soil is the premise of applying the $\delta^{13}\text{C}$ derived from sediments to paleoclimate reconstruction. Temperature and precipitation are two of the most important climatic indicators that palaeoclimatologists pay close attention to, and they are also two of the most important influencing factors of $\delta^{13}\text{C}$ in plants and soil. With respect to the precipitation effects, one consistent conclusion has been obtained. However, the temperature effects remain unresolved due to the interaction between temperature and precipitation. To evaluate the temperature influences on $\delta^{13}\text{C}$ in plants and soil more effectively, we sampled a large number of plants and soil across a temperature gradient along 400 mm isoline in China to minimize the effect of precipitation changes on $\delta^{13}\text{C}$. We measured the carbon isotope composition of bulk leaf tissues ($\delta^{13}\text{C}_{\text{bulk}}$) and soil total organic matter ($\delta^{13}\text{C}_{\text{som}}$). Considering that sediments contain organic matter from a variety of sources, such as plant sources, microbial sources and so on, to further facilitate paleotemperature reconstruction, we also evaluate the effects of temperature on leaf wax n-alkane traits and carbon isotope composition. This study shows that $\delta^{13}\text{C}_{\text{bulk}}$ of C3 plants increases with temperature with a slope of $0.11\text{‰}/^{\circ}\text{C}$ ($R^2 = 0.35$, $p < 0.001$) whereas C4 plants have no change in $\delta^{13}\text{C}_{\text{bulk}}$ across the temperature gradient. Leaf wax n-alkanes distribute from n-C₂₁ to n-C₃₅ with n-C₃₁, n-C₂₉ and n-27 as their dominant components. Total n-alkane concentration (Σalk) decreases whereas average chain length (ACL) increases temperature, especially for summer temperature. For the common plants grown along the gradient, *Artemisia* species, consisting of three species, *A. argyi*, *A. capillaris* and *A. scoparia*, $\delta^{13}\text{C}_{29}$, $\delta^{13}\text{C}_{31}$ and $\delta^{13}\text{C}_{27}$ are very similar in each species. There are positive relations between $\delta^{13}\text{C}_{\text{bulk}}$ and $\delta^{13}\text{C}_{29}$, $\delta^{13}\text{C}_{31}$ and $\delta^{13}\text{C}_{27}$ for each plants. Increasing trends in both $\delta^{13}\text{C}_{\text{bulk}}$ and $\delta^{13}\text{C}_{29}$ are found with temperature. However, correlation of $\delta^{13}\text{C}_{\text{bulk}}$ with temperature ($R^2 = 0.18$) is much weaker than that of $\delta^{13}\text{C}_{29}$ with temperature ($R^2 = 0.6$) for the pooled *Artemisia* species. This suggests that $\delta^{13}\text{C}_{29}$ is a better proxy of paleotemperature than $\delta^{13}\text{C}_{\text{bulk}}$. In addition, this study also observes that there is no relationship between $\delta^{13}\text{C}_{\text{som}}$ and temperature. One of the main reasons for this observed pattern is that soil contains other sources of organic matter in addition to terrestrial high plant sources. Therefore, $\delta^{13}\text{C}$ of total organic matter in sediments does not appear to be used for paleotemperature reconstruction. The future work should address the impact of temperature on carbon isotope composition of n-alkanes with long-chain in soil organic matter.

Physical processes of cooling and megadrought in 4.2 ka BP event: results from TraCE-21ka simulations

Mi Yan, Jian Liu
Nanjing Normal University, Nanjing, China

Abstract

It is widely believed that multidecadal to centennial cooling and drought occurred from 4500 BP to 3900 BP, known as the 4.2 ka BP event that triggered the collapse of several cultures. However, whether this event is a global event or a regional event and what causes this event along with the physical processes remain unclear due to the limitations of the previous reconstruction and simulation works. In this study, we investigated the spatiotemporal characteristics, the possible causes and the related physical processes of the event using a set of long-term climate simulations, including one all-forcing experiment and four single-forcing experiments. The results derived from the all-forcing experiment show that the cool and dry conditions related in this event occur over most parts of the Northern Hemisphere (NH), indicating that this event could have been a hemispheric event. The Southern Hemisphere (SH) experiences relatively warmer and wetter conditions. The simulated megadrought over the Mediterranean, Oman, inner North America and the wet South America are consistent with the reconstructions. The wetter SH indicates southward shift of the Intertropical Convergence Zone (ITCZ), which is also consistent with the reconstructions. The cooler NH and warmer SH illustrate that this event could be related to the slowdown of the Atlantic Meridional Overturning Circulation (AMOC). The comparison between the all-forcing experiment and the single-forcing experiments indicates that this event might be caused by the internal variability, while external forcings such as the orbital and greenhouse gases might have modulation effects. A positive North Atlantic Oscillation (NAO)-like pattern in the atmosphere (low troposphere) triggers a negative Atlantic Multidecadal Oscillation (AMO)-like pattern in the ocean, which then triggers a Circumglobal Teleconnection (CGT)-like wave train pattern in the atmosphere (high troposphere). The positive NAO-like pattern and the CGT-like pattern are the direct physical processes that lead to the NH cooling and megadrought. The AMO-like pattern plays a “bridge” role in maintaining this barotropic structure in the atmosphere at a multidecadal-centennial time scale. Our work provides a global image and dynamic background of the event. Whereas more model-data and inter-model comparisons are required to better understand the 4.2 ka BP event.

South Pacific Subtropical High since the late Holocene to the end of 21st century

Valentina Flores-Aqueveque^{1,2}, Maisa Rojas^{3,2}, Charles González^{1,2}, Catalina Aguirre⁴

¹Departamento de Geología, FCFM, Universidad de Chile, Santiago, Chile. ²Millennium Nuclei for Paleoclimate, Santiago, Chile. ³Departamento de Geofísica, FCFM, Universidad de Chile, Santiago, Chile. ⁴Escuela de Ingeniería Civil Oceánica, Facultad de Ingeniería, Universidad de Valparaíso, Valparaíso, Chile

Abstract

The South Pacific Subtropical High (SPSH) is a predominant feature of South American climate. It influences the rainfall intensity, the alongshore (meridional) wind strength and the upwelling events over most of the southwestern margin of South America (SA). In recent decades a strengthening and expansion of the SPSH have been observed leading an intensification of southerly winds along the coast of northern to central Chile and a decrease in precipitation from central to southern Chile. These changes have been recorded during the last centuries by several paleoclimate records of southern South America.

In order to broaden our understanding about the regional impacts of global warming in this part of Southern Hemisphere, we analyze the behavior of the SPSH during the late Holocene, particularly for the Current Warm Period (CWP; 1970-2005), by quantitatively comparing information from four CMIP5/PMIP3 simulation models for the historical period and reanalysis data. This information was contrasted with different paleoclimate records of the region to assess the level of agreement between simulation and climate proxies. Finally, we analyze the SPSH anthropogenically forced climate response for the 21st century under RCP8.5 scenario to evaluate the SPSH possible future behavior.

Our results indicate that climate model results are very consistent with most of climate records for the late Holocene. On the other hand, climate projections show that the strengthening and expansion trend observed during the late Holocene will continue throughout the 21st century, highlighting the need to establish adequate mitigation strategies to prevent its impacts.

Hydrologic and isotopic modelling of lakes: towards a mechanistic understanding of proxy data.

Martin Ankor, Jonathan Tyler
University of Adelaide, Adelaide, Australia

Abstract

Lakes sediments are an excellent source of terrestrial hydroclimate records, particularly via reconstructions of lake depth, lake water salinity and the stable oxygen isotope composition of palaeo-lake waters. However, lakes are complex systems, and the hydrological and geochemical response of lakes to climate is often non-linear, multifactorial and variable between sites. This complexity limits attempts to translate lake sediment records into quantifiable climate estimates, such as the amount of regional precipitation or evaporation. Coupled hydrologic-isotopic models - a type of 'proxy system model' - provide one means of addressing this complexity to constrain the interpretation of palaeoclimate proxies. Furthermore, such models facilitate a deeper understanding of the interaction between lakes, meteorology, and catchment/subsurface hydrology with value for addressing how lake ecosystems behave under past and future climate regimes.

A general lake model – CHIMBLE – coupling lake hydrology, groundwater, stratification (energy balance), isotopes, water chemistry and meteorology is being developed to try and resolve these challenges. CHIMBLE has been applied to the maar lakes Bullen Merri and Gnotuk in the Newer Volcanic Province (Victoria). These lakes (and 10 other lakes across the Newer Volcanic Province) have been monitored for the last 3 years for depth, chemistry and stable isotopes. Modelling and monitoring results demonstrate that for many lakes a simple lake model is insufficient and that there is a requirement to couple the lake hydrology to the surrounding catchment and subsurface flows.

An assesment of the spatial coherence of drought reconstructions through regional paleoclimatic simulations

Juan Pedro Montáñez¹, Salvador Gil-Guirado², Juan José Gómez-Navarro¹

¹Universidad de Murcia, Murcia, Spain. ²Universidad de Alicante, Alicante, Spain

Abstract

Climate reconstructions from proxy data are fundamental to better understand climate variability at long time scales. However these reconstructions are subjected to an important uncertainty.

In the case of reconstructions from historical archives, the noise caused by non-climate causes (epidemics, plagues, wars, speculation, etc.) produces drawbacks to establish unambiguous relationships, and therefore the different temporal evolutions obtained should be understood under the uncertainties associated.

In this work we present a description of the spatiotemporal patterns of droughts in the Mediterranean basin of the Iberian Peninsula by using monthly series of droughts covering the last four centuries. Correlations among the reconstructed series from historical archives show some temporal correlation that in most cases (not always) depends on the distance between the locations.

On the other hand, Regional paleoclimate numerical experiments can serve to evaluate the procedures for reconstructing series as well as the physical consistency of a set of reconstructions. In this work we use a set of runs performed with a Regional Climate Model with a spatial resolution of 30km over the Iberian Peninsula for the last millennium.

We analyse the spatial coherence between the reconstructed droughts by using the pseudo reality of the model. This permits us to impose an upper limit of the coherence/correlation that could be found in the reconstructed series. In addition, the stationarity of the relations between the different areas is also investigated. We found that spatial patterns slightly change along the studied period. Finally the relationship between the intensity of the dry episode and its spatial extension is analyzed. We obtain that high intensities are related with large extensions. although it appears some interesting exceptions.

Towards high-resolution climate reconstruction using an off-line data assimilation method and the COSMO-CLM Regional Climate Model

Emmanuele Russo^{1,2}, Bijan Fallah³

¹University of Bern, Bern, Switzerland. ²Oeschger Center for Climate Change Research, Bern, Switzerland. ³Freie Universitaet Berlin, Berlin, Germany

Abstract

Data assimilation (DA) methods have been recently used to constrain the paleo-climate model simulations by paleo-proxy records. In this work, we design a computationally affordable offline DA method to assimilate yearly pseudo-observations and real observations into an ensemble of COSMO-CLM high-resolution Regional Climate Model (RCM) simulations. As a testbed for the evaluation of the proposed method we consider the mid-to-late Holocene summer temperature evolution over Europe. This has been the subject of a long-standing debate among different members of the proxy community and between them and climate modelers. The pollen-based summer temperature reconstructions of Mauri et al. 2015 are used for the assimilation. Results suggest that interpretations of european summer temperatures evolution during the mid-to-late Holocene based on single proxy-sources or on climate models are not satisfactory. More efforts should be put in bringing together experts of different disciplines and the results of their analyses: Data Assimilation could be the way to go.

The role of subglacial meltwater in ice-sheet retreat through Marguerite Bay, Antarctica

Lindsay Prothro¹, John Anderson¹, Wojciech Majewski², Yusuke Yokoyama³

¹Rice University, Houston, USA. ²Institute of Paleobiology, Polish Academy of Sciences, Warsaw, Poland.

³Atmosphere and Ocean Research Institute, University of Tokyo, Kashiwa, Japan

Abstract

Geomorphology of the continental shelf reveals Marguerite Bay was once occupied by an ice stream that was underlain by extensive networks of meltwater channels and basins. This study examines the relationship of meltwater activity with grounding-line retreat since the Last Glacial Maximum as determined from sedimentologic and radiocarbon analysis of sediment cores and modifies previously published reconstructions of ice retreat. Existing geomorphic data suggest an embayment formed during initial retreat from the continental shelf edge, but the timing of initial retreat is not well-constrained. Whereas previous records of grounded ice retreat through Marguerite Bay were based only on minimum ages, we have produced more definitive grounding-line retreat ages by using an updated sediment facies model to guide us in selecting intervals for radiocarbon dating. Grounding line retreat occurred sometime well prior to 14 cal ka BP, with the ice shelf retreating to the middle continental shelf by 13 cal ka BP. The grounding line then continued to form embayments through the deep portions of Marguerite Bay as the grounding line and ice shelf gradually retreated through 11 cal ka BP. Marine radiocarbon ages indicate that by 10 cal ka BP, inner Marguerite Bay was nearly ice-free, corresponding to a 9.6 cal ka BP drawdown of nearby terrestrial ice. Meltwater deposits are found only within the basins of the rugged bedrock and are not found in cores on the shallower outer continental shelf, suggesting sediment was expelled within plumes at high enough velocities or sediment concentrations to prevent plumes from becoming hypopycnal. Meltwater deposition occurred throughout the gradual deglaciation beginning at 13 cal ka BP until just prior to the major 10 cal ka BP ice retreat. Marguerite Bay may be a useful model for estimating the future of the unstable Pine Island/Thwaites Glacier system, which is also underlain by an active hydrological system that produces sediment-laden meltwater plumes today.

Abstract

The main depo-centre in the North Sea, along the Central Graben and Viking Graben contains a rich sedimentary archive approaching, in places, 1000 m thick. Here we present a suite of evidence including detailed mapping from 3D seismic reflection data, borehole logs, chronostratigraphy, sedimentology and iceberg trajectory modelling. These data provide the opportunity to constrain the geometries of ice sheets around, and in, the North Sea Basin from the beginning of the Pleistocene. As early as 2.53 Ma a large marine terminating ice sheet/s repeatedly entered the North Sea basin, south of approximately 60°N, grounded in water depths up to ~250 m. By 1.87 Ma there is evidence for grounded ice across the entire basin, suggesting coalescence between British and Scandinavian ice masses and ice sheet geometries equivalent to those of the Late Pleistocene. Establishing the geometries of the early ice sheets is important for a number of reasons. The marine $d^{18}O$ record is interpreted to show that during full-glacial global ice volumes were less in the Early Pleistocene. Once large enough mid-latitude ice sheets, are known to reconfigure large scale atmospheric circulation, having implications for the interpretation of other environmental proxies. The rapid evolution from fluvial to glacial landscapes, concomitant stripping of regolith and erosion of bedrock have implications for weathering derived CO_2 drawdown and ice sheet dynamics.

Retreat dynamics of marine-based ice sheets: perspectives from diverse glaciated continental margins

Lauren Simkins¹, Sarah Greenwood², Lilja Bjarnadottir³, Monica Winsborrow^{4,5}

¹University of Virginia, Charlottesville, USA. ²Stockholm University, Stockholm, Sweden. ³Geological Survey of Norway, Trondheim, Norway. ⁴Centre for Arctic Gas Hydrate, Environment, and Climate, Tromsø, Norway. ⁵UiT - The Arctic University of Norway, Tromsø, Norway

Abstract

While the grounding lines of marine-based ice sheets are considered to be broadly governed by regional topography, sea level and ice flux, processes occurring at the interface between the ice base and the substrate on which it rests are a key control on ice flow behaviour. The specific and local-scale processes responsible for the style of flow and rate of retreat can be highly variable across diverse marine settings and, therefore, their wider significance remains poorly understood. The exposed beds of palaeo-ice sheets on formerly glaciated continental shelves are an accessible means of studying past marine-based ice flow and ice sheet margin behaviour. We use a large dataset of glacial landforms from a variety of marine-based ice sheets in both hemispheres to systematically characterise the style of ice flow and retreat from its documented landform products. We interpret these glacial modes - encompassing ice flow, thermal regime, and retreat style - within the context of the local landscape type (trough, bank, basin, and fjord) and bed properties (e.g., slope, aspect, substrate geology). This allows us to test whether certain glacial modes and, importantly, variability in glacial modes are prevalent in certain topographic and substrate settings.

At a first order, we find that basins exhibit the most diverse and, therefore, least predictable behaviour. Both troughs and banks house high variability of glacial flow/retreat mode; we do not find that either favours a 'typical' mode of ice flow or retreat. Surprisingly, substrate geology appears to have little influence on the occurrence of ice streams or whether grounding line retreat proceeds steadily or inconsistently. We explore here the degree to which and the scales over which modes of marine-based ice flow and retreat are sensitive to topographic parameters and substrate properties, and whether any such overarching controls manifest as or are modulated by sub-system-scale processes such as meltwater drainage, subglacial sediment flux and landform creation.

By analysing ice sheet dynamics without the confines of a geographically limited dataset, we aim to provide analogues to contemporary marine-based systems and offer hindsight perspective on potential retreat behaviour into the future.

Abstract

The reconstruction of the largest ice stream to drain the British-Irish Ice Sheet at the Last Glacial Maximum (LGM) can provide essential palaeoglacial observations required for constraining numerical ice sheet models. The Irish Sea Ice Stream (ISIS) was long considered to have terminated on the mid-shelf of the Celtic Sea, based on sediment cores and seismic data collected in the 1970s. Here we summarise findings from sediment cores and geophysical data acquired since 2009, and multi-beam bathymetric data acquired since 2001, which permit an updated evolution and palaeoglacial reconstruction of the Irish and UK sectors of the Celtic Sea shelf. In near-shore areas, multi-beam data reveal over 2000 glacial features, including moraine ridges, streamlined bedrock and meltwater channels, recording the southwest advance of the ISIS towards the shelf-edge and its subsequent retreat. The mid- to outer-shelf is characterised by the largest known linear shelf sediment ridges. These vary from long and linear features, the megaridges, in the northwest to sinuous and shorter ridges in the southeast. This ridge field was initially interpreted as tidal in origin, but glacial sediments have been recovered from the flanks of the megaridges. Correlating decimetric-resolution geophysical data to sediment cores, the megaridges comprise three main units. 1) A superficial fining-upward drape above an unconformity, inferred to record decreasing ocean energy during marine transgression. Underlying this drape is 2), the Melville Formation (MFm), which comprises the upper bulk of the megaridges, displaying dipping internal acoustic reflections and consisting of medium to coarse sand and gravel, characteristics that could be consistent with either a tidal or glacial origin. The MFm unconformably overlies 3), the Upper Little Sole Formation (ULSFm), previously proposed to be of late Pliocene to early Pleistocene age, but is here shown to contain glacial sediments dated to the LGM. This stratigraphy constrains the age of the MFm to between 24-14 ka BP, coeval with deglaciation and a modelled period of megatidal conditions during transgression. Stratigraphically and sedimentologically these megaridges could represent glacial features eroded during the post-glacial marine transgression. However, it is argued that they comprise a partially-eroded glacial topography (ULSFm) mantled by post-glacial tidal deposits (MFm), both subsequently eroded by a proposed mechanism of enhanced wave energy during decreasing tidal energy in the later stages of transgression. Regardless of the origin of the ridges, the evidence shows that the ISIS extended to the shelf-edge of the Irish and UK sectors during the LGM.

Retreat of the NE Greenland Ice Stream since the Last Glacial Maximum recorded in marine archives.

S. Louise Callard¹, David Roberts¹, Colm Ó Cofaigh¹, Jerry Lloyd¹, Boris Dorschel²

¹Durham University, Durham, United Kingdom. ²Alfred Wegener Institute, Bremerhaven, Germany

Abstract

The NE Greenland Ice Stream (NEGIS), the largest ice stream draining the Greenland Ice Sheet (GrIS), is stabilised by two floating ice-shelves of 79N and Zachariae Isstrom. Since 2010, Zachariae Isstrom has experienced an accelerated rate of grounding line retreat (~4 km) and significant ice-shelf loss. This suggests that this sector of the GrIS is now responding to changes in oceanic and/or climatic conditions. However, the adjacent 70 km long ice shelf of 79N has shown comparatively little change with some model outputs predicting this ice shelf will remain stable in the future, despite evidence that it previously collapsed during the Holocene Thermal Maximum. To place these observations into a longer-term context a better understanding of the response of NEGIS to past oceanic and temperature change beyond instrumental records is necessary.

The project 'NEGIS', led by Durham University and in collaboration with AWI and the GRIFF project, aims to reconstruct the history of the NEGIS since the Last Glacial Maximum (LGM) to better understand past ice stream response to a warming climate. Here we present results and interpretations from an offshore dataset collected on the RV Polarstern, cruise PS100, in 2016. Gravity cores, up to 11 m long, supplemented by swath bathymetric and sub-bottom profiler data were acquired. Analyses on the cores include x-radiographs, physical properties, foraminiferal fauna, and radiocarbon dating.

Based on the sediment stratigraphy preserved in cores collected across the shelf, a four-stage process relating to ice stream/shelf retreat has been identified. A basal diamicton, that is barren of foraminifera, is interpreted as a subglacial till and is evidence of grounded ice. Laminated clay and silts containing very low abundance of glaciomarine foraminifera and no ice rafted debris (IRD) directly overlie this diamicton. We interpret this sedimentological unit as indicating glaciomarine conditions most likely deposited in a sub-ice shelf environment. On the outer-shelf, the oldest age from this unit is 19.3 ka BP, and on the inner-shelf it is 10 ka BP. Towards the top of this laminated unit foraminifera abundance increases and the species *Cassidulina neoteretis*, an Atlantic water indicator, becomes dominant. The lack of IRD implies this is still a sub-ice shelf setting. A sharp transition to massive mud containing gravel to pebbly sized clast, rich in foraminifera and dominated by *Cassidulina neoteretis*, captures the timing of ice-shelf break up and is constrained to ~15.7 ka BP on the outer-shelf and 7.9 ka BP on the inner-shelf. This data provides the first constraint of grounding line and ice shelf retreat since the LGM across the NE Greenland shelf. Furthermore, the data suggests that Atlantic waters were present prior to ice-shelf break up and therefore oceanic forcing likely played a significant role in ice-shelf instability.

Abstract

Reconstructing the configuration and behaviour of palaeo-ice sheets is an important scientific goal as it provides new insights into how ice sheets respond to both internal and external drivers over a range of time-scales. During the last glaciation, the British-Irish Ice Sheet (BIIS) and the Newfoundland Ice Sheet (NIS) were situated on opposite sides of the Atlantic Ocean but at similar latitudes. Their position on the edge of the continent and the fact that they terminated in a marine environment make them key sites for examining ice sheet-ocean-climate interactions. The glacial history of the southern marine sectors of both ice sheets is still poorly understood. This project will shed new light on the extension and retreat of these ice sheets during the last glacial period, using high-resolution marine geophysical and sedimentary data collected on the SW Irish and southern Newfoundland shelves. Preliminary analysis of multi-beam bathymetric data from both sites show a series of linear to lobate and arcuate submarine ridges in both regions. Based on their geomorphology, these bedforms are provisionally interpreted as moraines in Ireland and fjord-mouth moraines in Newfoundland. They provide clear evidence of grounded ice and an opportunity to date ice sheets retreat across the continental shelves. Thirty-four sediment cores were acquired on and around these features, in both regions. Initial analysis of the cores has been focused on the interpretation of depositional processes. They include a diamicton facies assumed to be a subglacial till based on lithology, fabric and shear vane measurements, and glacio-marine muds displaying laminations and IRD in the X-radiographs. This presentation will include all of the results to date with the aim of testing the character and (a)synchronicity of the (de)glacial history of two ice sheets across the Northern Atlantic Ocean in order to assess the main drivers for ice sheet decay in the Late Quaternary.

Figure 1. Study area SW of Ireland, inshore of the Celtic Sea continental shelf. At the seafloor, ca 100 mbsl, a series of corrugate to linear and arcuate ridges are observed. Nine sediment cores has been collected on and around these glacial moraines.

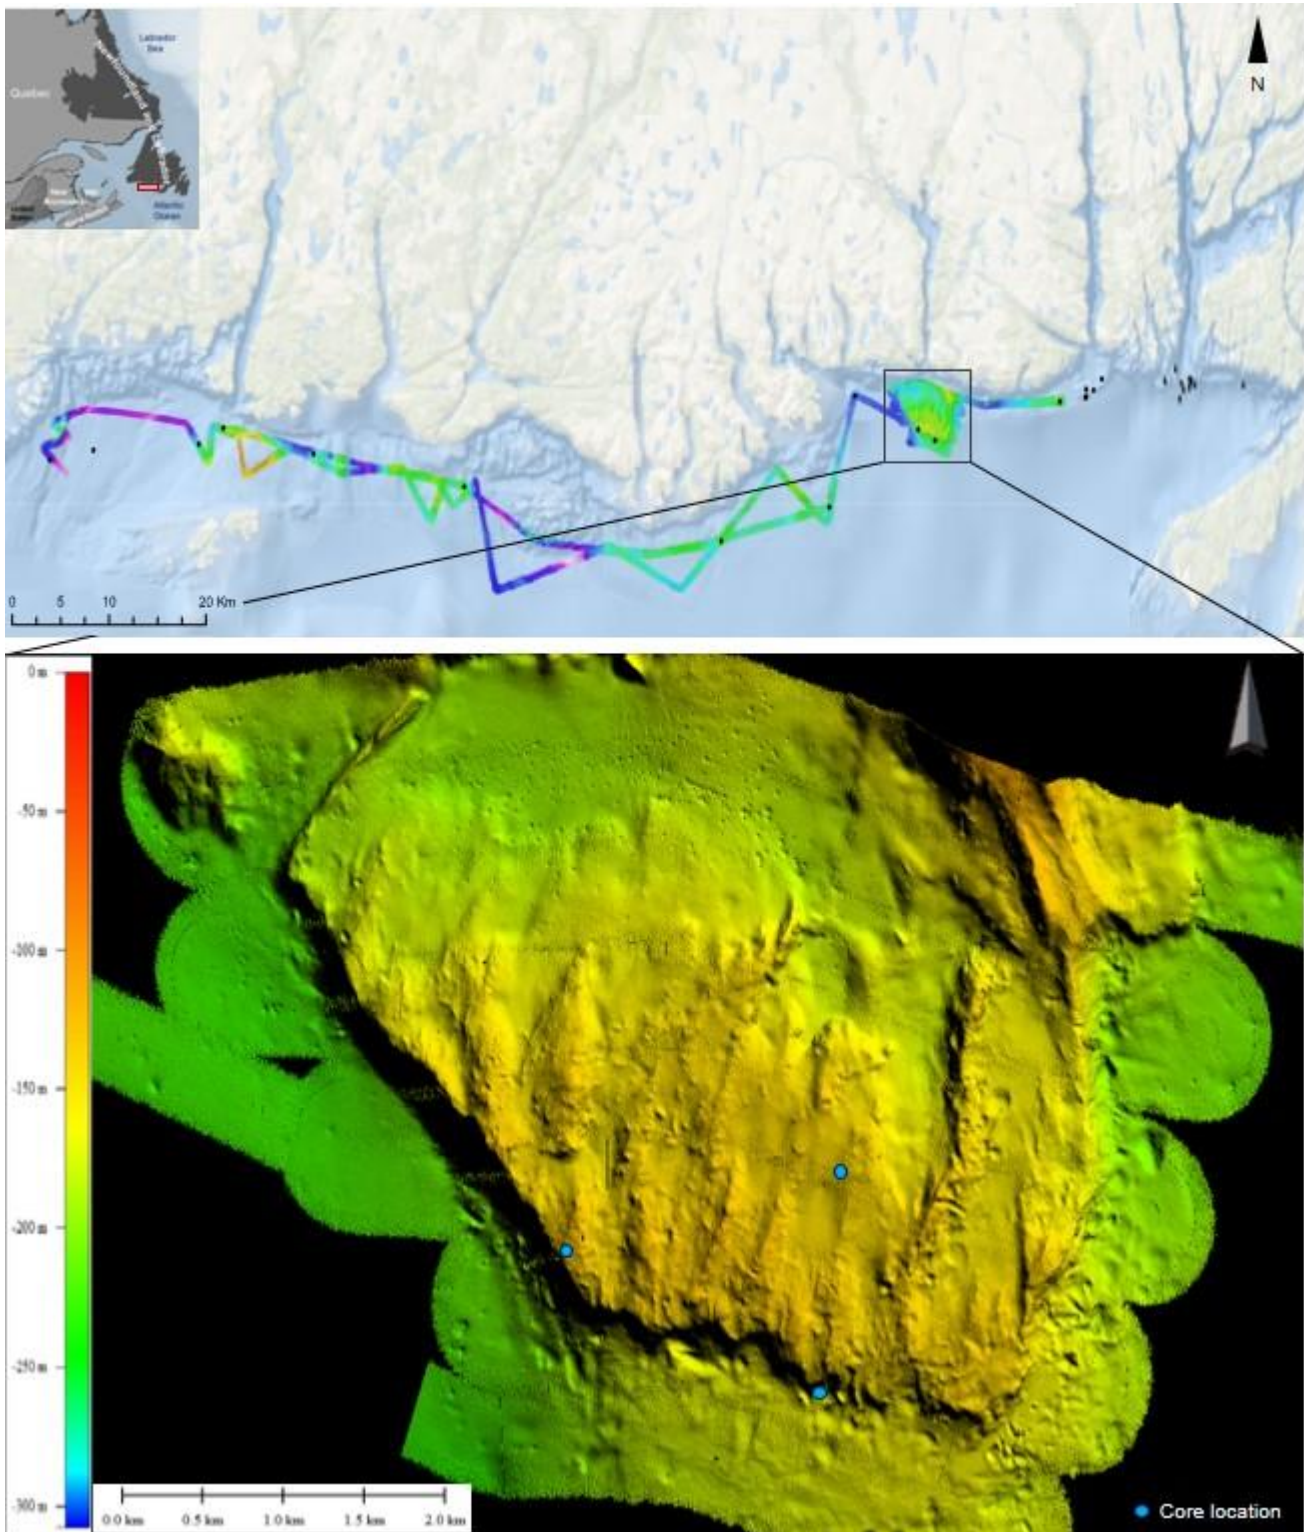

Figure 2. Study area, South of Newfoundland. A series of linear to lobate and arcuate ridges are located at the fjord mouths, thus interpreted as fjord-mouth moraines. Twenty-six cores were acquired in connection with the fjord-systems.

Abstract

Understanding the pace and drivers of marine-based ice sheet retreat relies upon the integration of numerical ice sheet models with observations from contemporary polar ice sheets and well-constrained palaeo-glaciological reconstructions. This presentation reconstructs the retreat of the last British-Irish Ice Sheet (BIIS) from the Atlantic shelf west of Ireland at, and following, the LGM. It utilises marine-geophysical data and sediment cores that are dated by radiocarbon, combined with terrestrial cosmogenic nuclide (TCN) and optically-stimulated luminescence dating of onshore ice-marginal landforms, to reconstruct the timing and rate of ice sheet retreat from the continental shelf and across the adjoining coastline of Ireland. Moraines and grounding-zone wedges on the continental shelf record an extensive, shelf-edge terminating ice sheet west of Ireland at the LGM, and this is supported by the presence of dated subglacial tills in sediment cores from across the Porcupine Bank, a westwards extension of the Irish continental shelf. Dates on benthic glaciomarine foraminifera from deglacial sediments indicate that initial retreat from the shelf edge was underway before 25.9 ka cal BP. However, dated tills in sediment cores from the Porcupine Bank indicate that the ice sheet remained grounded on the outer shelf until c. 24.4 ka cal BP, and thereafter retreated to the mid-shelf where it formed a grounding-zone wedge at c. 23 ka cal BP. Lithofacies and benthic foraminifera indicate that retreat occurred in a glaciomarine environment. Subsequent recession is constrained by TCN dates on erratic boulders on the Aran Islands on the inner shelf. These sites were ice free by c. 19.5 ka BP. TCN dates from coastal sites along the Connemara mainland to the north indicate the ice sheet had become terrestrially based by 17.4-17.1 ka BP. This suggests that the Aran Islands acted to stabilise and slow overall ice sheet retreat once the BIIS margin had reached the inner shelf. Our results constrain the timing of initial retreat of the BIIS from the shelf edge west of Ireland to the period of minimum global eustatic sea level. Early BIIS retreat is consistent with recent offshore studies on BIIS history from further to the north along the Irish margin. Initial retreat offshore of western Ireland was driven, at least in part, by high relative sea level but our retreat chronology implies that this was more likely to have been a product of local glacio-isostatic depression rather than eustatic sea level rise. A picture emerges of a shelf-edge grounded BIIS during the LGM on the Atlantic shelf west of Ireland which contributed to its own demise by glacio-isostatic depression and associated sea level rise.

Where is the Toba eruption in the Vostok ice core? Clues from the O and S isotopes

Joel Savarino¹, Elsa Gautier¹, Emmanuelle Albalat², Francis Albarède², Jean-Robert Petit¹, Volodya Lipenkov³

¹Institut des Géosciences de l'Environnement, Grenoble, France. ²ENS-Lyon, Lyon, France. ³AR, St Petersburg, Russian Federation

Abstract

The ca. 74 ka BP “super-eruption” of Toba volcano in Sumatra is the largest known Quaternary eruption. It expelled an estimated of 2800 km³ of dense rock equivalent, creating a caldera of 100 x 30 km. The eruption is estimated to have been 3500 greater than the Tambora eruption that created the “year without summer” in 1816 in Europe (Oppenheimer, 2002). However, the consequences of this “mega-eruption” on the climate and human evolution that could be expected for such eruption are still debated and uncertain. There is no evidence that this eruption has triggered any catastrophic climate change such as a “nuclear winter”. One of such lack of evidence lies in the ice.

In the ice core community, this eruption still remains a mystery. Indeed, the estimated size of the eruption should have left a gigantic mark in the ice, at least in the form of a huge sulfuric acid layer but none of the ice records covering this period show any such singularity. The sulfate record seems so common that it is in fact difficult to allocate a specific sulfate peak to this event.

In an effort to synchronize the Vostok ice core and the EPICA Dome C core, (Parrenin et al., 2012) have identified three possible sulfuric acid layers for the Toba eruption in the Vostok ice core. In order to see if one of such event could have been the Toba eruption, we have performed the sulfur isotope (and oxygen but still pending at the time of writing) analysis of these three sulfuric acid layers in the hope that it could reveal some particularity. The sulfur results show that 1- all these three events have injected their products in the stratosphere, 2- the sulfur isotopic compositions of these three events share a common array, array that is in lines with other stratospheric eruptions. Well, the mystery remains to why such huge event did not leave any remarkable imprint in the ice unless, as recently been speculated, the Toba eruption did not inject more sulfur in the atmosphere than the Tambora (Yost et al., 2018) or that the eruption was in fact not a single eruption but a series of few, spread over few hundred years.

Human reactions and escaping from an eruptive Santorini (Thera), Greece

Krista Evans, Floyd McCoy

University of Hawaii at Manoa, Honolulu, USA

Abstract

The Late Bronze Age eruption (*ca.* 1650 B.C.) of Thera (Santorini) was one of the largest known in history, burying and destroying a thriving Cycladic culture that occupied the island. The consequent thick tephra sequence provides detailed information on the eruptive sequence and mechanics – it also buried remnants of Cycladic towns and farmsteads, the most prominent being at Akrotiri on the south coast of the island. Here relationships between the tephra stratigraphy and archaeological excavations clearly indicate the eruption was signaled by a major seismic event and a minor eruption. This precursory sequence instigated an evacuation of the island, but a hiatus between the two eruptive events allowed inhabitants to return for pairs of seismic damage...until the first major phase of the eruption instigated rapid and complete evacuation, as documented by the lack of victims found at Akrotiri attributable to the eruption. Yet few archaeological sites on surrounding islands record an influx of Cycladians with Thera-type crafts, the exception being Crete: where did the evacuees go, or did they perish at sea? We propose that the latter is likely 0 that given the slow speeds of rowed/paddled boats characteristic of Bronze Age boats, evacuees were killed at sea while just offshore of Thera by pyroclastic flows and surges crossing the sea surface. That flows can move across the ocean surface is well documented by modern and past eruptions. That some Cycladians successfully arrive on Crete implies these flows issued through newly collapsed rifts that directed flows to the west and north rather than to the south.

Volcanic impacts on the Nile watershed. Historical implications

Joe Manning¹, Francis Ludlow²

¹Yale University, New Haven, USA. ²Trinity College Dublin, Dublin, Ireland

Abstract

We report here on our ongoing collaborative work that seeks to understand the societal impacts of explosive volcanism on the Nile watershed. The key insight from which our project got its start is the observation that explosive volcanic eruptions can be linked (“teleconnected”) to the reduction in global precipitation. This is particularly dramatic in the case of the African monsoon that drove the annual flood of the Nile. By exploring the many new techniques that integrate climate proxy with historical data to understand a new dimension of historical dynamics, our aim is to establish a new historical ontology for pre-industrial Egypt by describing, for the first time, a detailed example of a coupled natural-human system. This also has wider implications for the entire pre-industrial world. We will provide a few examples from our working this presentation focusing on the second century BCE.

Volcanic Pairs and Climate Modulations of the Last Millennium

Allegra LeGrande

NASA GISS, New York, USA. CCSR, Columbia Univ., New York, USA

Abstract

Paired volcanic events are associated with some of the largest climate anomalies of the last millennium; of the three largest volcanic events, two were part of a pair. The Kuwae event (pair) in the mid-15th century has come to be regraded as part of a pair. Likewise, the Tambora eruption 1815 event was the second of a pair of events with the first occurring in 1809.

Here we use GISS-E2.1 and GISS-E3 with the MATRIX aerosol microphysics module to investigate paired volcanic events. We find that the initial event has a meaningful impact on stratospheric chemistry for several years. We investigate how this pre-conditioning modulates the climatic response.

Local impacts of the 1783-84 Lakagígar eruption in Iceland

Arni Daniel Juliusson^{1,2}, Astrid Ogilvie^{3,4}, Gaston Demaree⁵

¹University of Iceland, Reykjavik, Iceland. ²Reykjavik Academy, Reykjavik, Iceland. ³Stefansson Arctic Institute, Akureyri, Iceland. ⁴Institute of Arctic and Alpine Research (INSTAAR), Boulder, USA. ⁵Royal Meteorological Institute of Belgium, Brussels, Belgium

Abstract

In early June 1783 a volcanic eruption began in the vicinity of Mount Laki in southern Iceland. It is often referred to in the non-Icelandic literature as the "Laki" eruption. This is a misnomer as the eruption did not occur on Mount Laki but on either side of it. In Icelandic it is called the *Lakagígar* eruption meaning the "Laki fissure" eruption. It is also referred to as Skaftáreldar, the "Skaftá fires" from the river Skaftá in southeast Iceland which dried up as a result of the eruption. The eruption lasted until February 1784 and was one of the most noteworthy and largest fissure eruptions in historical times. The Lakagígar eruption had a catastrophic effect in Iceland, not because the eruption caused direct loss of life, but because of the indirect effects as a result of the emission of volcanic gases and ashes distributed by wind. The grass, the basic food supply for the grazing livestock, became polluted and flourine poisoned. Within a year of the eruption, 53% of the cattle, 80% of the sheep and 77% of the horses died. The eruption was the primary cause of the ensuing famine which came to be known as *Móðuharðindin* or the "Famine of the Mist". However, the severe weather of the years 1782-84 also played a part in negatively impacting the human as well as the livestock population. It is estimated that the total death toll of *Móðuharðindin* represented 19 to 22% of the Icelandic population or approximately 10,000 people. The eruption occurred at a time when the full effects of the Enlightenment movement were being felt in Iceland. In consequence, there was a great general interest at this time in the observation of nature and natural events. In the year following the beginning of the eruption, six major contemporary descriptions of the event were published in Iceland. Other, unpublished records, such as reports by local officials to the Danish government, also give detailed accounts of the eruption. This presentation will focus on published and unpublished sources to analyse and describe the consequences of the Lakagígar eruption, in particular in northern Iceland, in the Mývatn district and the county of Eyjafjarðarsýsla. It will draw new and unused evidence into the discussion and analyse the effects of the catastrophe on a local level, relating this evidence to better known sources. It will also evaluate the effects of the catastrophe in these areas in relation to the general picture. The catastrophe did not hit every area with equal force, and the difference within and between regions will be discussed and analysed in search of explanations for these differences.

How do the volcanic eruptions influence the decadal megadrought over the eastern China?

Liang Ning^{1,2}, Jian Liu¹, Zhengyu Liu³, Mi Yan¹, Kefan Chen¹, Weiyi Sun¹, Chunhan Jin¹

¹Nanjing Normal University, Nanjing, China. ²University of Massachusetts, Amherst, USA. ³Ohio State University, Columbus, USA

Abstract

The influences and mechanisms of volcanic eruptions on decadal megadroughts over eastern China during the last millennium were investigated using a control (CTRL) and 5 volcanic eruption sensitivity experiments (VOLC) from the Community Earth System Model (CESM) Last Millennium Ensemble (LME) archive. The CTRL and VOLC experiments have similar decadal megadrought frequencies, which are all included in the 95% confidence intervals based on a 2000-member Monte Carlo simulation. The decadal megadroughts were associated with failures of the East Asia summer monsoon (EASM) resulted from a pattern of meridional tripolar sea surface temperature anomalies (SSTA) in the western Pacific stretching from the equator to high latitude, representing an internal mode in decadal-scale based on empirical orthogonal function (EOF). Composite analyses showed that, on inter-annual scale, within the decade after the eruptions, the volcanic eruptions firstly exacerbate the megadroughts, but then relieve the megadroughts due to the swift shifts from El Niño states to La Niña states on the third year after volcanic eruptions, with another damping process with smaller magnitudes. The impacts of volcanic eruptions on the megadrought magnitudes are linearly superposed on the internal variability. While, on decadal scale, the volcanic eruptions show little influences on megadrought magnitudes and lengths due to the smoothing on inter-annual influences.

Millennial-scale land-use changes and their effect on a small lake in southern Sweden based on pollen and lignin phenols

Bingjie Yang, Anne Birgitte Nielsen, Karl Ljung, Dan Hammarlund
Department of Geology, Lund University, Lund, Sweden

Abstract

In this study, a sediment sequence from Lake Skottenesjön, southern Sweden was investigated to reconstruct the effect of forestry and land-use on erosion rates and delivery of organic and mineral matter to the lake. Catchment-scale vegetation changes during the last 1000 years were reconstructed quantitatively using pollen analysis and the Landscape Reconstruction Algorithm (LRA). Organic matter in the lake sediments was analyzed using lignin phenols and bulk carbon stable isotopes. Changes in the delivery of mineral matter were analyzed using X-ray fluorescence scanning.

Variations in pollen assemblages, lignin phenol concentration and other geochemical proxies show that deforestation, agricultural activities and other human impacts on the lake catchment modified the organic and inorganic matter deposition in the lake. Between ca. AD 1000 and ca. AD 1350, the local land-use was characterized by small-scale agricultural activities associated with the medieval expansion. During this period, the woodland cover was dominated by deciduous trees, as revealed by both pollen composition and high values in the ratio between syringyl and vanillyl phenols (S/V). Increased deposition of terrestrial organic matter was indicated by the high concentration of lignin phenols. Around AD 1350, much of the farmland was abandoned and coniferous woodland cover increased as revealed by the pollen composition. A progressive decline in the lignin phenol concentration after ca. AD 1350 reflects a reduction of terrestrial organic matter input to the lake, probably as a direct effect of increased forestation of the catchment. After ca. AD 1650, both cultivated crops and pasture & meadows expanded in the catchment as seen in pollen assemblages. The increased land-use indicated by the pollen data is in agreement with the population increase documented in the study area between ca. AD 1700 and ca. AD 1850, but locally the human impact remained high for some time after the regional peak in population. Substantial increases in lithogenic elements (K, Ti, Rb) together with lower TOC content and higher C/N ratios indicate enhanced soil erosion from ca. AD 1650 to ca. AD 1950. Elevated $\delta^{13}\text{C}$ values during this period reflect an increase in lake productivity that can be attributed to higher nutrient input associated with intensive soil erosion. S/V ratios increased in concert with an increase in deciduous trees and a distinct drop in coniferous woodland cover due to timber exploitation. Cinnamyl to vanillyl phenol ratios (C/V) increased together with an increase in grassland cover. The flux of lignin phenols increased drastically reflecting a substantial elevation of terrestrial organic matter input as a consequence of intensive human activities. This study illustrates that the combination of pollen and lignin phenols is useful for investigating past changes in the delivery of organic matter in response to the anthropogenic impact on lake catchments.

Distinguishing between natural and anthropogenic drivers of recent environmental change in Arctic Russia to inform Bewick's Swan conservation

Vivienne Jones¹, Carole Roberts¹, Gina Charnley¹, Tatyana Moiseenko², Hannah Robson³

¹UCL, London, United Kingdom. ²RAS, Moscow, Russian Federation. ³WWT, Slimbridge, United Kingdom

Abstract

Arctic environments are highly sensitive to global climatic and environmental changes due to a number of feedback mechanisms. Responses to multiple stressors are already being observed with significant implications for the biota that rely on their ecosystems. The migratory Bewick's Swan is one such species whose population has declined since the 1990s, however significant uncertainties remain regarding the main driver(s) of its demise.

Applying a landscape-scale approach, using a combination of top-bottom core analyses and the more detailed investigation of 210Pb dated cores we reconstruct terrestrial and aquatic ecosystems over the last century in the Pechora Delta, northeast European Russia, one of the main breeding and summer feeding areas for the Bewick's Swan. Multi-proxy analyses, including cladocera, macrofossil, pollen, diatoms and geochemical analyses (XRF, ICP, C and N isotope) are employed to investigate ecological responses to pressures in the region and explore the ultimate impacts on breeding and moulting populations of the Bewick's Swan.

Since the late 20th century, there is clear evidence of community restructuring at the landscape scale across both aquatic and terrestrial ecosystems. The most prominent transformation within aquatic communities involves the replacement of large-bodied cladocera, primarily *Daphnia pulex*, by the smaller-bodied species, *Daphnia longispina*. Concurrently, major shifts in water level are inferred from declines in less moisture-tolerant mosses (*Dicranium fuscescens* and *Polytrichum* spp.) and littoral macrophytes (*Juncus* spp. and *E. hydropiper*), increased abundances of submerged macrophytes, and shifts from benthic (mainly *Fragilaria sensu lato*) to planktonic diatom species with evidence for increased primary production. There is a similar timing of ecosystem change in the terrestrial landscape with typical tundra heath communities being replaced by increasingly dominant boreal components, including *Betula nana*, *Alnus*, *Betula tortuosa* and *Salix* spp. The agreement between macrofossil and pollen records in the timing of community shifts corroborates a universal driver of ecosystem changes in the region. Although there is some evidence of atmospheric pollution, climatic variables appear to be most effective in explaining the trends observed with terrestrial vegetation potentially responding to increased air temperatures and enhanced moisture regimes, while changes in aquatic ecosystems may relate to enhanced hydrological connectivity promoted by increased river discharge and rising sea levels. Changes in vegetation and habitat indicated by the palaeolimnological evidence have significant implications for arctic species such as the Bewick's swan.

Early river deviations in the Swiss Alps and their effects on the lake system of Lake Thun

Stefanie Wirth¹, Linjing Cheng¹, Katrina Kremer², Lothar Schulte³

¹Centre for Hydrogeology and Geothermics, University of Neuchâtel, Neuchâtel, Switzerland. ²Swiss Seismological Service, ETH Zurich, Zurich, Switzerland. ³Department for Geography, University of Barcelona, Barcelona, Spain

Abstract

Lake Thun was affected by two river corrections during the past millennium. The younger and well-documented deviation of the Kander River into the lake in 1714 AD heavily modified the lake system by increasing the water inflow by 40% and the sediment input by 85%. This work has been considered to be the first major river correction in Switzerland and a pioneer engineering project. The older river correction is less well constrained and documented. In the course of the past millennium the Lütschine River was stepwise deviated away from Lake Thun to upstream Lake Brienz, thus reducing the sediment input to Lake Thun and peak water inflows during floods. Previous studies using a geomorphological and sedimentological approach (paleochannels on the fan delta) combined with historic documents showed that the works on the Lütschine River were probably completed by a final river detour between 1750 and 1797 AD.

In this current project, we aim at (i) exploring the changes in the lake's system caused by these river corrections and at (ii) better constraining the chronology of the Lütschine River deviation. Essential for these investigations are new long Kullenberg-type sediment cores retrieved in 2018.

Sediment cores passing at several locations through the stratigraphic level of the Kander River deviation allow us to document tremendous changes in the sedimentation processes induced by this engineering work. The three most evident effects are a strong increase in authigenic calcite precipitation due to the dissolved load of the Kander River from limestone-rich subcatchments, frequent sublacustrine mass movements due to a fast growing delta, and a better mixing and thus aeration of the lake waters.

The approach for better constraining the past periods or relatively short events (e.g. large flood events) of the Lütschine River inflow is based on the geochemistry and mineral composition of the lake sediments, as well as on Lütschine flood layers. Two approaches are applied: (i) tracking the crystalline signature of the Lütschine sediment load that contrasts with the other tributaries located in catchments purely composed of sedimentary rocks, and (ii) correlating discrete flood layers with historically documented floods. Applied methods are ¹³⁷Cs and ¹⁴C dating, XRF core scanning, and mineralogical analyses. Hence, our studies of the Lake Thun sediments support and refine the chronology of the gradual Lütschine River deviation. By clearly pre-dating the Kander River deviation these measures are an example of early human impact on river systems in the Alps that have not yet been well described.

Abstract

Over the past decades, organic carbon (OC) levels have increased in many lakes (i.e., “lake browning/brownification”) across Europe and NE North America. Identified drivers for this increase include reduced acid deposition, land-use/cover changes, and climate change, yet the specific contributions of these drivers are still debated. Recent paleolimnological studies have shown that it is possible to reconstruct past lake-water OC levels from sediment records using visible-near infrared (VNIR) spectroscopy models, thus providing key data about pre-human impact levels and natural long-term OC variability.

To determine the specific influence of acid deposition and climate change on lake-water OC concentrations, we inferred long-term OC trends from lake sediment records in low to high acid deposition regions over the past ~200 years. In contrast to their different acid deposition histories, our study regions in Canada have experienced a similar warming trend (1.3–1.6°C) since the early 1900s. OC reconstructions are based on a partial least square regression between VNIR spectra of surface sediments and corresponding lake-water OC measurements from 345 Arctic, boreal and northern temperate lakes (0–41 mg OC L⁻¹, R²_{CV} = 0.57, RMSE_{CV} = 4.4 mg OC L⁻¹). For lakes near Sudbury in northeastern Ontario – an area that has been heavily affected by acid deposition during the 20th century – we also estimated OC burial rates to identify the implications of changing lake-water OC levels for long-term OC storage in sediments.

Inferred lake-water OC trends show a strong response to changes in atmospheric deposition across the landscape in acid-sensitive as well as well-buffered lake systems. For example, in lakes located in the high acid deposition region around Sudbury, OC concentrations declined by ~50% compared to pre-industrial levels. After SO₂ emission reductions in the 1970s, OC concentrations started to slowly recover, but still remained ~30% below pre-industrial values by the 2000s. In contrast, in lakes of the low deposition Experimental Lakes Area of northwestern Ontario, OC values declined by only ~10% during the early 20th century and exceeded pre-industrial values by the 1970s (~10% relative increase by the 2000s), likely in response to climate change. Our findings confirm the widespread “re-browning” of lakes in former high acid deposition regions, but also suggest that OC levels will potentially exceed pre-industrial values with complete recovery from acidification in response to ongoing climate change. In contrast to lake-water OC dynamics, OC burial trends in Sudbury lakes are more complex, and appear to be primarily driven by local (e.g., land-use/cover change, eutrophication) rather than regional changes.

Long-term effects of contamination from arsenic-rich mine tailings and natural variability on lake ecosystems in Northeastern Ontario, Canada.

Jesse Vermaire¹, Amanda Little¹, Branaavan Sivarajah², Cristina Frendo¹, Dale Sprague¹, Drake Hyden¹, John Smol²
¹Carleton University, Ottawa, Canada. ²Queens University, Kingston, Canada

Abstract

A silver mining boom in the early twentieth century near the Town of Cobalt in northeastern Ontario, Canada, has left a legacy of arsenic-rich mine tailings spread across the landscape, including contamination of many lakes and rivers. Mining and the dumping of mine tailings ended in Cobalt around the early-1930s but these tailings remain largely unmanaged and continue to move around the environment contaminating lake ecosystems with arsenic and other metals. The objectives of this research were to investigate the impact, if any, of arsenic-rich mine tailings on lake ecosystems, define ecological baseline conditions, and assess natural variability and recovery in these ecosystems, if any has occurred since mining activity ceased in the 1930s. Mine tailings were clearly visible in the sediment record (²¹⁰Pb dated to ~1930) as a band of gray clay to silt material with elevated metal concentrations including arsenic levels of up to ~11,000 mg/kg. In fact, surface water concentrations of arsenic continue to be highly elevated at approximately 1,100 µg/L in some lakes. In the paleolimnological records, significant shifts in diatom assemblages occurred in response to the tailing contamination driven by an increase in the relative abundance of *Fragilaria construens*. *construens* to nearly 60% of the diatom assemblage, the loss of benthic diatom diversity, and a reduction in planktonic diatom abundance with no evidence of recovery in the diatom community nearly a century after mining activity has ceased. Surprisingly, at the landscape-scale, arsenic contamination is a poor-predictor of changes in surface sediment diatom, cladoceran, and chironomid assemblages, as well as open water zooplankton abundance and community, and phytoplankton concentration (measured as chl_a). These results suggest that, within a single lake, mining contamination resulted in pronounced changes to the ecosystem with little to no ecological recovery. At the landscape scale, however, site specific limnological characteristics (e.g. mean depth, nutrients, colour, pH) are more important in structuring the biological community than regional mining related contamination.

Abstract

Regime shifts in ecology are characterised by major, often abrupt changes in ecosystem structure and functioning in response to one or more driving variables, or pressures. These responses can be due to natural or anthropogenically-driven changes. However, natural and anthropogenic drivers can produce similar responses in lake systems and thus, present a challenge in distinguishing natural from anthropogenic change in lake sediment archives. Despite the current combination of rapidly increasing pressures on what are often highly important socio-ecological systems, the resilience of lakes in the warm tropics to human perturbation is far less well understood than those at higher latitudes. Less work has been done disentangling human disturbance responses from other signals found in tropical lake sediment archives, such as climatic warming. Distinguishing the past effects of human drivers of ecological change is becoming increasingly important to anticipating how tropical lake systems will function in future. This paper focuses on evidence of environmental change from a cluster of three deep, freshwater, volcanic crater lakes (Yambo, Mohicap and Sampaloc) at low altitude on the island of Luzon, Philippines. The lakes support different intensities of aquaculture and shoreline development, allowing anthropogenic signals associated with human activity to be disentangled from regional climatic signals. Measured and monitored climate and water quality data, in addition to sedimentary evidence from sediment cores collected from the three study lakes, were used to determine the magnitude and trajectory of changes in lake water quality in the surrounding catchment. Sediment cores were radiometrically dated and analysed for organic matter, spheroidal carbonaceous particles (SCPs), diatoms, chironomids, pollen and charcoal. Despite differences in human pressures, a common trajectory and timing of aquatic ecological changes is apparent at all three study sites. This potential regime shift is characterised by a replacement of benthic with planktonic diatoms and an increase in diatom accumulation rates from the early to mid-1980s, is evident, and attests a low threshold for disturbance effects. A predominantly planktonic diatom flora has persisted even after recent improvements in environmental quality. The timing of these changes coincide with shifts in chironomid taxa that support the idea of a regime shift. The potential new regime may be less resilient and more susceptible to harmful algal blooms, abrupt expansions of anoxic conditions, and periodic mass fish kills when compared with its former state. Changes in the local pollen taxa and charcoal abundance also reflect shifts in vegetation cover and the timing and magnitude of local human disturbance. The results of the multi-proxy analysis provide new insights into possible anthropogenic regime shifts taking place in this region. The research further highlights the sensitivity of freshwater ecosystems in the warm tropics to disturbance pressures, and the risks to livelihoods, ecosystem services and sustainable development.

Lake sediments and natural capital

Catherine Dalton

Mary Immaculate College, University of Limerick, Limerick, Ireland

Abstract

Lakes are important components of our landscape and provide a range of important ecosystem services and natural capital. Additionally lake sediments contain signals of their physical, chemical and biological ontogeny reflecting natural system dynamics as well as anthropogenic activity. A summary of the available lake data is vital to help shape research efforts to determine catchment and lake system contributions to biogeochemical processes, for example, carbon burial. This is particularly important in the context of global climate change. This presentation will summarise the publicly available spatial data on Ireland's lake population. Although small in area, lakes play a critical role in biogeochemical cycling by storing organic carbon produced by the catchment/lake and by releasing CO₂ and CH₄ to the atmosphere. While Ireland has considerable peat and lake rich landscapes, quantitative data on carbon sequestration/burial in lake sediments are largely lacking. A synthesis of the lake sediment geochronologies that have been established for Irish lacustrine systems will be outlined and sediment accumulation rates quantified to-date will be used to establish key patterns and trends in relation to lake type. This in turn will provide invaluable context in terms lake sediment studies and interpretations of Anthropocene change in this north-west Atlantic coastal region.

Mediterranean vegetation change, landscape dynamics and human population trends through the Holocene

Jessie Woodbridge^{1,2}, Ralph Fyfe¹, Alessio Palmisano³, Neil Roberts¹, Andy Bevan³, Stephen Shennan³

¹University of Plymouth, Plymouth, United Kingdom. ²University of Exeter, Exeter, United Kingdom. ³University College London, London, United Kingdom

Abstract

The Mediterranean landscape has undergone significant changes throughout the Holocene. This research utilises large databases of modern pollen (Davis *et al.*, 2013) and fossil pollen from sediment cores (Leydet *et al.*, 2007-2018) as a proxy for vegetation change. Radiocarbon-led archaeological population proxies (Shennan & Edinborough, 2007) and settlement surveys are used to compare vegetation change with demographic trends. Cluster analysis and community classification of pollen datasets have revealed numerous closed forest/wooded vegetation types (e.g. evergreen and deciduous oak woods) and several open or scrub vegetation types (e.g. sclerophyllous scrub, steppe, grassland, parkland) (Fyfe *et al.*, 2018; Woodbridge *et al.*, 2018). Pollen-inferred landscape change indicates both short and long-term variability, which reflects temporal variations in climate and human land use. The pollen-inferred vegetation patterns and archaeological-inferred demographic trends are compared with fire history and palaeoclimate datasets in order to explore the drivers of disturbance in time and space within Mediterranean ecosystems. The initial decline in forest cover overlapped in time with the adoption of Neolithic farming, which spread from southwest Asia across most parts of the Mediterranean between ~9000 and ~7500 BP. Similarly, the gradual opening of Mediterranean landscapes between 7500 and 3000 Cal yr BP coincided with demographic rise and the emergence of complex, socially-stratified societies between the late Neolithic and the Iron Age. Thus, both human impact and climate change seem likely to have been responsible for land-cover changes during the mid-Holocene. However, the increase in open landscapes after 3000 Cal yr BP is consistent with anthropogenic causation (Roberts *et al.*, *in press: Holocene*). Analyses from six case study regions spanning the Mediterranean indicate that this has been a dynamic landscape throughout the Holocene with frequent changes in land-cover and persistence of disturbance and drought-adapted plant assemblages within an extensively human-modified environment.

How does Holocene land use impact on land cover change at the national scale?

Ralph Fyfe¹, Jessie Woodbridge¹, Ruth Pelling², David Smith³

¹University of Plymouth, Plymouth, United Kingdom. ²Historic England, Portsmouth, United Kingdom. ³University of Birmingham, Birmingham, United Kingdom

Abstract

It is widely accepted that European vegetation and biodiversity patterns have been shaped by humans over long time-scales, with deforestation, agriculture, grazing, fire and settlement having significant impacts. The complexities of these relationships remain poorly understood, particularly the relationship between land use practice and land cover change. It is important in managing future change to know how long these activities have been impacting upon natural systems and how they have shaped landscape dynamics. Exploring environmental change within the context of the Holocene (the last ~11,700 years) allows comparison of ecosystem states across a wide range of land use strategies, from hunter-gathering to complex patterns of land use in later prehistoric and historical periods. This contribution presents a new major effort to characterise land use from archaeological datasets, using the British Isles as a case study region, and compare spatial and temporal patterns of land use with contemporary land cover and land cover change. Whilst previous research across Europe has started to relate patterns of forest cover to past population expansion and contraction (e.g. Woodbridge et al. 2014), what people were actually doing (their land-use strategies), and the impacts of these land use strategies had on biodiversity lacks detail and remains unclear at national or regional scales.

This Leverhulme Trust-funded project is collating and synthesising archaeobotanical datasets derived from on-site excavations, and synthesising these to develop information on regional-scale land use and land use change, analysing these data within a palaeoinformatics approach (cf. Brewer et al. 2012). Initial synthesis of palynological and palaeoentomological data has revealed clear relationships between palaeo-demographic changes (from Bevan et al. 2017), vegetation cover and insect assemblages (from Smith et al., 2018) related to major patterns of subsistence change at the national level.

Speeding up global landcover reconstructions with ROPES

Martin Theuerkauf, John Couwenberg

Institute of Botany and Landscape Ecology, University of Greifswald, Greifswald, Germany

Abstract

Over the past two decades, a better understanding of the pollen-vegetation relationship has triggered the development of quantitative methods in palynology, which enable pollen based reconstructions of past landcover. The methods are now increasingly applied in studies around the globe, initiated e.g. by the PAGES Landcover 6k project. However, in many parts of the world, application is still hampered by the fact that the methods available require pollen productivity as a key parameter. Calibration studies to calculate pollen productivity are laborious and time consuming; they so far focus on Europe and China with only single studies in other regions.

As an alternative method we present ROPES, which enables reconstructions from single pollen records alone, i.e. without predefined pollen productivity estimates. ROPES reconstructs regional cover of plant taxa using high resolution pollen profiles from large basins, which provide pollen accumulation rates (PAR). Unlike pollen percentage values, a change in the PAR of a taxon is linearly related to a change in its regional abundance. If, for example, the PAR of pine doubles at some point in time, this change is expected to represent a doubling in the mean regional cover of pine. To arrive at actual abundances, ROPES combines PAR data with count based reconstruction methods like REVEALS, in an iterative approach. REVEALS requires pollen productivity estimates, which are, as mentioned above, widespread unavailable. ROPES hence starts with random productivity estimates, which are then adjusted through optimization until the reconstructed cover of each taxon indeed shows similar changes along the profile as the respective PAR values (e.g. the doubling in pine). If successful, the approach thus arrives at past mean regional abundance *and* pollen productivity estimates for all relevant taxa in a data set. In other words: with ROPES pollen productivity is an observable or result rather than a pre-defined parameter.

To illustrate the potential of ROPES we first show applications for a number of sites across Central Europe, which demonstrate changes of pollen productivity in space and time. Changes in space, e.g. along climate gradient, have been postulated but could not yet be demonstrated with modern calibration studies. Calibration studies are moreover unable to detect variations of pollen productivity in time, e.g. in response to changes in climate or land management. ROPES can detect such changes and provide means for interpreting them.

Secondly, we show example applications for pollen records from all continents to illustrate the flexibility of ROPES.

Abstract

Reconstructions of pre-historic forest composition provide the means to establish natural baselines, variability, and trajectories of forest composition, both prior to and during the emergence of extensive anthropogenic land use. Pollen-vegetation models (PVMs), are used to reconstruct forest composition from sediment pollen data, typically by characterizing the processes of taxon-specific pollen production and dispersal.

Here we reconstruct changes in forest composition for the last 8,000 years at 300-year intervals for both the northeastern (NE) and upper midwestern (UMW) United States using the Bayesian hierarchical spatio-temporal PVM STEPPS and networks of fossil pollen records from the Neotoma Paleoecology Database. The quantitative, spatially explicit reconstructions of forest composition can be analyzed to test for significant changes over time, thereby advancing towards a long-standing challenge in palynology: distinguishing ecological signal from observational noise.

STEPPS is calibrated and validated using sediment pollen and land survey vegetation data from the early Euro-American settlement era (NE: 1700 – 1800 CE, UMW: 1800 – 1850 CE). For the calibration era, pollen-based reconstructions of forest composition compare favorably to observed vegetation, with accurate representation of both the main vegetational zones and ecotones.

In both spatial domains, we are able to reconstruct the spatial and temporal extent of the mid-Holocene hemlock decline (ca. 5400 cal BP). The hemlock decline is among the most prominent rapid vegetation changes seen in both regions; it results in the highest vegetation dissimilarities between consecutive time slices prior to large scale human influence. Hemlock begins to recover regionally after about 1500 years. In the NE, the relative abundance of hemlock does not reach the level prior to the decline, but in the UMW, hemlock returns to pre-decline levels.

In the NE, beech abundances increase during and after the hemlock decline, reaching maximum abundances at 4000 cal BP. Over the last 2000 years, beech decreases in central New England and spruce increases in northern New England. In the southwestern part of the NE, chestnut expands during the last 2000 years.

In the UMW, the single largest change over the last 2000 years is the in-filling of hemlock within its range, despite a largely stable range limit. Ash, elm, and other hardwoods expand in the Big Woods region. These changes took place against a regional backdrop of vegetation changes that were small in magnitude or insignificant, suggesting high complexity in the spatiotemporal patterns of past forest dynamics and the controlling environmental factors.

Overall, these reconstructions show how large networks of fossil pollen records, in concert with Bayesian hierarchical approaches like STEPPS, can detect the complex spatiotemporal patterns in past forest composition. A next critical step is to assess the possible influences of past variations in temperature and moisture availability upon these regional-scale vegetation change.

O-5082

New methods of estimating Relative Pollen Productivity, a key parameter for reconstruction of past land cover from pollen records

Yiman Fang¹, M. Jane Bunting¹, Chunmei Ma²

¹University of Hull, Hull, United Kingdom. ²Nanjing University, Nanjing, China

Abstract

Mathematic models illustrating pollen-vegetation relationships provides new insights into reconstructing past land cover from pollen data, and also have the potential to translate the many thousands of pollen records produced over the last century into formats relevant to ecologists, archaeologists and climate scientists. However, the reliability of these land cover reconstructions depend on the availability of model parameters. A key parameter, Relative Pollen Productivity (RPP), is usually estimated from empirical data using “Extended R Value analysis” (ERV analysis, Parsons & Prentice, 1981; Prentice & Parsons, 1983). Collecting sufficient field data for successful ERV analysis is time-consuming, and acts as a major barrier to wider use of reconstruction models. Lack of RPP estimates for many regions is currently a major limitation on reconstructing global land cover.

We present two alternatives to ERV analysis, the Modified Davis method and an Iteration method, which use the same underlying model of the relationship between pollen and vegetation to estimate RPP from empirical data, but with different assumptions. These models are shown in simulation to perform at least as well as ERV analysis with both small and large datasets, and have the potential to increase the speed and geographic range of RPP estimation. We will present examples of their application to modern datasets including an example from southeast sub-tropical China which is not suitable for standard ERV analysis, and show how they can be used to obtain useful RPP estimates from problematic data.

Adding these two methods to the “toolkit” for land cover reconstruction from pollen records opens up the possibility to extend RPPs to wilder areas with available datasets such as existing Tauber trap data across Europe from Pollen Monitoring Programme (PMP). This can both speed up the inclusion of more of the globe in past land cover mapping exercises such as the PAGES Landcover6k working group and improve our understanding of how this parameter varies within a single taxon across geographic areas and the factors control that variation.

Abstract

Questions related to conservation biology (e.g. biodiversity) and climate change often require a long-term historical perspective in which quantitative reconstructions of past vegetation abundance/land cover at local and regional spatial scales play an important role. The Landscape Reconstruction Algorithm (LRA; Sugita 2007 a, b) estimates vegetation abundance/plant cover at the regional scale (100 km x 100 km) and local scale (area of ca. 1-5 km radius) using the models REVEALS and LOVE, respectively. The LRA is the most widely tested, validated, and applied pollen-based quantitative reconstruction approach to date. However, the method has been used primarily in the northern hemisphere. Duffin and Bunting (2008) published estimates of relative pollen productivity (RPP), a parameter needed in LRA applications, for five plant taxa of southern Africa. Within the French research project C3A "Causes and consequences of the last great environmental crisis 3000 years ago in forests of Atlantic Equatorial Africa", we test the LRA in the mountain woodland and savannah vegetation of Cameroon.

We use modern pollen assemblages from soil samples and related vegetation surveys from 31 sites and the ERV-model to estimate RPPs of major taxa in the study region. We apply the LRA (REVEALS and LOVE models) using Holocene pollen records from two crater lakes/ponds (16.5 ha and 198 ha) in mountain woodlands and three lakes (46.7 ha, 25 ha and 8 ha) in savannahs.

The RPP estimates suggest that, relatively to Gramineae (RPP=1), taxa such as *Schefflera* and Combretaceae have high RPP values (>1), while e.g. *Podocarpus*, Asteraceae, and Cyperaceae have RPPs close to Gramineae, and e.g. *Alchemilla* and *Celtis* have low RPPs (< 1). LRA reconstructions of regional and local vegetation cover indicate more wooded landscapes than suggested by pollen percentages over the entire Holocene at sites located today in mountain woodland and mixed woodland-savannah landscapes. Moreover, the decreases in woodland cover at 3 ka BP and from 1.5 ka BP are generally more pronounced in the LRA reconstructions than in pollen percentages. LRA reconstructions in combination with land-use reconstructions inferred from archaeological data will be an important step towards more realistic descriptions of past anthropogenic land-cover and land-use change in western Africa for e.g. earth-system modelling.

Proglacial lake records of Holocene glacier behaviour, Zackenberg, Northeast Greenland

Kathryn Adamson¹, Timothy Lane², Cathy Delaney¹, Matthew Carney¹

¹Manchester Metropolitan University, Manchester, United Kingdom. ²Liverpool John Moores University, Liverpool, United Kingdom

Abstract

Arctic air temperatures are currently rising at twice the global average rate. Understanding Arctic glacier and ice cap sensitivity to past climate change is important for predicting future retreat patterns. Geomorphological records of glacier behaviour, including moraines and alluvial sequences, are inherently fragmentary, but proglacial lakes can provide continuous, high-resolution archives of glacier behaviour. However, they have not been widely examined in the High Arctic – one of the most environmentally sensitive parts of the world.

We present sedimentary records from proglacial lakes close to Zackenberg in Northeast Greenland (74°N), 60 km east of the Greenland Ice Sheet. The lakes are situated downstream of an ice cap outlet and a neighbouring independent valley glacier, allowing us to examine in detail the nature and timing of glacier behaviour in response to Holocene environmental change, and how this behaviour is recorded in the lake sedimentary archive.

A combination of high-resolution sediment geochemistry (X-Ray Fluorescence and X-Ray Diffraction), particle size, magnetic susceptibility, total organic carbon analysis, and ¹⁴C ages is used alongside geomorphological mapping to constrain glacier response to Late Holocene environmental change.

The sediment datasets indicate that lake sediment variation is driven by glacier activity. Importantly, by combining high-resolution XRD and XRF data, we are able to examine small-scale fluctuations in proglacial lake sedimentation that are not visible using XRF, or other sediment geochemical and physical parameters, alone. We identify two phases of enhanced glacier activity prior to the Little Ice Age (LIA), which is consistent with evidence of pre-LIA glacier advance recorded in Svalbard and Canada. A third phase, which represents smaller scale glacier fluctuations, is associated with the onset of the LIA.

Our analysis provides detailed insights into Late Holocene glacier activity in Northeast Greenland, at a level of detail that is not recorded in the geomorphological archive. This highlights the value of high-resolution geochemical analysis of lake sediments to establish glacier dynamics in regions where chronological and morphostratigraphical control is limited.

Control of large proglacial lakes on past outlet glacier dynamics during the Last Glacial Maximum in New Zealand

Jenna Sutherland¹, Jonathan Carrivick¹, Niall Gandy¹, James Shulmeister², Duncan Quincey¹

¹University of Leeds, Leeds, United Kingdom. ²The University of Queensland, Queensland, Australia

Abstract

Proglacial lakes are known to affect the stability of mountain glaciers and can partly disengage glacier behaviour from climatic perturbations. Ice-contact proglacial lakes are pervasive across New Zealand and 33 % of the country's perennial ice terminates within lake-calving glaciers. Proglacial lakes have been recognised as an integral part of the onset and progression of ice sheet deglaciation. It has been widely suggested that the retreat of glaciers in the Southern Alps immediately after the Last Glacial Maximum (LGM, c. 30–20 ka BP) could have been relatively rapid, not only because of climate forcing, but in addition to the widespread formation of large proglacial lakes. Ice-contact proglacial lakes formed during deglaciation from LGM ice advance limits, infilling the overdeepening. These lakes would have caused a shift from land-terminating to lacustrine-calving glacier termini, and that would have accelerated ice margin recession in many valleys and consequently ice mass loss. Despite the importance of glacier-lake interactions in influencing deglaciation, these mechanisms are generally ignored by ice sheet model simulations. The importance of this omission has not been quantified.

We use BISICLES, a higher-order ice sheet model capable of adaptive mesh refinement, to present a simulation of the Tasman Glacier at the LGM and beyond in an attempt to constrain the effect of proglacial lakes on glacier retreat. The Tasman Glacier has abundant empirical data and is well chronologically constrained at the LGM, which is used to inform, validate and analyse our numerical ice sheet simulations in this study. We perform idealised experiments of the retreat under a constant hypothetical climate forcing to isolate the effects of lake-terminating processes, simulating retreat of the glacier under a constant warm surface mass balance and sub-ice shelf melt. We look at the effect on the glacier margin by running two simulations, once with, and once without the presence of a lake. The influence of a proglacial lake accelerates deglaciation and reduces the relative influence of surface melting. The presence of the lake also changes the surface profile of the glacier during deglaciation, making it a stronger match for the empirical evidence. The change in surface slope in turn effects the influence of climate warming, introducing a positive feedback mechanism. As the lake evolves it creates hysteresis within the system. These results highlight the importance of including ice-contact proglacial lakes in palaeo-ice sheet modelling, as well as the need for a coherent regional model of ice-lobe and palaeo-lake evolution that reconciles all dating evidence in order to elucidate the pattern of retreat following the LGM in New Zealand.

The Development, Configuration and Chronology of the Ice-Dammed Lakes of the Ungava Peninsula (Northern Quebec, Canada) during the Last Deglaciation

Martin Roy^{1,2}, Marc-Antoine Lévesque^{1,2}, Hugo Dubé-Loubert³, Joerg Schaefer^{4,5}, Étienne Brouard^{1,2}, Paul Dunlop⁶

Abstract

The retreat of the Laurentide Ice Sheet over the Ungava Peninsula led to the formation of several large ice-dammed lakes that have left an extensive record of raised shorelines in the main river valleys and low-lying basins. These glacial lakes drained through Ungava Bay and into the Labrador Sea, a critical area of the North Atlantic where deepwater formation occurs. However, assessing the impact of the drainage of these lakes on the ocean system is prevented by the lack of data on their configuration, volume, and chronology. Furthermore, the development of these lakes is intimately linked to the configuration of the ice margin and its position throughout the deglaciation, which are still poorly constrained, as is the chronology of ice retreat for this sector. Here, we reconstruct the extent and bathymetry of 3 major glacial lakes of the Ungava Peninsula (Nantais, Klotz and Payne) through detailed mapping of raised shorelines and associated landforms. We also document the pattern of ice withdrawal through systematic mapping of eskers and moraines using aerial-photographs, high-resolution satellite imagery (RapidEye) and DEMs. Observations were validated through fieldwork that allowed elevation measurements of the main shoreline sequences using high-precision DGPS. The lake development chronology was constrained through Terrestrial Cosmogenic Nuclide (¹⁰Be) dating of boulders sampled from the most representative shorelines. Our mapping results indicate that these lakes formed along a NW-SE oriented ice margin that was retreating towards the west-southwest. The pattern of ice withdrawal caused the opening of a series of southward-flowing outlets formed by the Lepellé, Lestage and Vachon river valleys, which allowed the meltwater bodies to successively spread into lower-elevation basins. The shoreline sequences show a progressive lowering of lake surfaces and a temporary connection between Lakes Nantais and Klotz. Ultimately, ice retreat allowed the final drawdown of the lakes through the Payne River, a major E-W depression linking the Peninsula interior to Ungava Bay. Preliminary ¹⁰Be ages indicate that the sequential development of these glacial lakes occurred in a narrow timeframe centered around 8.7-9.7 ka. The context of ice withdrawal also implies that the lakes likely drained over a short time interval, suggesting that these meltwater discharges and those from other glacial lakes of the Ungava-Labrador region may have been an important component of the overall freshwater forcing(s) that altered the late deglacial and early Holocene climate. Altogether, these results refine our understanding of the development of glacial lakes in north-central Ungava and improve paleogeographic reconstructions by providing important constraints on the position and timing of the ice margin during the deglaciation of the Labrador Sector in this region.

Deciphering the palaeogeography of glacial Lake Fraser, British Columbia, Canada, using high resolution DEMs

Brendan Miller^{1,2}, Tracy Brennand², John Clague², Marten Geertsema¹, Nicholas Roberts²

¹British Columbia Ministry of Forests, Lands, Natural Resource Operations and Rural Development, Prince George, BC, Canada. ²Simon Fraser University, Burnaby, BC, Canada

Abstract

Glacial Lake Fraser (GLF) occupied the central interior of British Columbia (BC), Canada, at the close of the last Pleistocene glaciation. The lake was impounded behind the deteriorating Cordilleran Ice Sheet. This research focusses on understanding the changing palaeogeography of GLF and involves mapping shoreline features, such as beach ridges and wave-cut benches, using high resolution Digital Elevation Models.

Up to three phases of the lake have been defined: the McBride and Prince George phases, and possibly the Quesnel phase. The lake during the McBride phase is estimated to have been 370 km long, with an area of 8700 km². It covered the Rocky Mountain Trench between Summit Lake and south of the Mica Dam, and had a surface that ranged in elevation between 1160 and 806 m a.s.l. The lake during the Prince George phase extended between Valemount and to at least 25 km east of Burns Lake, a distance of 430 km, and between Summit Lake and Williams Lake, a distance of 250 km (Figure 1). It had an estimated area of 12,500 km² and its surface ranged in elevation between 806 and 708 m a.s.l. The Quesnel phase occupied the Fraser River valley between Williams Lake and north of Quesnel, a maximum distance of 170 km. This phase had an estimated maximum area of 340 km², and a maximum surface elevation of 548 m a.s.l.

During the McBride and Prince George phases, GLF drained northward into the Peace River watershed, drawing down lake levels by up to 452 m, from 1160 m a.s.l. to near 708 m a.s.l. The Prince George phase ended with rapid emptying of GLF during a jökulhlaup along the Fraser River valley. Evidence for this event within the GLF basin includes digitate, amphitheatre-shaped erosional forms in subaqueous outwash sands and silts produced during the rapid drawdown of the lake. The Quesnel phase drained southward through the Fraser River valley.

The evolution of GLF provides an opportunity to elucidate the distribution of remnant Cordilleran ice at the end of the Pleistocene Epoch in central BC. During the McBride phase, remnant glacier ice constrained GLF to the Rocky Mountain Trench. During the Prince George phase, much of the lower elevation areas of central BC, including the valleys of the Nechako and Fraser rivers, were occupied by a subaerial lake while glacier dams prevented westward flow beyond Burns Lake, and southward flow in the Fraser River valley south of Williams Lake.

Glacial Lake Shanadithit and regional ice dynamics in the Red Indian Lake Basin, Newfoundland, Canada

Jennifer Organ

Geological Survey of Newfoundland and Labrador, St. John's, Canada

Abstract

At the late Wisconsinan glacial maximum, the island of Newfoundland was covered by a series of coalescent ice caps that extended out to the continental shelf, forming the Newfoundland Ice Cap. The radial and diachronous pattern of retreat, coupled with the topography of central Newfoundland, created an environment for the formation of ice-marginal lakes.

The spatial distribution and elevation of features such as deltas and shorelines, along with the presence of fine-grained sediment, have enabled the delineation of glacial Lake Shanadithit which occupied a surface area of 349 km² within the present day Red Indian Lake Basin. The location of topographic lows, and the pattern of glacial retreat, suggest that glacial Lake Shanadithit experienced four phases of ice-marginal lake development.

The proposed paleogeographic reconstruction model has important implications for both glacio-isostasy and for regional ice-retreat dynamics, which differ from previous glacio-isostasy and ice-retreat models.

De-levelled shoreline features and corresponding outlets indicate that the basin has undergone a minimum isostatic tilt of 0.22 m km⁻¹. This is the first evidence of isostatic tilt within the interior of Newfoundland and indicates that the Newfoundland Ice Cap itself influenced the amount of glacio-isostasy on the island and was not over shadowed by the Laurentide Ice Sheet, as previously thought.

The active retreat and formation of glacial Lake Shanadithit within the Red Indian Lake Basin, as indicated by the proposed paleogeographic reconstruction model, indicates that the regional ice retreat pattern left isolated ice remnants on the highlands west of Buchans, and a larger ice remnant over the areas of northeast and south of Red Indian Lake. This is in contrast to the current model of a large ice mass situation over all of Red Indian Lake.

Proglacial environments and the southwest margin of the Laurentide Ice Sheet: Stratigraphy and geochronology of glacial Lake Great Falls

Christopher Hill^{1,2}, James Feathers³

¹Boise State University, Boise, USA. ²National Science Foundation, Alexandria, USA. ³University of Washington, Seattle, USA

Abstract

Ice-dammed proglacial lakes can form where glacial ice lobes obstruct river drainages, and sediments associated with the proglacial lakes thus can be linked to patterns of advance and retreat of glacial margins. Sedimentary deposits along the upper Missouri River in Montana (U.S.A.) are interpreted as proglacial lake (glaciolacustrine) and till deposits. The results of stratigraphic and chronologic studies provide information on the extent, depositional environments, and timing of the Late Wisconsin Laurentide Ice Sheet (LIS). Two stratigraphic localities were studied and sampled for luminescence dating: Holter Lake (near Wolf Creek, U.S.G.S. Beartooth Mountain 7.5 minute quadrangle) and Hower Coulee (the Belt Creek area, east of Great Falls, U.S.G.S. Morony Dam 7.5 minute quadrangle). At Holter Lake, lake sediments include laminated deposits interpreted as varves. Luminescence samples were collected from laminated silts (UW355) and from overlying sands (UW356). The luminescence measurements indicate that both the laminated silts and the overlying sands are associated with Oxygen Isotope Stage (OIS) 2. If the overlying sands (UW356) are post-glacial aeolian sediments deposited after the drainage of glacial Lake Great Falls, then the LIS margin would have been north of this ice-free location after about 15,000 years ago. In the Hower Coulee area, the lower part of the stratigraphic sequence consists of fluvial gravels and sands overlain by laminated lake silts and other sediments (the "lower lake"). In "Outhouse Coulee" this sequence is over 8 m thick. Rythmites consisting of silts and clays are interpreted as varves and there are also beds of cross-bedded sands. The lower lake sediments are buried below a diamicton interpreted as a till deposited by a lobe of the LIS (the Loma sublobe of the Havre lobe). The diamicton is composed of a matrix of silt and clay supporting gravels and boulders. The till is overlain by several lithofacies related to a later stage of glacial Lake Great Falls (the "upper lake"). U-series measurements on shells indicate that the fluvial gravels below the lower lake sediments may be associated with the last interglacial (OIS 5). Luminescence samples from deposits of the lower lake (UW468, UW469) and the deposits of the upper lake (UW454, UW467) indicate the proglacial lake sediments are associated with OIS 2. Direct-dating of the sediments support a late-Wisconsin age for the Holter Lake and Hower Coulee stratigraphic sequences. This implies that a proglacial lake was formed in this part of the present-day Missouri Valley by a lobe of the LIS, indicating the maximum extent of the Late-Wisconsin southwest margin of the LIS.

A 25,000-year history of glaciation from Fish Lake, UT and the potential to extend this record through multiple glacial cycles

Mark Abbott¹, Lesleigh Anderson², David Marchetti³, Arielle Woods¹, Brendan Reilly⁴, Joseph Stoner⁵, Scott Harris⁶, Andrea Brunelle⁷

¹University of Pittsburgh, Pittsburgh, USA. ²USGS, Denver, USA. ³Western State University of Colorado, Gunnison, USA. ⁴Oregon State University, Corvallis, USA. ⁵Oregon State University, Corvallis, USA. ⁶College of Charleston, Charleston, USA. ⁷University of Utah, Salt Lake, USA

Abstract

The Quaternary paleoenvironmental history of the Bonneville Basin has been the focus of numerous studies for over a century, but the region continues to attract attention because many uncertainties about the mechanism driving the expansion of pluvial lakes during glacial conditions remain. The lake is moderate in size (~7x1.5 km), relatively deep (37 m) and located within the high elevation, formerly glaciated, Fish Lake Plateau (3545 m) where precipitation is heavily influenced by the North American Monsoon. The lake occupies a NE-striking tectonic graben. Seismic and gravity measurements suggest that Fish Lake may contain sediment thickness on the order of 240 m. Fish Lake Plateau exposure ages indicate late Pleistocene moraine deposition during Pinedale (15-23 ka) and Bull Lake (130-150 ka) times. One outlet glacier deposited moraines and outwash into the northern margin of Fish Lake, but the main basin was never glaciated.

We collected cores through the ice in February of 2014 using a 9-cm-diameter UWITECH coring system in 31 m of water. An 11.2-m-long composite core was constructed from overlapping 2 m drives taken in triplicate and dated using 12 radiocarbon measurements and 3 know-age tephras. Core lithology, CT scans, magnetic susceptibility (MS), sediment density, organic matter content (OM), and biogenic silica concentration (BSi) demonstrate complete recovery with three distinct sediment packages: 1) a Holocene to post-glacial interval characterized by high OM and BSi, and low clastic content and MS, 2) a fine-grained, high MS minerogenic glacial section with low OM and BSi, and 3) a short section of inferred pre-LGM sediment with intermediate composition. The paleomagnetic record, though weak in the Holocene, compares well with the high-quality record from proximal Fish Lake, Oregon and Bear Lake, Utah. Beyond the Holocene, a much stronger MS signal is preserved that compares well with a paleomagnetic secular variation correlation template we are developing from marine records from the Northeast Pacific. These data and extrapolation of the age model to the maximum estimated sediment thickness suggest a complete Fish Lake record may be older than 500-700 ka, and that a complete sedimentary record likely contains paleoclimatic and paleoenvironmental information that spans multiple glacial cycles.

Few continuous geologic archives in the Bonneville Basin have sufficient duration, temporal resolution, and dating control to address multiple glacial-interglacial climate variations, including forcing and feedbacks and relationships with local glacial extents and vegetation change. Some existing paleoclimate records suggest that Bonneville Basin paleoclimate was asynchronous with orbital variations and global boundary conditions, which raises significant questions about the nature timing and length of previous interglacial periods and the influence of the North American Monsoon, which is relevant for understanding potential change for the region in the future.

O-5092

An empty desert? Hominin responses to environmental fluctuation in Arabia.

Huw Groucutt

Max Planck Institute for Chemical Ecology, Jena, Germany

Abstract

The Arabian Peninsula is a vast and poorly understood area at the interface of Africa and Eurasia. The area has traditionally been sidelined in accounts of human prehistory. Yet, understanding the prehistory of Arabia can cast light on hominin dispersals, biogeography and responses to environmental change. How, for example, did hominin populations respond to abrupt transitions to aridity at the end of humid phases? While the surface of Arabia is covered in millions of artefacts, it is only in the last decade that dated archaeological sites have been studied in the area. In this talk I will outline recent multidisciplinary fieldwork in Arabia, extending from Middle Pleistocene Lower Palaeolithic assemblages through to the early Holocene and the transition to the Neolithic. A variety of datasets – including vertebrate palaeontology, diatom ecology and sedimentology – provide contextual information to understand the ecological and environmental settings of different human occupations. Together these findings indicate multiple hominin dispersals into Arabia over at least the last 500,000 years, followed by contractions to southern Arabia as the monsoon rains faded with each return to aridity. This led to a complex pattern of indigenous cultural developments. I will explore how this emerging Arabian record is both fascinating in terms of local human behavioural and demographic dynamics, as well as being of profound global importance in terms of factors such as calibrating the dispersal of *Homo sapiens* into Eurasia. As an arid region at the nexus of Africa and Eurasia, Arabia is well positioned to elucidate human abilities to survive in extreme environments, in an area generally characterised by aridity, but punctuated by occasional humid episodes. This ability to survive extreme conditions was essential to the global spread of our species, and the Arabian record indicates the social and technological factors which need to be understood in sync with the ecological and climatic contexts of hominin occupation.

Adaptive strategy to dryland among Paleolithic hunter–gatherers: ethno-archaeological approach of using water and animals in southern Jordan

Kazunobu Ikeya¹, Seiji Kadowaki²

¹National Museum of Ethnology, Suita, Japan. ²Nagoya University, Nagoya, Japan

Abstract

The inland Levant, including southern Jordan, is currently characterized by hyper-arid environments with less than 50 mm annual precipitation. Although paleoclimatic records show occurrences of more humid conditions in the Pleistocene, they were still in the range of semi-arid environments. Paleolithic adaptation to such dryland areas is a key topic for investigations of densely distributed Paleolithic sites in southern Jordan, particularly late Middle Paleolithic, Upper Paleolithic, and Epipaleolithic sites (Henry 1995; Kadowaki and Henry 2019). Herein, we present results of ethno-archaeological fieldwork examining the procurement of water and bird hunting in mountainous drylands in southern Jordan. The study area is used today by people subsisting on livestock herding (sheep, goat, and camels). In this very dry area, our survey found that local people use several pools to retain water for a long time after rainfall. Some pools, natural depressions in sandstone bedrock, are located near some Paleolithic sites, particularly Upper Paleolithic sites. The water is depleted at various times depending on the pool, but some pools apparently maintained water almost year-round. We also report our survey of bird hunting by local people using stone fall-traps to catch chukars. Chukars are one species identified from faunal remains from Tor Hamar, an Upper Paleolithic site in the same area. The use of such small birds in the Upper Paleolithic contrasts against the use in that area of ostriches during the Middle Paleolithic. In this way, our ethnographic fieldwork found exploitation of water and small birds even in the currently hyper-arid settings. These resource-use behaviors were achieved using simple technologies that are expected to have also been available in the Paleolithic. Therefore, they might have been key adaptive behaviors used by Paleolithic hunter–gatherers in the marginal settings of southern Jordan.

This research was funded by MEXT KAKENHI (No. 16H06409 and 16H06411) and The Mitsubishi Foundation (No. 30205).

Climate as a driver of stage 3 human dispersal through northern Mongolia

Clea Paine¹, Nicolas Zwyns^{2,3}, Evgeny Rybin⁴, Arina Khatsenovich⁴, Tsendendorj Bolorbat⁵, Byambaa Gunchinsuren⁵
¹University of Cambridge, Cambridge, United Kingdom. ²Department of Anthropology, University of California, Davis, Davis, USA. ³Department of Human Evolution, Max-Planck Institute for Evolutionary Anthropology, Leipzig, Germany. ⁴Institute of Archeology and Ethnography of the Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russian Federation. ⁵Institute for History and Archeology, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia

Abstract

The fluctuating climate of stage 3 has been seen as an important driver of human dispersal and cultural adaptation globally; climate-dependent changes in the extent and carrying capacity of the Eurasian steppe may have driven human dispersals across it. While much is known about the effects of high amplitude climatic oscillation in Europe, the magnitude and nature of these events in extreme continental central Asia is now a subject of considerable research interest. In northern Mongolia, which currently sits at the limit of the influence of the East Asian monsoon, stage 3 may have experienced a different precipitation regime than today. New terrestrial sedimentary records at upper Palaeolithic sites in northern Mongolia give evidence for climate and precipitation in this region over the past 45,000 years and more. The records preserve evidence for several successive human incursions during climatic ameliorations throughout stages 3 and 2, and for regional abandonment during deteriorations. These incursions include what is likely to be the first AMH presence in the region; because of its topography, northern Mongolia may have acted as a gateway to East Asia, and our research shows that this gateway probably opened and closed several times during stage 3.

50,000 years of continuity and change in the southern Kimberley deserts of Western Australia.

Jane Balme¹, Susan O'Connor²

¹University of Western Australia, Crawley, Australia. ²The Australian National University, Canberra, Australia

Abstract

Excavations on the edge of the Great Sandy Desert, southern Kimberley, Australia, have revealed 50,000 years of Aboriginal occupation. Recent research on a variety of local records from both archaeological and non-archaeological sites, including from fauna, macrobotanical remains, pollen, charcoal and speleothems, has provided a very detailed picture of environmental changes for this region over the same period. These records show that despite periods of weakening monsoon during the LGM and late Holocene, the deserts and semi arid zone were continuously occupied, albeit with likely restructuring of groups in the landscape and seasonally. There is also good evidence in the archaeological sites for changes in technology that might reflect adaptation to weakening monsoon activity. In this paper we discuss the occupation of arid Australia in the context of the broader Australian archaeological record.

O-5096

People in an extreme climatic place? Tasmanian Aboriginal responses during the LGM.

Richard Cosgrove¹, Jillian Garvey¹, Georgia Roberts²

¹La Trobe University, Melbourne, Australia. ²ARC Centre of Excellence for Australian Biodiversity and Heritage, Monash University, Melbourne, Australia

Abstract

The remarkable story of the earliest Tasmanian people begins with sea crossings in the tropical north of Sahul (New Guinea-Australia-Tasmania) about 55,000 years ago. Over the next 600 generations, they traversed the length of the continent for thousands of kilometres reaching what was then a rugged peninsula jutting into the Southern Ocean. By at least 40,000 years ago people walked across the exposed Bassian Plain when sea levels were 130 m below the present day and entered the frozen Tasmania landscape, making them the most southerly people on Earth at that time. They lived through the peak of the Last Glacial Maximum, inhabiting the river valleys of southwest Tasmania. Archaeological research here has identified numerous limestone caves and open sites that attest to the resilience and skill of these people, particularly their economic and social adaptations to this extreme late Pleistocene environment (Allen et al. 2016). These people planned their land use and utilized resources in a systematic manner in a challenging palaeoenvironmental setting.

Using skeletochronology (Pike-Tay et al. 2008), stable isotopes $\delta^{15}\text{N}/\delta^{13}\text{C}/\delta^{18}\text{O}$ in teeth and bone and, Fatty Acid Profile (FAMES - Fatty Acid Methyl Esters) methodologies, we have identified significant patterning in the rich faunal assemblages for systematic, seasonal resource acquisition in late Pleistocene southwest Tasmania. Paradoxically however, there is very little nutritional variability in the major prey animal, Bennett's wallaby, based on sex, age, geography or season (Garvey 2011). This marsupial appears to remain a reliable and stable source of high quality fatty acids in their bone marrow. This differs significantly from northern hemisphere reindeer that have greater nutrient variability according to sex, geography and season. Given the hemispherical dichotomy between seasonally stable and unstable resources, we postulate that this is also reflected in the two region's differing stone technologies during the LGM.

In this presentation we review more recent research on stable isotopes, comparative nutritional returns from the hunted prey animals and the technology used to acquire them.

The Younger Dryas and the colonisation of the Amazon

Jose Robinson¹, Jose Iriarte¹, Gaspar Morcote Rios², Javier Aceituno³, Veronica Ramirez Ruiz⁴, Francisco Cruz Jr⁴
¹University of Exeter, Exeter, United Kingdom. ²National University of Colombia, Bogota, Colombia. ³University of Antioquia, Medellin, Colombia. ⁴University of Sao Paulo, Sao Paulo, Brazil

Abstract

New archaeological data from Serrania de la Lindosa, Colombia, suggest climatic impacts on resources drove early human colonisation of the Amazon forest during the Younger Dryas. At the end of the Pleistocene, humans had entered South America and colonised the Bogota plateau when rising temperatures and greater precipitation established marshes and oak/alder landscapes that supported an abundance of resources, including megafauna. The return to glacial conditions during the Younger Dryas stressed high-altitude resources and drove the tree line down 300-600 m. This period coincides with the first evidence of human colonisation of the lowland forest-savanna ecotone, as revealed by multiple new contexts dating to ca. 12.5 kya in the rock shelters of Serrania de la Lindosa. The rock shelters show evidence of sustained and continued occupation and are accompanied by extensive rock art, which includes depictions of plants, animals, hand prints, geometric designs and now extinct megafauna. Archaeobotanical data reveal an increasing reliance on plant resources, many of which later become Amazonian hyperdominants. Integrated archaeological, archaeobotanical, climatic, and paleoecological data indicate that climatic change during the Pleistocene-Holocene transition impacted resources, causing a “push” from the Andean Plateau, and a “pull” to lowland forests, establishing the early human colonisation of the Amazon.

Did extreme aridity drive the earliest efflorescence of human culture?

Eleanor Scerri

Max Planck Institute for the Science of Human History, Jena, Germany

Abstract

The Aterian technocomplex is associated with the Last Interglacial and the spread of early *Homo sapiens* across North Africa. Aterian lithic technology has been described as 'arid adapted', while ecological studies have documented substantial environmental amelioration across the Sahara. With the archaeological and environmental dynamics mapped at different scales, there is an apparent mismatch between a 'Green Sahara' and the idea of humans living on the desert fringes. In this paper, the reasons why Aterian lithic technology are regarded as 'arid adapted' are critically assessed in the context of climate proxies and models for North Africa in Marine Isotope Stages (MIS) 5-3. These give insights into the ongoing attempt to identify how 'green was green', when it comes to the Sahara in MIS 5. Carrying capacity, mobility patterns and regional cultural variation are also explored in order to shed light on varied subsistence strategies and their relationships with the broader ecological patchwork of North Africa between MIS 5-3. The results will settle the debate: was the Aterian innovation the result of extreme aridity or not?

Abstract

Small islands are paradigmatic cases of anthropogenic impacts on ecosystems. Using lake sediment cores to reconstruct past human activities can help retrieve information about the environmental responses to different rates and degrees of change on these vulnerable ecosystems. On islands in Remote Oceania, the origin and timing of the first human settlements, and consequent ecosystem modifications are still under debate. Past landscape changes have been demonstrated by archaeological, palaeontological, palynological and geomorphological investigations. However, few sedimentological studies have been conducted so far on this topic in the area. In our study, we used a multiproxy approach, combining geochemical tools based on biomarkers (fossil molecules of known origin) with traditional sedimentological methods (total organic carbon, biogenic silica, grain size) on cores from three lakes of the west coast of Espiritu Santo, Vanuatu, each dating back ~ 1000 years. The catchments of the three lakes are under different anthropogenic influence. Lake Nopovois is located near a village, lake Vesalea is located near a garden, and lake Wunawae has no human settlement nearby. From the results, it is possible to identify different phases of human occupation. Lake Nopovois shows at the bottom of the core (60-80 cm) an undisturbed baseline. Starting from 60 cm all proxies indicate a modification in the catchment, here interpreted as human induced changes (*i.e.* soil erosion – increase in total organic carbon and grain size; lake eutrophication – increase in biogenic silica; changes in vegetation – *n*-alkanes results indicating a shift towards a less forested area and an increase in macrophytes on the lake surface). This signal is interrupted by the occurrence of two volcanic eruptions, confirmed by preliminary observations of tephra layers as well as by a sharp decrease of mean grain size. The results from the other two lakes (lake Vesalea and lake Wunawae) will allow us to compare catchments with different histories of human occupation and trace anthropogenic impacts linked to land use changes in the area.

Reconstructing last millennium hydroclimate from Kiritimati sediments using lipid biomarkers

D. Allie Wyman¹, Jessica L. Conroy¹, Magdalena R. Osburn², Alyssa R. Atwood³

¹University of Illinois at Urbana-Champaign, Champaign, USA. ²Northwestern University, Evanston, USA. ³University of California, Berkeley, Berkeley, USA

Abstract

Tropical Pacific climate phenomena, such as the El Niño Southern Oscillation (ENSO) and the Intertropical Convergence Zone (ITCZ), are major components of the global climate system. Due to the short and sparse observational record from the tropical Pacific, paleoclimate archives are necessary to understand the full range of climate variability in this region. Lake sediment records are particularly advantageous for assessing decadal- to centennial-scale terrestrial climate variability as they are typically continuous with high temporal resolution. To date there are only two lake sediment records from the central tropical Pacific, a key ENSO 'center of action' where precipitation is also highly sensitive to movements of the ITCZ. Here we use a lake sediment record from Kiritimati (2°N, 157°W), to reconstruct changes in lake water chemistry and climate over the last millennium.

A 91 cm sediment core spanning ~1150 years was collected from Lake 30, a brackish lake (28 ppt), in June 2017. High resolution X-ray fluorescence measurements show an increase in S relative to Ca (S/Ca) from 900 to 1300 CE, indicating a period of gypsum deposition, consistent with previous work. To more quantitatively assess changes in lake water balance and salinity, bulk hydrogen isotope values of total lipid extracts (δD_{TLE}) were measured at decadal resolution over the last millennium, and biomarkers were extracted for subsequent compound-specific δD analysis. δD_{TLE} increases significantly from 900 to 1300 CE, coinciding with the episode of gypsum precipitation, and the two variables are significantly correlated downcore ($r=0.53$, $n=67$, $p<0.001$).

The presence of gypsum is qualitatively indicative of more saline conditions, and enriched δD_{TLE} values during this period also indicate higher salinity, based on the empirical relationship between salinity and δD_{TLE} in surface sediments in Kiritimati lakes (Sachse and Sachs, 2008). This relationship, thought to be driven by changes in net lipid-water D/H fractionation under changing salinity, suggests a salinity range of 4-135 ppt in Lake 30 over the last millennium, with maximum values from 900-1000 CE. However, comparison of δD_{TLE} values with core lithology show depleted δD_{TLE} values corresponding to thicker, darker microbial mat units. This association between δD_{TLE} and microbial mat structures suggests variations in δD_{TLE} may also be driven by varying microbial community structure downcore. As microbial communities and salinity are likely correlated, understanding the effects of both salinity and microbial community structure on δD_{TLE} requires additional analysis. We plan future research on compound-specific δD , paired with inorganic carbonate $\delta^{18}O$ and detailed isotope-based hydrologic balance modeling, to further define the relationship between biomarker δD , salinity, and lake hydrology.

Abstract

The island archipelagos of the South Pacific were among the last places colonised by humans. Debates exist over the precise timing of the arrival of people, and the duration of the “long pause” between arrival in Tonga and Samoa, and the move east into remote Polynesia. There is also a debate over the driving motivation for the long voyages east with different scientific communities advocating climate, social unrest, population growth and a process of exploration. In part the debates have been caused by two issues; first the disparity between archaeological dates and those from other palaeoenvironmental archives, and secondly the absence of robust palaeoclimate records from the region. In this paper we report a new suite of multiproxy lake sediment archives from Samoa and the southern Cook Islands that reconstruct both hydroclimate and the process of human arrival. Use of short-lived materials for radiocarbon dating, brings lake dates in line with archaeologically derived estimates for the date of human arrival in both islands. Reconstructed hydroclimate from the same cores, reveal settlement occurring during or shortly after major dry phases on Samoa that coincide with a period of regional climate change supporting arguments for a climatic forcing for the decision to migrate east into the Pacific.

Abstract

Drastic changes in the vegetation diversity on Easter Island have been fairly documented by pioneer studies (Flenley and King, 1984; Orliac and Orliac, 2000). These rapid modifications, estimated between the XVI and the XVIII century, have been attributed to different potential origins, such as anthropogenic forcings (Flenley and Banh, 2007) or flora consumption by rats (Hunt and Lipo, 2007). Climatic variations, such as changes in the hydrological budget (drought occurrence), have also been suggested (Orliac, 2000; Rull et al., 2016), according to a possible migration of climatic fronts over the Pacific, expected within the Little Ice Age period (LIA), and/or unusual ENSO activities such as long-lasting La Nina events (Sachs et al., 2008; Nelson et Sachs, 2016; Delcroix et al., 2018).

This study focuses on a lacustrine sediment core taken from the Rano Aroi pond in May 2017. According to ¹⁴C measurements, this record covers the last 1200 years. A multi-proxy approach, focused on both the organic and inorganic fractions of these lacustrine sediments, is developed along the core and includes classic pollen, geochemical (bulk elemental composition, stable isotopes) and mineralogical (clay mineralogy) analyses, as well as microcharcoal quantification. By combining the past variations of these different tracers, episodes of erosion and/or weathering associated with the deforestation observed around the lake will be discussed, remembering that a temporal and spatial heterogeneity can exist between different local environmental records, as recently observed by Rull et al. (2015), between inland and coastal records.

Abstract

The arrival of Maori in New Zealand brought tremendous environment modifications to the island including clearing of forests by burning. Aside from landscape modifications, the Maori practiced horticulture and pasture, introducing non-native animals. However, the timing of their arrival stirs a debate on when exactly they landed on New Zealand: archaeological evidence suggests that Maori arrival commenced around 700 to 800 cal BP. However, oral Maori traditions suggest otherwise and that Maori could have arrived earlier than existing archaeological evidence.

Here we present downcore fecal sterol and leaf wax records from Lake Pupuke in the North Island of New Zealand spanning the past ~1700 years. Fecal sterols (5β -coprostanol+ 5β -epicoprostanol) are found in human wastes and can be used as tracers for prehistoric human presence. Leaf wax data (long-chain *n*-alkanoic acids) will allow us to evaluate changes in horticultural and pastoral activities.

Downcore coprostanol concentrations sharply increased at around 70 cm (~700 cal BP) which coincides with the known Maori arrival. They then decreased to the top of the core. Average chain length (ACL) and even-odd predominance (EOP) of long-chain *n*-alkanoic acids also co-vary with the sterol data, with an increase at around 70 cm (~700 cal BP) then showed an overall declining trend towards the top of the core. Interestingly, coprostanols were also detected between 160 – 130 cm (~1700 – 1500 cal BP). Similarly, ACL and EOP of *n*-alkanoic acid data showed an increasing trend at the same depth.

The detection of coprostanol at lower depths could imply a pre-Maori human presence on the island. Recent results from this core will also help us unravel when Maoris started pastoral activities around the lake and its implications on the land use change. These biomarker footprints will also help us to further define the timing of the arrival of Polynesians in the North Island of New Zealand as well as possible implications of concurrent climatic changes.

Changing conditions – the impact on chronological models of human colonisation of the South Pacific.

Fiona Petchey

Waikato Radiocarbon Dating Laboratory, University of Waikato, Hamilton, New Zealand. ARC Centre of Excellence for Australian Biodiversity and Heritage, James Cook University, Cairns, Australia

Abstract

While Holocene climate is of major interest globally, the period of specific importance to human colonisation across the Pacific region – the last 3500 years – has been poorly studied. This dearth of information has obvious implications for our understanding of the development of human societies, but few researchers have considered the impact of environmental changes on the ^{14}C dates which form the backbone chronology for human dispersal. Indeed, many supposed erroneous marine and estuarine shell ^{14}C dates are caused by differences in carbon circulation in the immediate environment (Petchey et al. 2018) and, when correctly interpreted, these dates can provide valuable information about past environments as well as significantly refining temporal models. Of note, new research into ^{14}C reservoir offsets (delta R) using archaeological material collected from the central Pacific Gyre suggest that a significant shift occurred between 2650 and 2250 years ago in response to changes in ocean circulation (Figure 1). Consequently, previously reported calibrated shell ages for this time period have been up to 200 years too old. This added chronological uncertainty has contributed to our inability to identify directionality and the drivers behind human movement. Moreover, this reservoir shift occurs at a critical time – a period of transition between earlier Lapita and later Polynesian cultures.

In this presentation, I apply these new reservoir findings to radiocarbon dates from key early archaeological sites in Tonga and Samoa. The results display demonstrable refinement to the chronology of this region with a suggestion of settlement, abandonment and resettlement as people forged ahead into new lands.

Figure 1. Change in marine reservoir offset (delta R) within the South Pacific over the last 3500 years.

Tectonics and sedimentation along the southern margin of the Alps (northern Italy) during the Pleistocene

Giancarlo Scardia

Universidade Estadual Paulista (UNESP), Rio Claro, Brazil

Abstract

Sedimentation along the southern margin of the Alps (northern Italy) during Pleistocene has been mostly dominated by glacial and fluvioglacial depositional systems. New stratigraphic and chronologic data gathered in the last decade provided new hints about the role of tectonics in controlling their spatial distribution and preservation during the Pleistocene. Early Pleistocene morainic deposits at the foothills of western and central Alps (Piedmont and Lombardy) have no preserved morphology and are usually completely buried under younger Middle Pleistocene deposits (stratigraphic mode 1). Conversely, Middle Pleistocene landforms are partially to fully preserved, according to a dominant pattern of nested morphologic units, getting progressively younger toward the inner part of the morainic amphitheatre (stratigraphic mode 2). In the Lake Garda area (Lombardy-Veneto), Early Pleistocene deposits are also preserved according to the mode 1. The mode 2 is only observed in its western part, as mode 1 remains dominant also during the Middle and Late Pleistocene. More eastward (Veneto and Friuli), the mode 1 is the only dominant stratigraphic style.

The occurrence of mode 1 and mode 2 stratigraphic arrangements is interpreted to reflect specific tectonic regimes, which acted along the southern margin of the Alps during the Pleistocene. Mode 1 is produced by low to moderate subsidence, getting the older units progressively buried under the younger ones, with no preservation of morphology. Such subsidence is ascribable to the geodynamic activity of Apennines, which dominated since the Pliocene tilting southward the Alpine foreland. To the East, Apennines-driven subsidence may have been locally enhanced by Alpine thrusts load. Mode 2 is interpreted to have been produced by the isostatic rock uplift of the Alpine range because of erosional unloading. Such isostatic uplift apparently became the dominant tectonic regime in the western and central Alps since Middle Pleistocene, due to enhanced climatic-drive erosion in the axial chain and likely to a progressively weaker activity of Apennines tectonics. In this scenario, the Lake Garda area lies well at the boundary between the western-central Alpine area, dominated by passive isostatic tectonics and the eastern Alps, where active tectonics produced by the Apennines northward migration and Adria plate indentation is still the main regime. The net product of this two competing regimes produced a progressive counterclockwise rotation of successive morainic amphitheatres during the Pleistocene. Geodetic topographic levelling is consistent with this interpretation, suggesting that both tectonic regimes are still ongoing today.

Middle– early Late Pleistocene Faunal complexes of Eastern Europe: recent interpretation

Vadim Titov¹, Alexey Tesakov², Vera Baigusheva³, Mikhail Golovachev⁴

¹Southern Scientific Centre RAS, Rostov-on-Don, Russian Federation. ²Geological institute RAS, Moscow, Russian Federation. ³Azov museum-reserve, Azov, Russian Federation. ⁴Astrakhan museum-reserve, Astrakhan, Russian Federation

Abstract

The main biostratigraphic subdivisions of the Pleistocene of Eastern Europe were traditionally based on large mammal associations (Gromov, 1948; Vereshchagin, 1957; Alekseeva, 1990). Subsequently, data on small mammals and other animal groups were added to their definitions (Shevchenko, 1965; Aleksandrova, 1976; Markova, 1982; Tesakov, 2004). The stratigraphic limits and sequence of faunal associations are constantly revised and modified with the emerging new data on stratigraphy, taxonomic diversity, and methods of dating. Currently Tiraspol and Khazar faunal complexes are distinguished for Eastern European Middle Pleistocene.

The Tiraspol theriocomplex (0.8-0.5 Ma, Galerian, MIS19-12) is characterised by *Lagurus transiens*, *Microtus gr. ratticepoides*, *Microtus nivaloides*, *Stenocranius gregaloides*, *Ursus deningeri*, *Mammuthus trogontherii*, *Equus suessenbornensis*, *E. cf. mosbachensis*, *Stephanorhinus hundsheimensis*, *S. kirchbergensis*, *Praemegaceros verticornis*, *Cervus acoronatus*, *C. elaphoides*, *Capreolus suessenbornensis*, *Alces latifrons*, *Bison schoetensacki* (Verestchagin, 1959; Nikiforova, et al. 1971; Vislobokova et al., 1990; Vangengeim et al., 2001). This association, typical for Eastern Europe, was also widespread in northern Eurasia. It is known from the south of Western Siberia (Vyatkino complex), Kazakhstan (Koshkurgan complex), and from North-Western China. In Western Europe its close biochronological match is the Cromerian fauna.

The Khazar faunistic complex (0.5-0.08 Ma, Aurelian, MIS11-8-5) includes *Spermophilus pygmaeus*, *Castor fiber*, *Trogontherium cf. cuvieri*, *Cricetulus migratorius*, *Ellobius talpinus*, *Lagurus lagurus*, *Eolagurus luteus*, *Arvicola ex gr. mosbachensis-chosaricus*, *Microtus oeconomus*, *M. arvalis*, *M. gregalis*, *Ursus (Spelearctos) savini rossicus*, *Mammuthus trogontherii chosaricus*, *M. intermedius*, *Palaeoloxodon antiquus*, *Stephanorhinus kirchbergensis*, *Elasmotherium sibiricum*, *Camelus knoblochi*, *Megaloceros giganteus*, *Cervus elaphus*, *Bison priscus*, *Saiga tatarica* (Gromov, 1933; Alekseeva, 1969; Titov, Golovachev, 2018). The volume of the Khazar theriocomplex has recently been extended after the revision of the fauna and stratigraphy of its type region in Lower Volga area. It is reasonable to merge the Singil and Shkurlat complexes with the Khazar one (Zastrozhnov et al., 2018). Thus, the Khazar complex spans a time interval between the Likhvin (=Holsteinian) interglacial up to the end of Mikulino/Eemian interglacial. It is also operationally reasonable to consider the Khazar complex as a biochron between the early Middle Pleistocene Tiraspol complex and the Late Pleistocene Mammoth complex. But until the better knowledge of the large mammal association of the mid Middle Pleistocene warm interglacials (MIS9 + MIS11), previously known as the "Singil theriocomplex", it is proposed to refer to it as "Likhvin" or "Gun'ki" fauna (Markova, 2007). This association is mostly characterized by small mammals. The range of the Khazar complex comprised a vast area from East Europe in the west through southern Western Siberia to Kazakhstan (Irtys complex) in the east. The correlative Aurelian faunas of Western Europe were generally similar in composition but had a number of differences at the genus/species level.

The study was supported by projects of the RSF No.16-17-10170, the RFBR No.18-05-00746.

⁶Department of Earth Sciences "Ardito Desio", University of Milano, Milano, Italy

Abstract

Grotta Romanelli (GR) is a cave opening along the Apulian coastline, considered since decades a key-site for the Paleolithic of Europe because of its infilling sediments revealing human frequentation since the Middle Pleistocene and. At the beginning of the last century, excavation activities developed in the cave until 40 years ago when a stratigraphic framework supported by radiometric datings (C14 and U/Th), geomorphological evidences, abundant fossil remains and archaeological findings was assessed. The stratigraphic setting recognized by Blanc (1928) revealed a complex sedimentary sequence. The lower succession was described, from the bottom to the top, as a high-energy beach deposit (K), referred to the MIS5e, a bone breccia (I) covered by a stalagmitic layer (H) U/Th dated at <69ky by Fornaca -Rinaldi and Radmilli (1968), the so-called 'terre rosse' (G), bearing Middle Palaeolithic artefacts and vertebrate fauna bounded on top by a second stalagmitic layer (F), U/Th dated at 40 ± 3 ky by Fornaca-Rinaldi and Radmilli (1968). However, the chronology of this lower sequence was repeatedly questioned and thus a new campaign of field work initiated in 2015, focussing on its reassessment.

The overall litho-stratigraphic framework was confirmed although the new detailed investigations revealed a more complex and differentiated succession of layers with different palaeoenvironmental significance. In order to solve the questions related to the reliability of the radiometric datings performed more than 50 years ago, eight samples from the two stalagmitic layers were U/Th dated and yielded dates ranging from 359 ± 86 ky (2σ) to 112 ± 1.3 ky (2σ). These new dates indicate that the succession formed between MIS11 and MIS5. To better constraint the palaeoenvironmental conditions for the succession we performed also C and O isotope analyses on the stalagmites, and micromorphological, sedimentological and mineralogical analysis of the 'terre rosse' layers. The new chrono-stratigraphical setting casts new light also on the sea-level changes features observable inside and outside of the cave. In fact, the beach deposits at the base of the succession overlay a notch carved in the Cretaceous limestone with *Lithophaga* boreholes extending from 7.3 m (cave entrance) up to 9.8 m asl (cave interior). The previous interpretation correlated the notch to the Last Interglacial sea level. The new studies evidenced the presence of a lower notch and a sub-horizontal terrace with gravelly beach deposits at about 4.4 m asl that, in the framework of the new chronostratigraphic framework, might be correlated to the MIS5e.

Abstract

The Younger Dryas (YD) climate episode (~12,850–11,650 calendar years before present [cal BP]) is an event recorded widely across the Northern Hemisphere. We conducted multiple analyses at high resolution of a YD-age sedimentary sequence from Stara Jimka, a paleolake in the Bohemian Forest, Czech Republic. Age-depth modeling indicates that, in our record, a central European warming trend was interrupted at ~13,020+/-110 cal BP by the sudden onset of cooling (120 y) known as the Gerzensee climate oscillation and marked by the deposition of fine-grained sediment at this location. That cooling episode ended at ~13,001+/-66 cal BP and was followed by a ~120-y-long warming trend. After that, the Laacher See tephra depositional event, dating to ~12,820+/-20 cal BP, continued an overall warming trend. The composition of the Laacher See volcanic tephra in this section likely corresponds to the middle eruption sequence. Finally, the deposition of glassy microspherules marks the onset of the YD climate change at ~12,755+/-92 cal BP. The sequence across the YD onset is marked by (1) a peak in glassy microspherules (117,000/kg), (2) a peak in framboidal spherules (14,000/kg), (3) significant changes in the lake's weathering proxies, and (4) major changes in local fauna (cladocerans, chironomids) and flora (pollen record, fire regime), showing a shift to unfavorable environmental conditions (decrease in temperature and lake trophy status). Collectively, this evidence is consistent with the co-called YD impact hypothesis and evidence of one or more cosmic airburst events occurring at this time. We have analyzed the radar ice record and both gravity and magnetic data over the Hiawatha crater in northwest Greenland and found not only that the impact was likely directed southward, but also that this impact could be the source of iron rich microspherules observed in the lake sediments in Czechia 12750 cal years BP.

Why should we care about biogeography when correlating Quaternary deposits? A perspective from the Europe's eastern border

Aleksandr Borodin^{1,2}, Evgenia Markova¹, Tatiana Strukova¹, Lidia Yalkovskaya¹, Sergey Korokin³

¹Institute of Plant and Animal Ecology UrB RAS, Ekaterinburg, Russian Federation. ²Ural Federal University, Ekaterinburg, Russian Federation. ³Nizhnevartovsk State University, Nizhnevartovsk, Russian Federation

Abstract

Biological proxies are traditionally used for relative dating and for correlation of sedimentary layers over different spatial scales. This study aimed to consider the potential and challenges of the geographic variation in implementing biotic proxies for geological correlation and for integration of regional data into continent-wide stratigraphic frameworks. The study is undertaken in the region of Trans-Urals, which delineate the Europe's eastern border along the meridionally stretched Ural Mountains. Among a variety of biotic proxies, we primarily focus on arvicoline rodents as the most biochronologically informative taxonomic group of small vertebrates in the Quaternary terrestrial ecosystems of the Northern Hemisphere. A region-wide revision of the subfamily Arvicolinae in the quaternary micromammal assemblages and correlation with the European micromammal faunas reveals incongruent positioning of several officially accepted stratigraphic units in the regional stratigraphic chart of the Southern Trans-Urals. Considering possible causes of those incongruences, we raise the question on the need to distinguish clearly between a biochronologically significant change and a biogeographical or ecological specificity of the species assemblages. Underestimated biogeographic patterns appear to be a major challenge for accurate geological correlation and for integration of regional data into continent-wide stratigraphic frameworks. However, when properly studied, geographic variation in the structure of natural communities provides a potential solution for the problem of continent-wide correlations across multiple natural landscape zones. Five latitudinal biochronological zones are established using the key taxa of arvicoline rodents for trans-zonal correlation of the Quaternary deposits across the Northern Eurasia. The developed approach of trans-zonal correlation is applied to link the European, Trans-Uralian, and West Siberian micromammal faunas dated back to the Early, Middle, and Late Pleistocene, including new data from the north of Western Siberia obtained during the field campaigns of 2016-2018. The study is supported by Russian Foundation for Basic Research, grant № 19-04-00966.

A radical reassessment of the stratigraphy, palaeoenvironmental processes and dating of the Middle Pleistocene deposits at Schöningen, northern Germany

Charles Turner¹, Brigitte Urban², Thijs van Kolfschoten³

¹Quaternary Environments Group, Department of Geography,, University of Cambridge, United Kingdom. ²Leuphana University, Lüneburg, Germany. ³Faculty of Archaeology, Leiden University, Netherlands

Abstract

Middle Pleistocene sediments exposed, between Elsterian and Saalian glacial deposits, during lignite quarrying at Schöningen have been a subject of continuing controversy. Famous for the discovery of Palaeolithic wooden hunting spears and evidence of horse butchery, Mania (Mania & Altermann 2014) and Urban (2007) recognised three separate interglacial intervals, associated with channel infills traversing the site. Authors of a Monograph on Schöningen (Behre 2012), however, considered the deposits assigned by Urban to Holsteinian and the Reinsdorf Interglacial as both of Holsteinian age, related to MIS 9, and laid down in a lake infilling a glacial tunnel valley, like other Holsteinian sites in northern Germany, consequently proposing, that the Elsterian glaciation related to MIS 10, not MIS 12, as generally believed in northern Europe.

This controversy highlights a failure to recognise the palaeoenvironments in which the channels and sediment sequences deposited within them were formed. Our new interpretation recognises a series of alluvial fans, on the western side of the valley in which the sequence of Quaternary deposits was conserved. These fans were initially formed at the onset of the Elsterian late-glacial, following melting of permafrost covering the Elm, the adjacent Muschelkalk massif, and reactivated after subsequent cold-climate stages. Powerful meltwater streams incised channels down the face of the alluvial fans and channels draining along the distal margins of the fans, cutting into glacial sediments flooring the valley.

In the North Pit organic deposits within channels cut into the fans, yielded characteristic but discontinuous Holsteinian pollen records. Some, originally referred to late-glacial interstadials, are reinterpreted and assigned to the earliest part of the interglacial. In the South Pit deposits of the Reinsdorf Interglacial, were preserved in a wide, well-incised marginal channel, cut by powerful meltwater, then abandoned and infilled by partly organic sediments, a repeated series of five shallowing cycles, showing typical seral development from open-water to fen woodland or reedswamp. Pollen analysis showed a sequence, beginning with fully temperate zones of an interglacial vegetational succession to a succeeding stadial and interstadial. Palaeolithic artefacts occur at all levels in this sequence, with the spear horizon belonging to cycle 4 (interstadial). The Reinsdorf Interglacial vegetational succession differs from that of the Holsteinian in significant characteristics, but also well-preserved large and small mammal faunas are distinctly different from those from Hoxnian deposits in England and other Holsteinian deposits, all ascribed to MIS 11. We relate the Reinsdorf sequence to MIS 9,

A third interglacial horizon, the Schöningen Interglacial of Urban, occupied a similar, smaller channel, incised along the margin of the fans in the North Pit. Palynologically, differing considerably from the Holsteinian and Reinsdorf Interglacials, it correlates closely with the Dömnitz Interglacial of Erd (1973) and is referred to MIS 7.

From classic to modern stratigraphy in the European context – an Alpine perspective (a contribution to the DATESTRA project)

Markus Fiebig, Christopher Lüthgens, Stephanie Neuhuber
University of Natural Resources and Life Sciences, Vienna, Austria

Abstract

Marine Isotope stratigraphy (MIS) shows that numerous glaciations (> 50) had a significant impact on a global scale, but it is a well-known challenge that these glaciations are only represented in a highly fragmented terrestrial records. This calls for an undisputable way of correlating terrestrial sediment records like the fourfold Alpine terrace staircases of fluvial meltwater terraces with the marine stratigraphy. Morphostratigraphical correlations, especially of meltwater terraces, by counting backwards using isolated continental erosional remains in a world of multiple sedimentation events during the Quaternary induced by bundles of cold spells, may likely be misleading.

In addition, it was demonstrated in Middle Pleistocene palynological maar sequences in Central France, that the pollen successions of different interglacials may resemble each other very closely. For Early Pleistocene pollen sequences this issue is also well known and documented. The close resemblance of the sedimentological and petrographical characteristics of the fragmented glacial and glaciofluvial sedimentary records on a regional scale, makes over-regional or global correlations highly challenging. However, during the last decades, numerical dating techniques have evolved as an important tool for the correlation of such records on a continental or even global scale. As the boundaries of dating techniques, and their resolution has been constantly pushed forward on a methodological level, an increasing number of data is available for time slices beyond the penultimate glacial cycle. For example, staircases of cover gravels in northern Switzerland were likely deposited during multiple glaciations, as revealed by numerical dating. First results from the Vienna basin area also indicate the preservation of deposits originating from multiple glacial cycles reaching back to the Early Quaternary. Furthermore, results based on numerical dating techniques may often contradict existing stratigraphical models. However, a thorough interpretation of numerical dating results against the background of sedimentological, petrographical, and geomorphological evidence is inevitable. Additionally, existing numerical data may have to be re-evaluated because of methodological progress during the recent past.

For the DATESTRA project it is recommended to focus on a thoughtful evaluation of numerical age data, to create a new backbone of European Quaternary stratigraphy. This attempt should be undertaken without the confining heritage of classical local and regional concepts of Quaternary stratigraphy.

The importance of Periglacial Processes in the Mercia Mudstone weathering profile, seen through current infrastructure projects in the English Midlands

Adrian Collings¹, Sebastian Gibson²

¹Arup, Solihull, United Kingdom. ²Cambridge Quaternary, University of Cambridge, Department of Geography. , Cambridge, United Kingdom

Abstract

The weathering profile of the Mercia Mudstone, as described by Chandler and Davis, reflects a variety of physical and chemical processes. Data from various infrastructure projects, including High Speed Two (HS2) Limited, has highlighted the importance of periglacial processes in the weathering profile of the near-surface Mercia Mudstone. A revision of the overlying glacial deposits in the English Midlands to the younger Wolstonian Stage, has further implication for identifying periglacial activity. The brecciation of the rock mass seen in the weathering profile (Zone III) and the inclusion of rare to occasional glacial-fluvial gravel in the near surface profile, are identified as the result primarily of periglacial processes, from the action of repeated cycles of permafrost advance and retreat over multiple Middle - Upper Pleistocene glacial stages. Near the surface this largely overprints the weathering resulting from the dissolution of the Carbonate and Sulphate component, which is more prominent with depth, particularly where there was originally a notable minor gypsum component.

The intense periglacial brecciation of the Mercia Mudstone in the Midlands, from multiple cold stages, generates a material with extremely closely spaced discontinuities, traditionally described as 'lithorelics'. The 'breccia' has enhanced permeability, and minor amounts of groundwater is frequently present, within a material that normally has low permeability. Sampling disturbance of the periglacial breccia, especially when little completely commutated material is present (clay matrix), can unhelpfully result in the material being described as 'gravel'. This is misleading, as Mercia Mudstone Zone III periglacial breccia is a very weak / extremely weak rock.

Distribution, morphology and preliminary dating of past thermal-contraction-cracking features in the Czech Republic

Tomáš Uxa^{1,2}, Marek Křížek¹, David Krause¹, Piotr Moska³, Lukáš Vohradský¹

¹Department of Physical Geography and Geoecology, Faculty of Science, Charles University, Prague, Czech Republic.

²Department of Geothermics, Institute of Geophysics, Czech Academy of Sciences, Prague, Czech Republic. ³Institute of Physics – Center for Science and Education, Silesian University of Technology, Gliwice, Poland

Abstract

Thermal-contraction-cracking features, such as ice or sand wedges, develop due to rapid temperature drops in perennially frozen sediments. They typically occur in regions with mean annual air temperature lower than -8 to -4 °C and at least discontinuous permafrost. Their relict imprints therefore testify to very low temperatures and permafrost presence at the time they evolved. These pseudomorphs and casts have been extensively surveyed across Europe in order to delimit former permafrost extent and to infer paleoclimate conditions. The evidence from Central Europe and the Czech Republic in particular is, however, very scattered and mostly concealed to the international audience. Our intent therefore is to describe the distribution and morphology of past thermal-contraction-cracking features in the Czech Republic and to provide their first dating results.

We inventoried relict ice-wedge and sand-wedge occurrences based on mapping of their polygonal cropmarks identifiable on aerial images (from 2001, 2003, 2006, 2009–2010, 2012, 2014–2015, 2016–2017), field investigations in mining pits or technical excavations, and literature survey. Surface and subsurface morphology of former ice and sand wedges was investigated on selected sites in detail and samples of their infill as well as host materials were collected for sedimentary analyses and OSL dating.

We identified over 2000 sites where ice-wedge pseudomorphs and sand-wedge casts occur. The patterns concentrate particularly in the lowlands of the Bohemian Cretaceous Basin, Moravian Basins, and South Bohemian Basins, with altitudes of up to around 300 m asl. The wedges mostly occur in sand-gravel materials of Pleistocene river terraces or silt-rich loess covers and consist of aeolian sands, fossil soils, or collapsed host materials. They usually have a width of 0.1–1.5 m and are mostly up to 1.5–2.0 m deep. The polygons are between 2 and 32 m in diameter and usually have five to six sides. Their networks are therefore believed to have reached the mature stage of development. The preliminary OSL ages suggest that the wedges underwent multiple periods of activity during the Last Glacial Period, with the final phase probably coincident with the Last Permafrost Maximum.

Our database of past thermal-contraction-cracking features in the Czech Republic is one of the most extensive in the world and well documents the Late Pleistocene permafrost extent and its evolution in Central Europe.

The Czech Science Foundation, project number 17-21612S, supported this research.

Abstract

The European Loess Belt is the most extensive continental archive of the Last Glacial period (Weichselian) in Europe. Located eastward of the North Atlantic region, this large area was ideally situated to record the impact of millennial-timescale climatic fluctuations (i.e. Dansgaard-Oeschger cycles, Heinrich Events). In the western part of the European Loess Belt, strongly affected by periglacial processes during the Last Glacial, recent investigations focusing on the most continuous loess-palaeosol records (pedostratigraphy, dating, sedimentology, malacology), allowed to evidence numerous occurrences of periglacial features and especially large ice-wedge casts. Several networks of ice wedge casts have been studied and dated by luminescence (OSL) and radiocarbon (¹⁴C) methods during the last 10 years. By comparison with present-day high-latitude tundra environments, these features are considered as the best witnesses of permafrost conditions in northwestern Europe. In this presentation we will focus only on the northern France loess-palaeosol records in which at least four large ice wedge casts polygonal networks (10-20 m in diameter), separated by loess deposits, have been identified within the Last Glacial sequences. They are systematically connected with tundra gley horizons representing former permafrost active layers. On the basis of a new ¹⁴C dating protocol developed for earthworm calcite granules, which are particularly abundant in the upper part of tundra gley horizons, a robust chronology is now available. It reveals that tundra gley layers associated to the four main ice wedge cast networks are dated between ca. 45 and 22 ka. According to their geographical distribution pattern, these features appear to be typical of the west-European loess domain where they are connected with permafrost environments richer in ice than eastward. However, based on accurate dating of the loess infilling of the different ice-wedge casts, and detailed correlations with the North GRIP climate record, ice-wedge networks appears to have developed only during some specific phases. Thus, these features typify original palaeoenvironmental and palaeoclimatic conditions that are still to be characterised in the frame of a modelling approach involving inlandis, sea-ice extent, atmospheric circulation and North GRIP temperature reconstructions.

Abstract

Perennial frost mounds (pingos, palsas and lithalsas), also known as 'ice-cored hills', are indicative of cold, periglacial environments. During the Last Glacial Maximum (LGM) (c. 23–19 ka) frost mounds formed across northwest Europe, North America and northern Asia. Upon melting, frost mound relict forms comprise depressions with surrounding ramparts, otherwise known as periglacial ramparted depressions (PRDs). The surface geometry of PRDs is well-documented, but there is little agreement on: (i) the definitive identification of PRDs, and (ii) PRD genesis. This research characterises the internal structure of a PRD (a relict lithalsa), on the Belgium-German border at the micro-scale. Microstructures include those indicative of (i) cryogenic origins (e.g. frost-jacked grains, aggregates, fragmented domains, silt/clay grain and void cappings etc.), and (ii) PRD formation (e.g. tilted strata, grain arrangements/concentrations/coatings, multiple domains, fragmented domains, plasmic fabric etc.). This specific suite of microstructures, for the first time, provides a toolkit for the identification of suspected relict frost mounds elsewhere, which is critical to inform (i) landform evolution, (ii) palaeoenvironmental reconstruction, and (iii) civil engineering projects in Quaternary periglacial deposits.

Glacial ice-buttressing controls occurrence and timing of a rock slope failure (RSF) during Late-Pleistocene deglaciation: English Lake District case study.

Paul Carling^{1,2,3}, Teng Su^{4,5}

¹Henan University, Keifeng, China. ²University of Southampton, Southampton, United Kingdom. ³Lancaster University, Lancaster, United Kingdom. ⁴University of Chinese Academy of Sciences, Beijing, China. ⁵Chinese Academy of Sciences, Beijing, China

Abstract

The role of glacial ice in buttressing rock slopes and thus preventing slope failure until ice down-wasting leads to loss of ice-support is speculative/controversial, as are the mechanics of failure where ice-support is progressively removed. The latter two issues are the focus of this presentation. An arrested, translational, rock slope failure (RSF) is described, dated, and the controls on the failure mechanisms are modelled. The hypothesis '*that glacial-ice buttressed an otherwise steep, faulted, and incompetent rock slope*' is tested. The RSF location is within Great Coum (Lat. N: 54.392311; E: -2.605696), a small cirque in the Southern Shap Fells.

The bedrock is Silurian Coniston Group, a jointed, friable greywacke, in thin beds <3m thick. Nevertheless, the bedding in the RSF is undistorted showing the wedge descended very slowly. Small-scale faulting in the parent rock is frequent, so fault alignment and dips in the vicinity of the RSF were mapped. The unsupported rock wedge was modelled using *Swedge*[®] version 6.0 (2018) rock-slope stability software, to analyse the 3D failure as the rock mass slid along a basal failure plane bounded on each side by a fault. Field-derived parameter values determine the stability of an ice-free rock mass. Uncertainty was considered: > 30,000 simulations, varying values systematically to isolate the most probable model. The probability of slope failure was 96%; factor of safety: 0.74 - 0.94. In 4% of cases, a marginal factor of safety: 1.07 - 1.22 was achieved, but wetting 20 - 30% of the fault planes caused the slope to fail.

Thus, the need to consider the role of ice buttressing of the wedge is evident, as there is no other way in which the slope could have been supported to descend slowly. Three scenarios were considered: (i) ice was a static load variably distributed across the slope; (ii) ice moved towards the slope; (iii) ice moved away from the slope. In any permutation, the ice cover required to maintain slope stability is 17 - 29% of the potential maximum ice volume above the slope, indicating that the slope would have remained stable as long as there was a sufficient small degree of ice buttressing - which implies slow failure occurred beneath partial ice cover during final cirque deglaciation, supporting the hypothesis.

To determine when the slope was first exposed to light as ice receded from the cirque, two surface rock samples were obtained from a prominent thick strata within the RSF mass. In addition, two samples were obtained from a slickenside surface in the headwall above the RSF to determine when the RSF first exposed the failure plane. Two samples are submitted for cosmogenic dating and two samples are submitted for luminescence exposure dating. These results should be available in July 2019.

Glaciation of the northern Peak District, England: Evidence of plateau icefield and cirque glaciations

Benjamin Boyes¹, Chris Clark², Stephen Livingstone², Henry Patton³

¹University of Brighton, Brighton, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom. ³UiT The Arctic University of Norway, Tromsø, Norway

Abstract

The northern Peak District, England, has traditionally been considered a relict periglacial landscape that lay beyond the limits of the last Quaternary glaciation (Burek, 1991; Clark et al., 2018). However, a variety of landform assemblages and sedimentary evidence indicates two independent episodes of glaciation: cirque glaciation, and more extensive plateau icefield glaciation.

Three cirques are proposed: two on the Peak District's highest hill, Kinder Scout, and one on Bleaklow Hill. Evidence includes rounded head walls, morainic ridges, and channel-like features. The Seal Coombes, on Kinder Scout (first described by Johnson, 1987), are the most unequivocal palaeo-glaciers in the northern Peak District. Reconstructed Equilibrium Line Altitudes (ELA) for these glaciers is c. 549 m asl. Barrow Clough, on Bleaklow Hill, has undergone significant post-glacial fluvial erosion. Nevertheless, the compelling glacial landforms indicate cirque glaciation at this site. Reconstructed ELA for this glacier is c. 555 m asl.

Plateau icefield glaciation is proposed for the plateaux of the northern Peak District. The glacial signature is recorded in channel-like features, hummocky terrain, and arcuate and linear ridges. The orientation of the landforms, radiating from the plateaux, suggests that ice cover on the plateaux flowed down pre-existing valleys. This is supported by analysis of clasts within morainic landforms, which indicates glacial transportation of material from the plateaux to the valleys. Gritstone tors across the Peak District were recorded to assess their distribution. A lack of tall (> 1 m) tors in the centre of expansive plateaux was observed, with tall tors being more abundant on narrower summits. This suggests that ice cover on plateaux preferentially removed tors or inhibited their development, while protective ice cover on narrower summits above valleys would have protected tors. Degraded tor stumps are observed on narrow summits away from plateaux, indicating a lack of ice cover during glacial episodes on these summits. Plateau ice would have been predominantly thin and protective, while channelled ice at valley heads would have been thicker, allowing modest glacial erosion. Transient, 3D model experiments, forced under a range of probable climate scenarios through the last glacial period, support the evidence for independent cold-based ice cap(s) within this marginal region of upland glaciation.

The geomorphological and sedimentological implications of bedrock megarrafts in central Alberta

Emrys Phillips¹, David Evans², Nigel Atkinson³

¹British Geological Survey, Edinburgh, United Kingdom. ²Durham University, Durham, United Kingdom. ³Alberta Geological Survey, Edmonton, Canada

Abstract

The creation of subglacial bedforms by substrate groove-ploughing remains as a hypothesis in need of more systematic testing, especially in field settings. The accomplishment of groove-ploughing by rough ice stream soles has so far not received much support, but small scale groove-ploughing by clasts has long been acknowledged in till sedimentology and hence the potential for large bedrock blocks to be ploughed through ice stream beds to create streamlined landforms needs to be investigated. Glacitectonically displaced and glacial overridden/streamlined bedrock blocks are widely recognized on the prairies where their landform imprint has been classified as “rubble moraine/terrain”. Landform mapping from LiDAR imagery combined with sedimentological investigations of the palaeo-ice stream beds of central Alberta has identified a range of diagnostic landforms indicative of substrate ploughing and grooving by bedrock megarrafts. We identify: a) isolated bedrock plough marks and shallow grooves flanked by paraxial ridges with terminal bedrock blocks in place; b) ridge/furrow corrugations terminating at arcuate frontal sediment prows; c) flutings extending down-flow from bedrock blocks; and d) elongate assemblages of apparent bedrock blocks that comprise “rubble flutings”. In situ bedrock megarrafts are associated with complex glacitectonites derived partially from the disintegration of the rafts in combination with the cannibalization of pre-existing Quaternary deposits. Such stratigraphic relationships support the notion that the megarrafts have been dragged through the substrate, ploughing it up to form prows and ridges and thereby lodging at the ice stream bed. The styles of landform so created are indicative of the stage of ice stream operation at their time of production in the deforming layer.

Leveraging Big Data in palaeoentomology: direct linking and conceptually mapping between archaeology and palaeoecology

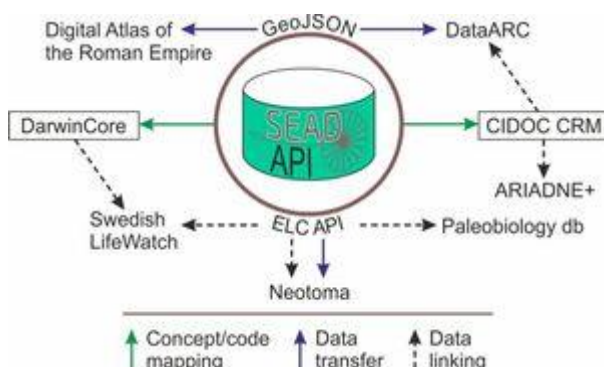

Philip Buckland, Francesca Pilotto, Mattias Sjölander
Environmental Archaeology Lab, Umeå University, Umeå, Sweden

Abstract

The Bugs fossil insect database evolved from a research bibliography (www.bugscep.com/qbib.html) into a database of palaeoentomological research results, with species internally linked to referenced modern habitat and distribution data. Its current form, the Bugs Coleopteran Ecology Package (www.bugscep.com), is a freely downloadable integrated database and software package for analysing both fossil and modern insect assemblages, including a number of statistical tools for interrogating the fossil and modern data in combination. Approximately half of the 1300 datasets are from archaeological sites, and half from other Quaternary sites. The system is being replaced by components in the online, collaboratively managed, multiproxy Strategic Environmental Archaeology Database (www.sead.se), where insects are just one of numerous data types.

SEAD forms part of a network of palaeoecological and archaeological research data infrastructure, including Neotoma, PBDB, DataARC, Ariadne and a number of other systems linked through API's, data feeds and concept maps. This network provides almost limitless possibilities for interrogating changes in Quaternary environments, climates and human-environment interactions. It also poses a number of challenges for both users and developers in terms of the use of the data across disciplinary boundaries, and the provision of tools that facilitate powerful, reproducible analyses through intuitive interfaces.

This presentation will highlight recent advances, and emerging challenges, in the use and development of this infrastructure ecosystem, and showcase some preliminary results provided by the linking of fossil insect data to modern biodiversity platforms through the Swedish LifeWatch (www.swedishlifewatch.se) and Swedish Biodiversity Data Infrastructure (<https://bioatlas.se/>) initiatives.

The HORNET project: applying 'big data' to reconstruct the climate of the Northern Hemisphere during the Holocene

Philipp S. Sommer¹, Basil A. S. Davis¹, Manuel Chevalier¹, Jian Ni², John Tipton³

¹University of Lausanne, Lausanne, Switzerland. ²Zhejiang Normal University, Jinhua, China. ³University of Arkansas, Fayetteville, USA

Abstract

Pollen data remains one of the most widely geographically distributed, publicly accessible and most thoroughly documented sources of quantitative palaeoclimate data. It represents one of the primary terrestrial proxies in understanding the spatial pattern of past climate change at centennial to millennial timescales, and a great example of 'big data' in the palaeoclimate sciences. The HORNET project is based on the synthesis and analysis of thousands of fossil and modern pollen samples to create a spatially and seasonally explicit record of climate change covering the whole Northern Hemisphere over the last 12,000 years, using a common reconstruction and error accounting methodology. This type of study has been made possible only through long-term community led efforts to advance the availability of 'open big data', and represents a good example of what can now be achieved within this new paradigm.

Primary pollen data for the HORNET project was collected not only from open public databases such as Neotoma, Pangaea and the European Pollen Database, but also by encouraging individual scientists and research groups to share their data for the purposes of the project and these open databases, and through the use of specifically developed digitisation tools which can bring previously inaccessible data into this open digital world. The resulting project database includes over 3000 fossil pollen sites, as well as 16000 modern pollen samples for use in the pollen-climate calibration transfer-function. Building and managing such a large database has been a considerable challenge that has been met primarily through the application and development of open source software, which provide important cost and resource effective tools for the analysis of open data.

The HORNET database can be interfaced through a newly developed, simple, freely accessible, and intuitive clickable map based web interface. This interface, hosted on the version control system Github, has been used mainly for quality control, method development and sharing the results and source database. Additionally, it provides the opportunity for other applications such as the comparison with other reconstructions based on other proxies, which we have also included in the database. We present the challenges in building and sharing such a large open database within the typically limited resources and funding that most scientific projects operate.

Recent advances with the Neotoma Paleoecology Database

Eric C. Grimm¹, Thomas Giesecke², Simon Goring³, Suzanne E. Pilaar Birch⁴, John W. Williams³

¹University of Minnesota, Minneapolis, USA. ²Utrecht University, Utrecht, Netherlands. ³University of Wisconsin, Madison, USA. ⁴University of Georgia, Athens, USA

Abstract

Databases incorporating paleodata across time and space have been instrumental for understanding earth system history. Initially, computerized databases were typically designed for individual data types or groups of organisms. These databases were highly successful, used to address a broad range of scientific research questions, and supported numerous publications. A major advantage of the single proxy databases was that disciplinary experts controlled taxonomy and data quality. Disadvantages were maintenance of continued funding and difficulty of using single-proxy databases to address interdisciplinary multiproxy questions. In addition, no databases existed for some data types, and the existing databases were not easily extensible. To address these problems, the Neotoma Paleoecology Database (www.neotomadb.org) was developed.

Neotoma was initially developed to incorporate a range of existing databases for pollen, plant macrofossils, vertebrate fauna, ostracodes, and diatoms, with the intent to incorporate additional data types for which no databases currently existed. The database is highly normalized, which facilitates the wide range of data types. New tables can be added to accommodate idiosyncrasies of additional data types. Although Neotoma is a centralized database, it is designed as underlying cyberinfrastructure for a consortium of constituent databases for individual proxies. These constituent databases can control their own taxonomies and data quality. Central to the concept of Neotoma is that it is a community-curated data resource (CCDR). Constituent databases appoint data stewards who ensure data completeness and quality; thus the data are curated and vetted, not simply deposited. Moreover, Neotoma is a living database. While original contributions are archived, the living database incorporates updated, taxonomic revisions, and new age models based, for example, on new radiocarbon calibration curves or new age modeling techniques.

New data types incorporated into Neotoma include, among others, insects, testate amoebae, organic biomarkers, stable isotopes, and deep-time palynological data. Some of these data types, such as insects, testate amoebae, and organic biomarkers, fit within the existing Neotoma data structure. Others required additional tables or fields. Accommodation of stable-isotope data required the addition several new metadata tables. An addition to the general Neotoma structure has been support for specimen-level data, for example, individual mammal bones or teeth, which may have museum catalog numbers. Currently, stable-isotope measurements and radiocarbon dates can be stored for individual specimens. Deep-time palynological data are “form taxa” that may have well to poorly understood affinities to modern taxa. While, the form taxa can be accommodated within the existing Neotoma Taxa table, a new table is required to record differing opinions regarding taxonomic affinity. Neotoma welcomes inquiries from potential contributors and collaborators with expertise in existing or new paleo data types.

Specimen Level Stable Isotope Data in the Neotoma Paleoecology Database: Mobilization and Applications in North America

Suzanne Pilaar Birch, Matthew Veres
University of Georgia, Athens, USA

Abstract

The Neotoma Paleoecology Database (neotomadb.org) functions as an interdisciplinary, open access database for the paleoecology community. Primary data types include proxies such as pollen, vertebrate remains, diatoms, and middens. A new repository within Neotoma has recently been created, allowing for the integration of specimen-specific stable isotope data with existing data types at the site and regional level. Neotoma serves as a hub for storing and accessing diverse types of data and offers an unparalleled opportunity for visualizing the intersection of multiple strands for paleoecological reconstruction from the macroscopic to microscopic and biogeochemical scales. To date, one of the limiting factors in stable isotope studies for our understanding of variability across not only spatial but also long-term temporal scales has been a lack of data exchange and integration. As multiple stable isotope data repository initiatives have arisen in the last few years, Neotoma has the ability link these various open data sources, allowing a cross-comparative, big-data approach. This paper discusses the development, launch, and initial population of the stable isotope repository with published stable isotope data from archaeological sites across North America. It explores data integration along with issues that exist as challenges for the future, including establishing best practices and standardization in recording/reporting, monitoring data quality, linking datasets, and increasing accessibility while protecting sensitive information.

Abstract

Speleothems provide highly resolved records with the potential to reconstruct past changes in mean regional climate and climate variability on annual to millennial timescales. The most common type of measurements made on speleothems – the stable isotopes of oxygen ($\delta^{18}\text{O}$) – can be used to evaluate climate models that explicitly include isotopic tracers, although this has rarely been done because of the lack of a global synthesis of the records. Here we compare speleothem isotope data from the SISAL (Speleothem Isotopes Synthesis and Analysis) database and the outputs of the isotope-enabled ECHAM5-wiso model for the Last Glacial Maximum (21 ka; LGM), the Mid-Holocene (6ka; MH) and the modern (1850 – 2013) periods.

The speleothem records have less temporal variability than either the GNIP measurements or model outputs, as a result of the low-pass filter that is effectively applied to these records because of the groundwater residence time in the aquifer. However, ECHAM5-wiso is able to reproduce the SISAL observations both globally and for several key transects during the MH and the LGM. Similar global patterns are found in the oxygen isotope MH anomalies of both SISAL data and ECHAM5-wiso simulations ($n=34$), albeit with different absolute values probably due to the temperature-dependent isotope fractionation between $\delta^{18}\text{O}$ in precipitation and that of calcite. The limited availability of SISAL data covering both the LGM and the pre-industrial ($n=11$) precludes the construction of global anomaly patterns for this time period. Yet, MH vs LGM comparisons ($n=20$) are in accordance with simulated deviations in $\delta^{18}\text{O}$. We observe a good agreement in $\delta^{18}\text{O}$ gradients over a N-S transect from mid-latitude Europe to south Africa during the LGM, although sites adjacent to the Black Sea and some sites in coastal regions of western Europe show strong differences from the simulated data. A good data-model agreement is also observed in a NE-SW transect over America. These results are also consistent with pollen-based mean annual temperature reconstructions. Speleothem age-depth model uncertainties, and choices of the temporal window width do impact the mean isotope values obtained for the LGM and thereby the uncertainties for data-model comparisons, but not strongly.

In this presentation, we will also highlight the use of metadata included in the SISAL database to screen the paleorecords used for data-model comparisons, discuss the benefits and weaknesses of using speleothem records for such comparisons, and how our approach can be applied to assess other isotope-enabled climate model simulations.

O-5125

Evaluating the influence of climate and humans on functional diversity gradients in North America and Europe

Thomas Brussel, Simon Brewer
University of Utah, Salt Lake City, USA

Abstract

The latitudinal biodiversity gradient (LGB) is the fundamental, global pattern of species distributions and is described as the phenomenon of declining net biodiversity with increasing absolute latitude. Although the LGB is hypothesized to be a universal biogeographical diversity pattern, there has yet to be a consensus reached on the causal mechanisms driving the gradient. Additionally, modern patterns are dependent on previous environmental conditions that established over geologic time, but an understanding of how these patterns developed in relation to climatic configurations over long-time scales is largely uncertain. Within the global configuration, however, is an apparent macro-scale pattern of functional biodiversity.

In the current study, we assess how the latitudinal functional diversity gradient changed in North America and Europe over the past 15,000 years. Functional traits are linked to pollen records and Hutchinsonian hypervolumes are used to quantify estimations of functional trait space at alpha and gamma diversity scales. We also compared trends in diversity to known, large-scale paleoclimate drivers of vegetation change, namely humans and temperature reconstructions from the NGRIP ice core to identify drivers of biodiversity.

Results indicate the dynamics of this diversity pattern, in that the functional gradients of the two continents developed independent from one another as the exchange of function between sub-regions varied through space and time. Significant changes in the gradients of the two continents correspond with climatic and anthropogenic influence. In total, the outcomes provide a basis for understanding how the LGB may be altered with continued global change.

Abstract

Despite long history of investigations, reconstruction of the Late Weichselian ice sheet retreat through the eastern Gulf of Finland (EGoF) basin, the Baltic Sea, is still a problem due to lack of data from the marine environment. Morphological and chronological deglaciation markers are primarily located onshore, showing that deglaciation occurred between 13.8 ka BP (Pandivere-Neva stage) and 12.25 ka BP (Salpausselkä I stage).

Geographic Information System (GIS) analyses of modern sea-bottom relief map of the EGoF, recent bottom and relict (till surface) relief, and sediment cores description allowed to establish the most probable location of the submerged Late Weichselian end-moraine complexes.

In 2017, a detailed study of the eastern Gulf of Finland seafloor was executed to identify and map submerged glacial and postglacial geomorphologic features. Two key areas within the Gulf were investigated using a multibeam echosounder SeaBat 8111 and an EdgeTech 3300-HM acoustic sub-bottom profiling system. These data and resultant thematic maps revealed for the first time such features as streamlined till ridges, end-moraine ridges, and De Geer moraines that are used for reconstruction of the deglaciation in the eastern Gulf of Finland.

High-resolution study of sediment cores has shown that varves of proximal facies consist of alternation of brown clays and grey silty-clays; varves of distal facies are finer. Sedimentation rate of glaciolacustrine proximal facies varies from 20 to 100 mm/year; distal facies – from 6 to 37 mm/year. Sediments of the Baltic Ice Lake for the most part of the cores are characterized by very fine grained composition indicating very calm near-bottom dynamics, and practically do not change laterally. Paleomagnetic investigations of the Baltic Ice Lake sediments allowed to receive the first dates for sequence forming the Baltic Ice Lake deposits of EGoF. It was dated for time period from 13.3 to 11.7 ka BP. According to paleomagnetic data, sedimentation rates in the upper part of Baltic Ice Lake sediment sequence is about 1 mm/year.

Interpretations of the seismic-reflection profiles, 3D models showing the surfaces of till, and the identification of the Late Pleistocene sediment and modern bottom relief indicate deep relative water-level fall in the Early Holocene.

Several 4D models of ice thickness and relevant isostatic transformations during the late-glacial deglaciation are tested different methods and sets of constraints. The approach is to get best fit scenarios of ice retreat and landscape evolution in agreement with geological - geophysical research in key areas, chronostratigraphy and reasonable parameters in GIA reconstructions.

Field work undertook with a support of the state assignment of IO RAS (Theme No. 0149-2019-0013). Data analyses and interpretation carried out under project № 17-77-20041 of Russian Science Foundation. High-resolution sedimentological research and modeling supported by RFBR project 19-05-00768. Results was used in EMODNET-geology project.

Abstract

The Irish Sea Ice Stream (ISIS) has long had one of the best documented retreat histories of the British-Irish Ice Sheet (BIIS) and was the first ice stream to be constrained by Bayesian analysis of geochronological data. These attributes made it a model system for the BRITICE-CHRONO research project, which aims to produce the best constrained retreat record of any palaeo-ice sheet contributing key observational constraints for ice sheet modelling. The project has generated a suite of new radiocarbon ages from deglacial sequences offshore in the Celtic and Irish seas and terrestrial cosmogenic nuclide and optically-stimulated luminescence ages from ice-marginal sites in the Isles of Scilly, Ireland, Wales and NW England. The ISIS was unusual within the former BIIS, in that it was a compound ice stream with two outlets, one marine terminating that flowed through the Irish Sea Basin into the Celtic Sea, and a terrestrial terminus that flowed southwards through Cheshire-Shropshire lowlands into the English Midlands around 25.5 ka. Here we assess the retreat dynamics across the entirety of the ISIS, integrating the new chronology in a revised Bayesian analysis that constrains the pattern and timing ice marginal fluctuations. The retreat chronology in the Irish Sea is better constrained than in the Celtic Sea, where the ISIS is now recognised to have extended as far as the continental shelf break to the SW of Britain and Ireland between 24 and 27 ka; this advance was synchronous with independently-dated ice-rafted detritus from ISIS in adjacent deep-sea cores. The ISIS then retreated rapidly northwards through the Celtic Sea, with evidence for readvance phases, deglaciating the Isles of Scilly at 25.5 ka, reaching St Georges Channel by 24.3 ka and the Llŷn Peninsula by 23.9 ka. The initiation of retreat from both the eastern (terrestrial) and western (marine) components of ISIS was synchronous. The eastern terrestrial lobe had vacated the Cheshire-Shropshire lowlands by 22-21 ka. The complex readvance sequences identified on the Llŷn (24-20ka) and in eastern Ireland have now been tightly constrained to register centennial-scale oscillations of the ice front driven by internal ice dynamics over topographic pinning points and constrictions of the ice-stream. Retreat northwards into the northern Irish Sea then accelerated, first evacuating the deeper water of the western Irish Sea, and developing pronounced ice margins across the northern Isle of Man by 19.1 ka. The final retreat phase, with ice margins pulling back onto terrestrial settings in the English Lake District, the north of Ireland and SW Scotland around 17 ka, was a deglaciation accomplished in a fully marine context evidenced by the preservation on the seabed of subglacial landforms and by increasing influence of local ice sources with flow realignment during draw-down and ice margin retreat.

The erosional impact of the Eurasian ice complex during the Weichselian glacial cycle

Henry Patton, Alun Hubbard, Karin Andreassen, Monica Winsborrow
UiT The Arctic University of Norway, Tromsø, Norway

Abstract

The Eurasian landscape has experienced repeated large-scale glaciations throughout the Late Quaternary. However, the scarcity of empirical evidence for glaciations prior to the Last Glacial Maximum has limited modelling insights, despite the importance of recurring ice sheet glaciation on, for example, landscape evolution, geohazards and hydrocarbon reservoir dynamics. We simulate the evolving Eurasian ice sheet complex since the last interglacial (Eemian; MIS 5e, < 122ka) by extending and adapting previous empirically constrained, high-resolution experiments of the Late Weichselian ice complex to a full glacial cycle. Three major ice advances are considered: 1) the Early Weichselian (MIS 5d-5a; 100-75 cal ka BP), 2) the Mid Weichselian (MIS 4-3; 70-50 cal ka BP), and 3) the Late Weichselian (MIS 3-2; 35-10 cal ka BP). Current consensus indicates a general east-to-west trend of glacial dominance during these successive glaciations, shifting from a Kara Sea-centric ice complex to one monopolized by the terrestrial-based Fennoscandian ice sheet. The broad-scale pattern and impacts of glaciation thus diverged significantly, likely intensified by shifting patterns in the distribution of snowfall through the glacial cycle. Using seismic-based volume estimates of glacial sediments deposited off the Norwegian and Barents Sea continental shelves, model outputs are scaled according to lithological variations to quantify the pattern and rates of glacial denudation across Eurasia since the last interglacial. Up to 160 m of bedrock erosion is predicted beneath corridors of greatest ice discharge, with long-term subglacial erosion rates up to 5.5 mm per year comparable with inferred estimates from the Greenland ice sheet. Conversely, areas of landscape preservation and extremely low rates of erosion are widespread, largely found in upland and diverging flow areas of the British Isles, Fennoscandia and Barents-Kara seas. Despite complex patterns of glacial readvance, the widespread conservation of preglacial surfaces in these interior regions is interpreted to be the result of topographically induced and self-sustaining basal thermal patterns.

Abstract

The southern North Sea is a particularly important area for understanding the behaviour of the British-Irish Ice Sheet (BIIS) during the last glacial cycle. It preserves a record of the maximum extent of the eastern sector of the BIIS as well as evidence for multiple different ice flow phases and the dynamic re-organisation of the BIIS. This paper explores the origin and age of the Dogger Bank (DB); re-assesses the extent and age of the glaciogenic deposits across the shallow areas of the North Sea adjacent to the Dogger Bank and; re-examines the dynamic behaviour of the BIIS in the southern North Sea between 30 – 19 ka.

The DB is composed predominantly by glaciolacustrine sediment deposited between 31.6 – 25.8 ka. Following its formation the western end of the Dogger lake was overridden with initial ice override and retreat northwards back across the Dogger lake complete by 23.1 ka. This resulted in widespread compressive glaciotectonism of the lake sediments and the formation of thrust moraine complexes. Along the northern edge of the DB, moraines are on-lapped by later phase glaciolacustrine and marine sediments but do not show evidence of subsequent ice override.

The seafloor to the west/southwest of the DB records several later phases of ice advance and retreat as the North Sea Lobe (NSL) flowed between the DB and the Yorkshire/Lincolnshire coast. New OSL ages limit the arrival of the BIIS on the Norfolk coast to 22.8 – 21.5 ka, after which multiple till sheets and moraines on the seafloor mark northwards retreat of the NSL. This pattern of behaviour is broadly synchronous with the terrestrial sedimentary record along the Yorkshire coast which relates to post Dimlington Stadial NSL oscillation and retreat (~ 21.5 ka)

With respect to forcing mechanisms it is likely that during the early phases of the LGM (~30-23ka) the interaction between the southern margin of the BIIS and the Dogger Lake was critical in influencing flow instability and rapid ice advance and retreat. However, during the latter part of the LGM (22 - 21 ka) late-phase ice advance in the southern North Sea became restricted to the western side of the DB which was a substantial topographic feature by this time. This topographic confinement, in addition to decoupling of the BIIS and the Fennoscandian Ice Sheet further north, enabled ice to reach the Norfolk coast, subsequently overprinting the seabed with late-phase tills of the Bolders Bank Fm.

Abstract

Subglacial lakes are important components of subglacial drainage systems, regulating water supply to the bed and influencing basal shear stress, with implications for ice sheet dynamics and mass balance on potentially rapid timescales. Improving our understanding of subglacial hydrological systems is therefore important, but challenging due to the inaccessibility of contemporary subglacial environments. Whilst the beds of palaeo-ice sheets are easier to access, few palaeo-subglacial lakes have been identified due to lack of clear sedimentological and geomorphological diagnostic criteria. In this study we address these uncertainties, using a suite of sedimentological, geomorphological and modelling approaches to investigate sites of potential palaeo-subglacial lakes in the central Barents Sea. Hydraulic potential modelling indicates several possible locations for subglacial hydraulic sinks within the Sentralbankrenna glacial system during the early stages of ice retreat from the Last Glacial Maximum. These correspond with many of the sites where we observed geomorphological signatures of subglacial drainage, including basins interlinked by meltwater channels, esker systems, and tunnel valleys, some of which breach ice marginal deposits (grounding zone wedges and recessional moraines). Sedimentological analyses indicate that the depositional environments within the basins were influenced by their positioning within the subglacial hydrological system and later due to their proximity to the retreating ice margin. Using the combined results of the modelling, geomorphology, and sedimentological analyses, we propose that subglacial lakes were present on the northwestern flank of Thor Iversenbanken, central Barents Sea. This drainage system likely played a role in regulating water supply to the subglacial environment of the Sentralbankrenna Ice Stream, influencing ice stream dynamics and stability. In addition, our observations suggest that this drainage system remained active throughout the later phases of local deglaciation, when the ice margin was retreating through this area. Numerous other potential locations for palaeo-subglacial lakes are also identified in the central Barents Sea, which may be good target sites for future sedimentological studies.

A Race for Ice Discharge between Ice Streams on Glaciated Continental Shelves

Etienne Brouard^{1,2}, Patrick Lajeunesse^{1,2}

¹Université Laval, Quebec City, Canada. ²Centre d'Études Nordiques, Quebec City, Canada

Abstract

Ice stream networks constitute the arteries of ice sheets through which large volumes of glacial ice are rapidly delivered from the continent to the ocean. Modifications in ice stream networks have a major impact on ice sheets mass balance and global sea level. Reorganizations in the drainage network of ice streams have been reported in both modern and palaeo-ice sheets and usually result in ice streams switching their trajectory and/or shutting down. While some hypotheses for the reorganization of ice streams have emerged, the mechanisms that control ice stream switching remain poorly understood. Here, we interpret a flow switch in an ice stream system that occurred during the Pliocene-Pleistocene on the northeastern Baffin Island shelf (Arctic Canada) through glacial erosion of a marginal trough, i.e., deep parallel-to-coast bedrock moats located up-ice of cross-shelf troughs. Shelf geomorphology imaged by high-resolution swath bathymetry and seismostratigraphic data in the area points to the extension of ice streams from Scott and Hecla & Griper troughs towards the interior of the Laurentide Ice Sheet. We interpret that up-ice propagation of ice streams through marginal troughs led to the piracy of the neighboring ice catchment, which in turn induced an adjacent ice stream flow switch and shutdown. These results suggest that competition for ice discharge between ice streams, which implies piracy of ice-drainage basins via marginal troughs, was the driving mechanism behind ice flow-switching. In turn, the union of ice catchment by piracy increased the volume and discharge of Scott Ice Stream, allowing it to erode deeper and flow farther on the continental shelf. Similar trough systems observed on many other glaciated continental shelves may be the product of such a competition for ice discharge between catchments.

O-5133

Ice-driven relative sea-level changes and sediments deposition: a proposed algorithm for a fully coupled system

Paolo Stocchi

NIOZ Royal Netherlands Institute for Sea Research, Coastal Systems Department, and Utrecht University, 't Horntje, Netherlands

Abstract

Marine sediments play a fundamental role in reconstructing past ice-sheets fluctuations. These are responsible for global ocean volume variations that can be extracted from the isotope record and that also show up as relative sea-level (RSL) changes in the geomorphological and stratigraphic records. The consequent bathymetric variations, which result in changes of accommodation space and distance from shore, affect the deposition of marine sediments. The RSL changes that stem from the exchange of mass between the continental ice-sheets and the oceans are not globally uniform. According to the theory of glacial isostatic adjustment (GIA), the meltwater redistribution is accompanied by solid Earth deformations and perturbation of the gravity field. The GIA signal is a function of the ice-sheets thickness chronology as well as of the solid Earth's rheology and it strongly depends on the distance with respect to the ice sheets. In the proximity of a fluctuating ice sheet, the RSL changes are opposite in sign and up to one order of magnitude larger than the global average (eustatic). A clear example of this discordance is found in the geological record of the Eocene-Oligocene Transition (~34.0 Ma). The first appearance of the Antarctic Ice Sheet (AIS), in fact, was accompanied by a regressive phase in the northern hemisphere (~70 m RSL drop, Priabona, North Italy) while sediments were deposited and preserved in the proximity of the AIS margins (Wilkes Land, East Antarctica) in response to a local RSL rise (>100 m) and consequent increase of accommodation space. In this work the contribution of GIA-driven RSL changes in drawing the architecture of stratigraphic sections is investigated by means of a novel numerical modeling approach. The latter consists in the full coupling between a GIA model, which is based on the Sea Level Equation, and two sedimentation models that are based, respectively, on (i) fuzzy logic and on (ii) the numerical solution of the diffusion equation. Among the several variables that regulate marine sedimentation, changes in bathymetry and distance from shore and ice-sheet margin are directly linked to the gravitationally self-consistent RSL changes that are driven by GIA. The latter is also influenced by the load of the sediments that contribute to solid Earth and gravitational perturbations. The proposed algorithm, therefore, handles the biunivocal relationship between RSL changes and sediment loading in a synergistic manner. Preliminary results show that the reconstructed ice-proximal stratigraphic sections, either based on fuzzy logic or diffusion, are significantly affected by the GIA process and that the eustatic approximation should be discarded. This model is proposed as a tool for the geology community.

O-5134

Vegetation Response to Past and Present Climate change in Nigeria

Emuobosa Orijemie

University of Ibadan, Ibadan, Nigeria

Abstract

Part of the projections of the current climate change model is that the tropics would be one of the most vulnerable regions to the effects of climate change. To test this hypothesis, the response of forest and savanna vegetation types to past episodes of climate change namely the Early Holocene (*ca.* 10,000-9000 BP), Mid Holocene optimum (*ca.* 8500-5,000 BP) and Late Holocene dry phase (*ca.* 4,500-2,000 BP) in southern and north-central Nigeria was investigated. During the Early and Mid Holocene, the rainforest in southern Nigeria was extensive and diverse such that this vegetation belt moved slightly northwards; the savanna vegetation in north-central Nigeria was predominantly humid but occasional dry conditions existed. During the Late Holocene, in the southern parts, rainforest vegetation generally decreased but in certain areas, especially wetlands and areas with reliable hydrological systems, parts of the rainforest recovered subsequently. On the other hand, the savanna became drier, more open and cooler. The significance of this is that the savanna is comparatively likely to be more sensitive to climate change, and with more devastating impact on its human and animal population. However, despite these climatic challenges, human populations in both vegetation zones had interactions that led to the exchange of ideas, technologies (mainly pottery and lithics) and language, which had lasting effects on their collective survival.

Sedimentological and palynological assessment of three wells in eastern Dahomey Basin, southwestern Nigeria, West Africa

Olugbenga A. Boboye¹, Christabel Chidiebere²

¹University of Ibadan, Ibadan, Nigeria. ²Shell Petroleum Development Company, Warri, Nigeria

Abstract

Integrated studies have been carried out on one hundred and eleven (111) ditch samples retrieved from Lagos coastal area of Nigeria. The study aim at determining the provenance, heavy mineral assemblages, establishing the lowstand-highstand Quaternary episodes, deducing the palaeoenvironment and age estimation of the sediments. The lithofacies constitute sandstones and siltstones with thin beds of lignite. The sandstone range from medium to fine grained with the lignite consisting of plant fragment remains. The petrographic results show abundant detrital minerals with average modal composition of quartz (90%), feldspar (2%) and rock fragments (4%). The Quartz-Feldspar-Rock fragments (QFR) ternary plots revealed that the sands are super-matured quartz arenites derived from the continental block under humid climatic setting which have experienced medium transportation history and have been subjected to mechanical and chemical weathering. Heavy mineral assemblages suggest matured sediments. The Zircon-Tourmaline-Rutile (ZTR) index indicates the super maturity of the sediments. The Apatite: Tourmaline (ATi) ratio showed variations within the wells indicating differences in the rate of weathering and period of residence on the flood plain despite similar provenance and fluctuation in ratios suggesting sea level changes. Fifty two (52) species of palynomorphs recovered include *Rhizophora* sp., *Avicennia africana*, *Acrostichum aureum*, *Laevigatosporites* sp., *Combretaceae* sp., *Mitrogynaciliata*, *Sapotaceae* sp., *Disopyros* sp., *Elaeis guineensis* and *Alchronea* sp. The palaeoenvironment of deposition suggest graduation from mangrove to fresh water swamp due to occurrence of *Zonocostites ramonae*, *Acrostichum aureum* and *Avicennia africana*. The abundance of *Podocarpus milianjanus* and *Retitricolporites hians* and the absence of Miocene diagnostic forms suggest Pleistocene age (Tarantian 0.126Ma).

Phytogeographic dynamics on crystalline-sedimentary contact in South-Benin (West Africa)

Ismaïla TOKO IMOROU

Institute of Geography, University of Abomey-Calavi, Abomey-Calavi, Benin

Abstract

The geographical distribution of flora and vegetation is governed by biotic and abiotic factors and their discrimination therefore represents the best analysis of the relationships between vegetation and climatic, edaphic, topographical and human factors. This study aims to analyze the influence of climatic, morpho-pedological and anthropogenic factors on vegetation dynamics in South-Benin. The diachronic methods based on SPOT images from 1995 and 2015, phytosociological, predictive through Land Change Modeler and Maxent models, morphopedological surveys, socio-economic surveys and the Pettitt test were used. The study area is a contact zone between the sedimentary basin and the crystalline basement, a transition zone between the Guinean climate and the Sudanese climate, and a region of millennial cohabitation between two major sociolinguistic and cultural groups of Adja and Yoruba origin. Phytogeographically, it is part of the Guinea-Congolese region and the Sudano-Guinean regional transition zone. Between 1995 and 2015, natural plant formations developed mainly regressively (48%) to the benefit of crop and fallow mosaics and urban areas. Seven plant communities were determined, three on the crystalline, two on the transition and two on the sedimentary. A total of 223 species split into 179 genera and 63 families have been identified. The most dominant families are Leguminosae (15%); Poaceae (7.17%) and Rubiaceae (7.17%). The lowest Shannon diversity index is found on the lens (3.64 bits) and the highest on sediment and transition (4.54 and 4.67 bits). The crystalline lens is characterized by savannah formations with a high density (450 stems/ha) and a low basal area (10.72 m²/ha) of ligneous trees. However, sedimentary rocks are characterized by lower density forest formations (386 stems/ha) and a high basal area (37.42 m²/ha). Phytogeographically, there is a migration of Sudanese and Sudano-Guinean species to the Guinea-Congolese region. MaXent predictive modelling indicates that most species will undergo a reduction in their ecological niche. The annual rate of decline of around 18.30% and projections to 2030 predict a reduction in forests in favour of field and fallow mosaics and savannahs. Socio-economic surveys revealed that anthropogenic (98.87%) followed by climatic factors (82.86%) and edaphic (43.41%) factors are the main causes of vegetation decline dynamics. Besides, the fight against the vegetation deterioration should take both ecological and cultural dimensions into account.

Paleoecological reconstruction of the core of Venvé marsh in northwestern Benin: palynological study

TOSSOU Monique¹, TOSSA DOGNON Aurice², AKOEGNINO Akpovi²

¹University of Abomey-Calavu, Cotonou, Benin. ²University of Abomey-Calavi, Abomey-Calavi, Benin

Abstract

The detailed analysis of a core (length 2m) taken from a marsh located in Copargo (Djougou) allows us to reconstruct the environment from the beginning of its formation to the present day. The sporopollinic study is completed by stratigraphic analysis of organic sequences and floristic inventory. However, the chronostratigraphic framework remains undetermined. The results obtained make it possible to 1) understand the sedimentary dynamics of the marsh and its gradual transformation into a peat bog and 2) verify the correspondence between fossil pollens and the current vegetation of the marsh. It was found that the old vegetation has not changed significantly from that found on the site today. Indeed, pollens of forest species such as *Trichilia* type, *Diospyros* type, *Entada* type, *Terminalia* type, *Bombax* sp, *Newbouldia laevis* were observed during the pollen analysis. Studies on the climate in this area and dates would explain the establishment of this type of vegetation in the region.

Vegetation and Climate Change in Lejja, Southeastern-Nigeria: An Archaeobotanical Investigation

Chioma Ngonadi¹, John Uche Ngonadi²

¹University of Cambridge, Cambridge, United Kingdom. ²University of Nigeria, Nsukka- Enugu State, Nigeria

Abstract

Climatic changes and response are linked in various ways to human behaviour and socioeconomic processes, especially during the Holocene. In this study, macrobotanical evidence from an iron smelting site was used to examine late Holocene climatic perturbations and cultural transformation. Located in Igboland, Southeastern Nigeria -Lejja- is a small village where iron smelting as an indigenous craft specialization flourished on an industrial from around 2000 BC and lasted until the later part of the twentieth century, The vast number of slag blocks on the surface reveals that iron working in this region was a highly sophisticated, long-lived and well-developed tradition with techniques that involve relatively large scale metal production.

Carbonized and mineralized plant remains from two trenches of 2 X 2 meters provide proof of availability with regards to the various plant foods exploited 2,000 years ago in this region. A wide range of forest savannah plants was exploited in the lower and upper layers respectively. In the lower layers (Layers 4, 5 and 6) there was evidence of *Vigna spp*, *Senna tora*, *Syzygium aromaticum*, *Asteraceae*, *Cleome*. These layers marked the beginning of agricultural activities which is indicated by the presence of *Asteraceae* suggesting intense agricultural activities. Additionally, two pottery traditions which include maize cob rouletting and net impression were identified together with other ironworking remains.

The presence of *Elaeis guineensis*, *Dracaena*, *Cyperaceae esculenta* in the upper layers (Layer 1, 2 and 3) suggests very humid and wetter conditions which may have favoured the growth and development of plants. In Africa, *Dracaena* plants are indicative of moist evergreen or semi-deciduous forest while *Cyperaceae* demonstrates lowering of lake levels. Other finds include dimpled base potsherds, horizontal/vertical grooves, comb stamping, channelling, punctuates, slag, tuyere fragments, furnace remains and charcoal. A significant change to the environmental conditions at Lejja could be attributed to the intensive iron smelting activities, indiscriminate cutting down of hardwood for charcoal which must have led to deforestation among other environmental factors. Understanding the diversity of the plants exploited and the climatic condition in this region will elucidate the general framework of the occupation of the landscape and will inform our knowledge of late Holocene palaeoenvironmental record.

Pollen preservation in Late Stone Age Rock Shelters in the Tropics: implications for palaeoenvironmental reconstruction.

Chiamaka Anyanwu

Department of Archaeology and Anthropology University of Ibadan, Ibadan, Nigeria

Abstract

It is assumed that most tropical soils are acidic. However, few archaeological materials (human skeletal remains) have been recovered from West Africa compared to East and South Africa. Hence, due to the dearth of human remains in West Africa, attention has been focused on plant remains to understand Late Stone Age culture and environment. These plant remains, mainly pollen and spores known to preserve well in acidic soils have been successfully used to reconstruct palaeoenvironment.

This study attempts to determine the preservation status of palynomorphs in Late Stone Age rock shelter sites and ascertain its implication on the reconstruction of palaeoenvironment of the sites. The study is based on archaeological excavation of Iresi, a LSA rock shelter site in the forest zone of southwestern Nigeria, palynological, sedimentological and pH analyses of sediment samples obtained from the rock shelter.

The pH result of the sediment samples ranged from 3.75 to 5.04 which was presumably conducive for the preservation of pollen grains. However, the recovered pollen grains were poorly preserved such that pollen identification was very difficult, and pollen sum was very low; pollen sum of duplicate or triplicate slides/sample ranged from about 100-230 pollen grains per gram. In contrast, however, non-pollen palynomorphs (NPPs) such as pteridophyte and fungal spores were abundant between about 1667 and 15,000 spores per gram and diverse in occurrence. The palynomorph data from Iresi were comparable to Mejiro Cave, Ita-Ogbolu, and Abeokuta (AB1) (other LSA rock shelter sites) in southwestern Nigeria hence the potentials of NPPs in providing Palaeoecological data are high and should serve complementary role to pollen.

Keywords: Archaeopalynology, Rock shelter, Late Stone Age, Pollen preservation, Non-pollen palynomorphs, southwestern Nigeria.

Palynological evidence of Climate Change in the Plio-Pleistocene transition in the Continental Shelf of the Niger Delta, Nigeria.

Ayobami Oyelami^{1,2}, Jacob Mateawo¹

¹GEC Energy Solutions Ltd., Lagos, Nigeria. ²University of Ibadan, Ibadan, Nigeria

Abstract

The climate has significant effects on a wide spectrum of environments from terrestrial to estuarine and marine. Since the composition and structure of the vegetation in a region respond to change in climate, the climate of such region can be deciphered by its vegetation.

Consequently, climate change in tropical equatorial region is marked by wet and dry climate trends which is reflected by variations on vegetation rainforest (wet) and savanna (dry). These alternations between wet and dry climate phases result in correlatable cyclicity within a region.

Ditch cutting samples have been analysed palynologically from four wells from the Continental Shelf of the Niger Delta basin. The resultant palynofloral assemblage from the quantitative study is made of a variety of pollen (mangrove, savanna, freshwater/rainforest), fern spores, fungal elements, dinoflagellate cysts and algae. The identified palynomorphs have been attributed to parent plants derived from the proximal and distal provenances such as the coastal swamp, tropical rainforest, savanna and mountain regions.

From the identified plant, vegetation trends and changing abundances are recognized which are related to climatic cycles. These cycles are, in most cases, associated with identified condensed sections of Haq *et al.* (1988).

Impacts of sedimentation and erosion on the inference of the Antarctic deglaciation history by GIA modeling

Jun'ichi Okuno^{1,2}, Takeshige Ishiwa¹, Yusuke Suganuma^{1,2}, Hideki Miura^{1,2}

¹National Institute of Polar Research, Tokyo, Japan. ²SOKENDAI, Tokyo, Japan

Abstract

Late Pleistocene and Holocene sea-level records along the coast of Antarctica mainly reflect on the glacial isostatic adjustment (GIA) due to the deglaciation of the Antarctic Ice Sheet (AIS). Numerical modeling of the GIA has contributed to the inferring deglaciation history of AIS as a surface load change, effectively using geomorphological and geological evidence of Antarctica (e.g., Whitehouse et al., 2012).

On the other hand, sediment redistribution due to sedimentation and erosion is supposed to induce the isostatic crustal deformation and to influence the relative sea-level changes in the coastal regions (e.g., Blum et al., 2008). We can find the sediment redistribution driven by glacial activity in the topographic relief around Antarctica, and Antarctica and the marginal seafloor have experienced gradual changes in topography since the intensification of the AIS glaciation at about 34 million years ago. Previous studies on the GIA in the Antarctic region did not accurately take into account the component of crustal deformation caused by the sediment redistribution. Therefore, we have modeled solid Earth deformation and sea level change in response to sediment loading as well as past ice and ocean loadings in the Antarctic region. In this presentation, we show the numerically estimated crustal deformation induced by sediment loading and its contribution to observed sea-level changes along the coast of Antarctica. And also, based on the numerical results, we discuss the impacts of sediment and erosion around Antarctica on the GIA-inferred AIS deglaciation history.

Reconstruction of paleo-channel and sea level around the ancient port related to Dangseong Fortress during the Medieval Warm Period

Dong-Yoon Yang¹, Min Han¹, Kaoru Kashima², Han Woo Choi¹, Jin Cheol Kim¹, Sangheon Yi¹

¹Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of. ²Kyushu University, Fukuoka, Japan

Abstract

The trade route between the Unified Silla's Dangseong and Tang's Dengzhou seems to have been optimal in the respect of the sailing distance and the seasonal wind direction. The seasonal winds is thought to have been used for a main driving force of sailboats about 1000 years ago. That is, the bilateral trade routes of Dengzhou to Dangseong and Dangseong to Dengzhou were relied on the winter northwesterly and the summer southwesterly, respectively. This estimation is supported by the historical record of the trade activities between the Unified Silla and Tang, and by the archaeological data which are analyzed by a number of relics excavated from Dangseong. The Korean media reported that the Dangseong fortress in the West Sea was the starting point of eastern Silk Road based on the excavation report. However, it was not known that the exact location of the nearest ancient port toward the fortress and the sailing channel to the place. In this study, the nearest tidal channel from the coast to Dangseong was estimated to be the present agricultural channel similar to that shown in the 1918 map. The ancient port site connected with the channel was also analyzed by geological/geomorphological methods. In 3D graphics, the best location as an ancient port related to Dangseong was estimated, and it was also confirmed by 3D graphic results through the borehole sediments analysis and seismic exploration. Diatom data was used to estimate the sea level about 1000 years ago. Considering the load waterline of the sailboat, the minimum water depths of the channel and the port were calculated under the condition of the sea level change during the Medieval Warm Period and the Little Ice Age. Lastly, it was verified whether the trade sailboat could enter the ancient port through the estimated channel through the computer simulation.

P-1003

Paleoenvironmental Context of Postglacial/Early Holocene Maritime Occupation on Isla Cedros, Baja California, Mexico

David Rhode¹, Loren G. Davis², Matt des Lauriers³, David B. Madsen⁴, Antonio Porcayo⁵

¹Desert Research Institute, Reno NV, USA. ²Oregon State University, Corvallis OR, USA. ³California State University Northridge, Northridge CA, USA. ⁴University of Texas, Austin TX, USA. ⁵Instituto Nacional de Antropología e Historia, Mexicali, Baja CA Norte, Mexico

Abstract

Isla Cedros is a large mountainous island located in the Pacific Ocean ~23 km off Punta Eugenio, midway along the western margin of the Baja California peninsula. Part of the mainland during the early post-glacial period, the island separated by ~11,000 cal yr BP as sea level rose. Isla Cedros is predominantly arid desert heavily influenced by marine-layer moisture, giving it the native moniker “Island of Fogs”; its highest mountains support remnant patches of coniferous woodlands.

Recent archaeological work on the island has revealed a rich prehistoric record of human occupation (des Lauriers 2010, *Island of Fogs*, U Utah Press) including several maritime-oriented shell middens provisionally dating between 11,000-12,300 cal yr BP and likely earlier. These early sites are located near extinct freshwater springs at the heads of alluvial fans, locations that saved them from drowning under rising post-glacial seas. A sophisticated maritime subsistence economy is indicated by the tool assemblage, including the oldest dated fishhooks known from North America (des Lauriers et al. 2017, *Am. Antiq.* 82:498-516), and by abundant remains of shellfish, near-shore and pelagic fish, and other marine biota. These sites provide invaluable evidence for early coastal colonization of the Americas, and we are initiating a long-term program to explore these early occupations in detail. The paleoenvironmental context of these occupations remains largely unknown in detail. Important questions concern the nature and resource richness of the coastal marine and terrestrial habitats around the sites during occupation, and the marine ecosystems the inhabitants exploited.

These occupations depended on the fresh water supply from local springs. What sources fed these now-dead springs, and what climatic conditions allowed them to be active? Greater groundwater flow may have derived from stronger tropical inputs or greater winter Pacific frontal storm inputs. We are examining this issue using isotopic analyses of sediments, plant remains and gastropods in the spring deposits as well as modern water isotope analyses.

Local shellfish reserves differed from today, with extra-local species such as red abalone and lion’s paw scallop represented in the sites. We are developing near-shore environmental reconstructions that give us a better understanding of the rich maritime environment upon which these early North American colonists survived, and the near-shore maritime conditions that prevailed during the postglacial/early Holocene. We are also developing a better understanding of the history of local terrestrial biota. Plant resources such as agave may have been important not just for food but also for critically important fiber for fishing nets and line. Pollen, packrat midden, starch and detailed faunal analyses help us gain a better understanding of terrestrial habitats and available resources.

Recent changes of the diatom assemblages in relation to anthropogenic impact in Baltic Sea coastal inlets

Kotaro Hirose¹, Hanna Nilsson², Karin Rengefors³, Olof Berglund³, Anna Godhe⁴, Helena Filipsson²

¹Dept. of Resources and Environmental Engineering, Waseda University, Tokyo, Japan. ²Dept. of Geology, Lund University, Lund, Sweden. ³Dept. of Biology, Lund University, Lund, Sweden. ⁴Dept. of Marine Sciences, University of Gothenburg, Gothenburg, Sweden

Abstract

Diatoms are dominant primary producers, and are sensitive to the environmental change in coastal ecosystems. We investigated the distribution of diatoms in sediment records from two coastal inlets to place the consequences of multiple stressors on coastal ecosystems into a larger temporal context. The Baltic Sea coastal zone is a naturally vulnerable system and subject to significant human-induced impacts such as eutrophication and pollution. In this study, we present temporal changes of diatom assemblages from two coastal fjord-like inlets: Gåsfjärden (site VG1; core length 45 cm) and from Gropviken (site Gp2, c.l. 49 cm) on the Swedish southeast coast. Gåsfjärden has been the recipient of copper mining waste whereas Gropviken has “only” been affected by eutrophication.

The cores from VG1 represent the last ~400 years whereas the Gp2 site has a higher accumulation rate and represent the last 100 years, the cores were using ²¹⁰Pb and ¹³⁷Cs as well as correlated with previous dated cores at the Gropviken site.

The diatom analyses from the two sites resulted in a distribution of many typical taxa in this type of environment from the Baltic Sea (e.g. Snoeijs, 1993), such as *Skeletonema costatum*, *Thalassiosira levanderi*, *Cyclotella choctawhachiana*, and *Paulinella taeniata*. The in situ-planktonic diatoms, which reflect the surface-water production displayed increasing trend in the uppermost horizon at VG1, and in 36.5-32.5cm and 2.5-0.5 cm at Gp2. The epiphytic taxa, which include allotropic (freshwater) diatoms at Gåsfjärden (VG1) was more abundant than at Gropviken (Gp2) with relative abundances. The temporal variation of diatom assemblage suggested as follows: 1) Diatom production of GP2 site is much higher than site VG1, 2) Many of epiphytic taxa are transported from shallower part close to the core sites, 3) The effect of freshwater in Gåsfjärden is stronger than in Gropviken, 4) Change in diatom assemblage in western Baltic Sea coincides with the substantial use of artificial fertilizers after the 1950s, and further change occurred in 10 years. The results from the diatom analyses will be compared with a suite of environmental variables such as elemental - and grain-size distribution.

Magnetic properties of core sediments in the southwestern sea area of Hainan Island: implications for provenance and sea level change

Tingping Ouyang^{1,2}, Mingkun Li^{1,3}, Chengjing Tian^{3,4}, Shasha Peng³, Zhihua Tang^{3,5}, Zhaoyu Zhu³, Hongjun Chen⁴
¹School of Geography, South China Normal University, Guangzhou, China. ²Key Laboratory of Ocean and Marginal Sea Geology, Guangzhou Institute of Geochemistry, Guangzhou, Christmas Island. ³Key Laboratory of Ocean and Marginal Sea Geology, Guangzhou Institute of Geochemistry, Guangzhou, China. ⁴Guangzhou Marine Geological Survey, Guangzhou, China. ⁵Guangzhou Institute of Energy Conversion, Chinese Academy of Sciences, Guangzhou, China

Abstract

Material source is one of the most important research topics for coastal offshore sediments. It has been one of the controversial issues whether the imported materials from the Beibu Gulf can enter the South China Sea (SCS). Environmental magnetism is an effective method for sediment provenance research and has been widely used for marine research.

Detail rock and environmental magnetic investigation is performed for a sediment core (located at 108.29° E, 18.36° N with water depth 74 m) to analyze their provenance and sea level change implication collected from the Southwestern Waters of Hainan Island in the present study. The results and previous study suggested that the lower section of the core (below 15.25m) should be the Late Pleistocene paleo-delta deposits. Magnetic properties and their significance is discussed for sediments deposited after the paleo-delta formation. Combining the previous research for the paleo-delta and AMS ¹⁴C dating results for upper part of the core, the time span of this study is 5.4~33.2 ka.

The rock magnetic results indicate that main magnetic-carries of the core sediments are different fraction of single-domain and multi-domain magnetite and a small amount of hematite. Similar to previous studies, the ratio parameter χ_{ARM}/χ can represent the variation of magnetic particle size and then reflect regional sea level change, i.e. transgression and regression. From the variation of magnetic particle size, the sampling site of the study core was undergone at least four regression-transgression cycles since 33.2 ka. A significant positive correlation between magnetic susceptibility and non-hysteretic remanence is appeared in transgressive sediments but not in regressive sediments, indicating that more ocean action produced single domain magnetic particles were occurred in transgressive sediments. The significant positive correlation between χ_{ARM}/χ and S-ratio of transgressive sediments indicates that relative content of magnetite increases with the fineness of magnetic particles. The significant negative correlation among L-ratio, hard remanence and S-ratio indicates that the absolute and relative content of hard magnetic minerals decreases and increase with the source change of hard magnetic mineral such as hematite, respectively. Using the scatter plot of S-ratio and χ_{ARM}/χ , which is effective for material source identification, the sediments of transgressive and regressive period are compared with those of the surrounding possible provenances. The results the transgressive period sediments was relatively single provided by the Beibu Gulf. However, many sources such as Beibu Gulf, Qinzhou Bay, Red River and Hainan Island rivers were contributed for regressive sediments.

This work was partially funded by the Natural Science Foundation of Guangdong province (Grant No. 2018B030311056), Natural Science Foundation of China (Grant No. 41272384), projects of China Geological Survey (Grant No. DD20160138, GZH201500207, 1212010611302), and the Chinese-Polish collaborated project ERES.

Geoarchaeological evidence of the Bronze Age occupation along the Black Sea coast of Georgia – the Colchian settlement mounds

Hannes Laermanns¹, Giorgi Kirkitadze², Simon Matthias May¹, Daniel Kelterbaum¹, Mikheil Elashvili², Helmut Brückner¹

¹University of Cologne, Cologne, Germany. ²Ilia State University, Tbilisi, Georgia

Abstract

More than 70 settlement mounds (local name: *Dikhagudzuba*) are evidence of a once densely populated landscape on the Colchian plain in western Georgia. According to ceramic finds they date to the Bronze Age. As yet, only limited information is available on their internal architecture, their palaeoenvironmental context, and the chronology of the different layers.

Based on archaeological sources, sediment cores taken from three mounds and their closer surroundings, as well as remote sensing data, the spatial extent, internal structure, and environmental setting were revealed. Analyses of element contents (XRF) and granulometry helped to identify stratigraphical layers and differentiate between natural and anthropogenic strata; by means of orthophotos and the Structure-from-Motion (SfM) technique the mounds' dimensions and distribution were calculated.

The investigated settlement mounds are similar in their stratigraphy and relatively small dimension. Heavy metal and phosphorus pollution in the anthropogenic layers indicate metallurgic and agricultural activity during the occupation phase(s). According to the ¹⁴C chronology, their formation occurred during the first half of the 2nd millennium BC, which confirms the archaeological interpretation of their Bronze Age origin. The narrow age difference between the lowermost and uppermost anthropogenic layers indicates an intentional construction of the mounds rather than a successive accumulation of construction debris. Therefore, the mounds are classified as intentionally constructed dwelling forms, not as tells. The construction material originated from their direct vicinity, most likely from the surrounding circular moats. The environment of the mounds was dominated by fluvial and alluvial processes in a warm and humid climate, and the majority of the mounds is located in close vicinity to (palaeo-) river beds.

P-1007

Aeolian sand influx in peat deposits as an indicator of past storminess: a critical evaluation and its application

Egert Vandel¹, Tiit Vaasma¹, Shinya Sugita¹, Hannes Tõnisson¹, Jaak Jaagus², Kadri Vilumaa¹, Agnes Anderson³, Are Kont¹

¹Institute of Ecology at Tallinn University, Tallinn, Estonia. ²Institute of Ecology and Earth Sciences, University of Tartu, Tartu, Estonia. ³School of Natural Sciences and Health, Tallinn University, Tallinn, Estonia

Abstract

Records of aeolian sand influx (ASI) are frequently used to reconstruct the past changes in storminess along coastal areas in southern Scandinavia and other parts of Europe. However, this method has not been critically evaluated against instrumentally or historically recorded changes in storminess. We obtained high resolution records of ASI from four peat bogs along the Estonian coast and evaluated the extent to which the ASI-based estimates reflect the changes in past storminess in the region. All the peat cores are well dated (10 AMS dates per each peat core ca. 30 cm in depth), covering at least the last 150 years. Samples are analysed contiguously at every 3 mm to provide ASI and grain-size records (>65 μm) with a high temporal resolution. The results were compared with instrumentally-recorded storminess records (starting from 1920 A.D.) from Estonia and with meteorological records and reconstructions from around the Baltic Sea since the mid 19th century. Changes in forest cover within a 5-km radius from each site were estimated from historical maps available to evaluate the effects of land cover change on ASI.

Among the three sites, the ASI records show significant positive cross-correlations; however, the fourth site differs from the others, indicating potential variations in local sedimentary conditions. The ASI is high around the mid 19th century and the period from the 1950s to the 1980s at those three sites; those ASI sequences have also significant positive cross-correlations with the instrumentally-recorded storminess data. The ASI peaks in the mid 19th century correspond to positive NAO and intensive cyclonic activity reconstructed in southern Sweden. Sand grains smaller than 250 μm proved to be more informative for detecting the changes in storminess than those >250 μm that are less abundant and often miss the periods of increased storminess. Records of the grain-size distribution and median diameter of mineral grains indicated several shifts in the source material. Changes in forest cover around the study sites appear not to correspond to the changes in ASI. Previous studies have hypothesized that winter storms are the main factor affecting ASI; however, our results do not support it. We conclude that the ASI in peat bogs of coastal areas is effective for detecting the changes in past storminess, in general, but a careful examination of local sedimentary conditions is necessary.

In addition, we obtained long ASI records at those four sites covering the last 8000 years. Our preliminary analyses suggest that: (1) there were distinct stormier periods around 7500, 6400, 6000, 3500, 3000, 2000, 1500 cal yr BP, and during the last 1200 years, and (2) major regime shifts in storm frequency and/or magnitude occurred around 3500 and 1200 cal yr BP.

P-1008

Updated mangrove pollen keys: an aid to palynological interpretation of tropical estuary and marine deposits

Limi Mao

Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China

Abstract

Pollen analysis of mangrove sediments is a useful method for both palaeoecological reconstructions of coastal vegetation and determinations of palaeoenvironment in tropical regions. Effective reconstructions based on pollen data largely depend on accurate identifications of pollen and spores, and in this respect keys to the products of the extant mangrove flora are very valuable. Morphological studies have been carried out previously on mangrove pollen from both sides of the Atlantic Ocean, the Indian subcontinent, south-east Asia and the western Pacific, but keys to the identification of the palynological products of a wide range of mangrove taxa are not generally available. In this study, a pollen morphological “atlas” and identification keys for most of the mangrove flora are presented, including an interspecific key to the major mangrove elements in *Rhizophora* and *Sonneratia* (Fig. 1: example of triporate pollen types & interspecific key). The morphology of the pollen from more than 45 species of living mangrove and associated plants is described and illustrated by transmitting light photographs and/or scanning electron micrographs. These descriptions and illustrations, and the identification keys are presented at the achievable taxonomic level. The keys are yet open to the future development, so that pollen of other mangrove and associated plants can be accommodated when available. In their present form they should nevertheless aid palynological analyses of Quaternary mangrove and associated estuarine and marine deposits.

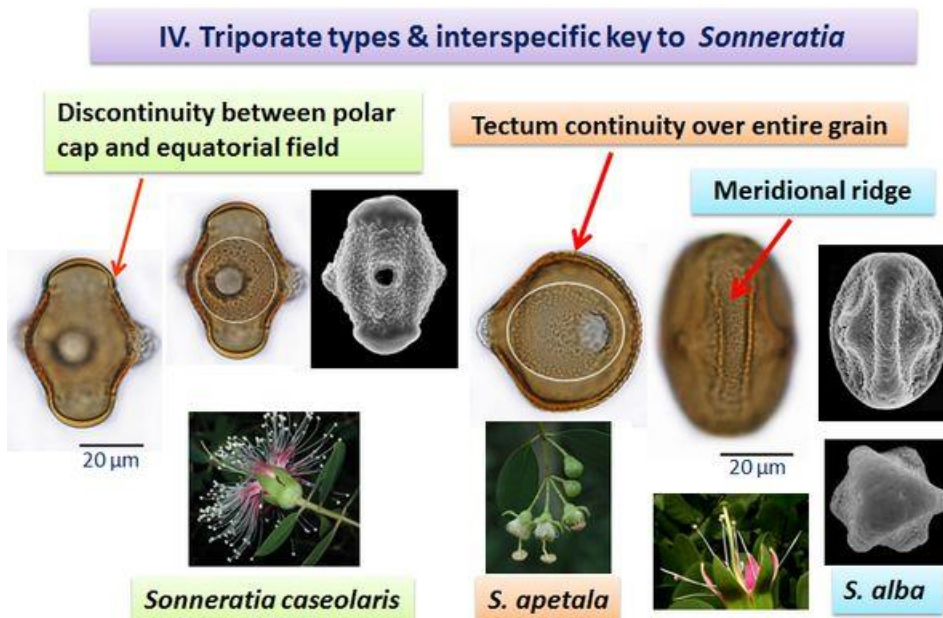

Fig. 1: Example of triporate pollen types & interspecific key to *Sonneratia*

Reconstruction of environmental change in northern Japan after the mid-Holocene and its implication for human activity

Hodaka Kawahata¹, Yoshiki Hatta¹, Hiroto Kajita¹, Yuki Ota¹, Yoshida Akihiro², Junko Habu³

¹The University of Tokyo, Kashiwa, Japan. ²Kagoshima University, Kagoshima, Japan. ³University of California, Berkeley, USA

Abstract

Coastal sediments collected from bays provide a special advantage to present quantitative estimates of summer atmospheric temperature (AT) based upon the high correlation between AT and sea surface temperature (SST) and to examine the relationship between climatic changes and the human activity. The SSTs (ATs) around Funaka Bay, northern Japan, showed long-term increases due to gradual warming up in summer by stronger ocean currents and milder winter by weaker atmospheric circulation during the mid-late Holocene with low-frequency oscillations in the millennial-scale to sub millennial-scale. The alkenone SSTs showed a variation of 8.7 °C (14.5 °C to 23.2 °C). Large temperature falls occurred in 6.4-6.0, 4.5-4.0 and 1.2-0.9 cal. kyr BP with smaller peaks in 6.5, 4.5, 1.2 cal. kyr BP and the modern day. Although the SSTs (ATs) observed in this study were generally lower than those near Sannai-Maruyama, a famous archaeological Jōmon site, because the location of the present study is over 150 km north, both sites showed a similar general profile. Although a large decline in temperature in 0.95-0.65 cal. kyr BP, excluding the possibility of Medieval Warm Period in Japan, might have been influenced by an El Niño occurrence, a cold climate was definitely observed in the ash layer in 1640–1894 AD, which almost corresponded to the Little Ice Age. Our results are consistent with the contention that cold periods (5-10th century BC, 6th century AD, 11-12th century AD and 18-19th century AD) coincided with major shifts in social systems in Japan. Two additional cold episodes that correspond to the major societal changes were identified in this study using high-time resolution.

Topography and sediment characterizing tide-dominated large-river deltas: the Mekong and other four examples

Yoshiki SAITO^{1,2}, Marcello GUGLIOTTA¹

¹EsReC, Shimane University, Matsue, Japan. ²Geological Survey of Japan, AIST, Tsukuba, Japan

Abstract

The fluvio-distributary channels of tide-dominated large-river deltas have characteristic features of upstream to downstream morphological trends in width, sinuosity, and depth. The river morphology (depth, width, and sinuosity) and bottom sediment of the Mekong River delta show clearly these characters. Here we show that these morphological trends in five modern tide-dominated river deltas in the world are summarized, using original data collected from satellite images and bathymetric maps, and published data from field surveys. The studied channels show two distinct upstream and downstream tracts separated by areas of morphological changes. The upstream tracts are characterized by constant width, relatively high sinuosity, and seaward-increasing depth, and are mainly controlled by the fluvial dynamics. The downstream tracts are characterized by seaward-increasing width, relatively low sinuosity, and seaward-decreasing depth, and are mainly controlled by the tidal dynamics. The delineation of this morphological configuration of the channels is crucial to understand the response of deltas to the interacting fluvial and marine dynamics. Additionally, this has important implications for understanding the controls on sedimentation, hydraulic models, the long-term evolution of these systems, and the assessment of natural versus human-induced modifications.

P-1011

Recent anthropogenic signature on the coastal vegetation of the eastern Cantabrian coast (N. Spain).

Aitor Fernández Martín-Consuegra¹, Sebastián Pérez-Díaz², Alejandro Cearreta¹

¹University of the Basque Country, Bilbao, Spain. ²Université du Lyon, Lyon, France

Abstract

The Anthropocene concept refers to the recent history of our planet characterized by a rapid and profound geological change provoked by numerous human activities and reflected in the sedimentary record. This impact can be studied through a great variety of proxies as, for example, buried pollen in estuarine settings. The objective of this work is to reconstruct the process of anthropization of the coastal vegetal landscape in the eastern Cantabrian coast (northern Iberian Peninsula).

We present here the results obtained from two cores, one located in the central area of the Suances estuary and the other from the upper Zumaia estuary. Both cores have a length of 50 cm and contain a sedimentary record that spans approximately from 1850 CE to the present.

The results show that, at present, the forestry exploitation is reduced in both areas, since the arboreal pollen of the typical taxa of the Cantabrian coastal vegetation (e.g., *Alnus*, *Betula*, deciduous *Quercus* and *Pinus pinaster*) increases through time. Additionally, presence of pollen from herbaceous and shrubby plants (e.g., Apiaceae, *Cerealia* t., Chichorioideae, Poaceae and *Erica* t.) is greater in the lower samples and decreases towards the top. Abundant taxa as *Cerealia* t., Poaceae (whose expansion is often linked to deforestation and infrastructure construction) and *Sordaria* t. in the lower core sections are indicative of intense agricultural activities and the presence of livestock animals.

Human activities have left a clear signal on the recent paleopalynological record of this region. Firstly, with the agricultural and timber exploitation that caused a reduction of the arboreal species in favour of the herbaceous taxa (e.g., Apiaceae, *Cerealia* t., Chichorioideae and Poaceae) since the 1850s until 1970s. Secondly, with the abandonment of these activities in the 1970s the arboreal forests recover naturally their spaces appearing forms like *Alnus* that usually grow in humid environments near coastal areas or river courses. In the case of the Suances estuary, the presence of the allochthonous taxon *Eucalyptus* sp. since 1990s is also very significative. Before that date, its presence is rare although it appears practically in the whole core. It is also present in Zumaia although more scarcely, and reflects abundant human plantations to take advantage of the qualities of this fast-growing tree for its timber and medicinal properties that now leaves its signature on the coastal sedimentary record of the northern Iberian Peninsula.

P-1012

Coastal submergence and the peopling of the Arafura Sill, northern Australia

Matt Cupper¹, Tim Stone¹, Brian Lees²

¹The University of Melbourne, Melbourne, Australia. ²The University of New South Wales, Canberra, Australia

Abstract

The Wessel Islands chain in the Northern Territory forms part of the Arafura Sill, a Pleistocene land bridge between northern Australia and New Guinea. This was breached by rising seas from ~12,000 years ago flooding the eastern Arafura Shelf, swamping freshwater Lake Carpentaria and forming the Gulf of Carpentaria. A record of this transition from land bridge to fully marine conditions is contained in the beach ridge and dunefield sequences of the island chain. Trafalgar Bay at the northern end of Marchinbar Island is a shallow, northwest-facing embayment on the gentle backslope of a sandstone cuesta. The bay shore is protected by two prominent headlands and two small offshore islands. Shoreline progradation under fair-weather wave conditions has resulted in the development of a ~500 m wide beach ridge plain. The most landward beach ridge is entirely siliclastic and has a well-developed dune podsol. It also has a steep shoreface. The ridge seaward is built on the lower part of this shoreface and is composed of beach calcarenite capped by pale yellow dune sand. The younger ridges that complete the sequence are dune-capped coarse shelly sand. We dated these units using OSL to determine the onset of beach ridge formation, the timing of the transition from siliclastic to bioclastic sedimentation and the rate of shoreline progradation. The chronology is relevant to understanding human occupation of the Wessel Islands. The breaching of the Arafura Sill would have displaced Aboriginal peoples from the continental shelf to the Wessel Islands and mainland coast. Human habitation from this early period, or even earlier, is likely to be present in the abundant rockshelters of the Marchinbar Sandstone. However, resource-rich coastal environments favourable to Aboriginal occupation had probably not been established until after the siliclastic-bioclastic transition.

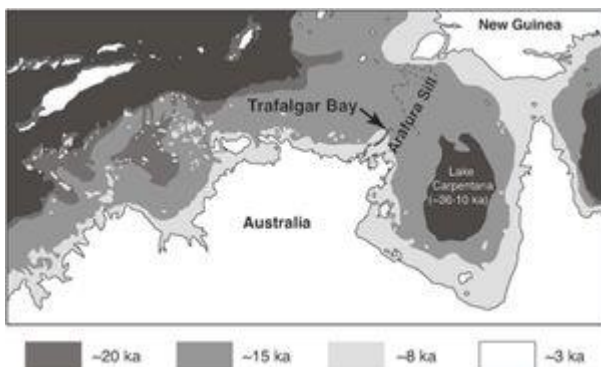

Figure 1. Trafalgar Bay in the Wessel Islands chain and shorelines since ~20,000 years ago.

Abstract

Marine coasts and river deltas are environments that are strongly subjected to human activities as much as to natural effects of climate changes. Therefore, they represent ideal areas to estimate the anthropogenic and/or natural factors that have a significant impact on land/marine environments. The morpho-sedimentary dynamic evolution of the Arno River delta has been increasingly driven by human activities since the Roman Age (e.g., reclamation of wetland areas, widespread centuriation of the coastal plain). During the Middle Ages additional waterworks such as meander channel cuts, excavation of artificial ditches, erection of levees, were carried out extensively. However, the most dramatic changes occurred during the last 500 years: in 1606 CE the mouth was artificially offset north of its natural location, which determined a huge seaward progradation of the delta. The progradation went on for about 250 years; later, changes in land use, reforestation, riverbed dredging, resulted in a harsh decrease of river sediment bedload, which was responsible of a massive coastline retreat of about 1.5 km since 1850. The erosion processes were tackled only with protection structures such as seawalls, breakwaters, and groynes. Recently, the coast was further engineered by raising artificial pebble beaches that replaced the sandy beaches wiped out by the sea. Along with human activities, climatic oscillations also triggered remarkable hydrological changes within the Arno River delta and in the adjacent areas. In particular, changes in frequency and severity of intense rainfall episodes directly impact the occurrence of floods, which in turn end up affecting many human and natural systems. As this kind of studies requires a multidisciplinary approach, in this work we highlight the evolution of the Arno River delta describing its current state throughout the correlation of data from land and marine archives provided by different surveys and analyses. Land archives comprise datasets including the geoarchaeological context, results of sedimentological and micropaleontological analyses of boreholes, geophysical surveys, coastal sediment dynamic and satellite image analyses. Marine archives consist of two relatively shallow-water sediment cores, recovered in the shelf in front of the Arno River mouth, that have been used for a high-resolution micropaleontological study of the calcareous nannofossils. Micropaleontological data have been correlated with some indexes which reflect variability of precipitations and river discharge (e.g., large and exceptional floods during the last 2 millennia, changes of the distance of the sea from Pisa) in order to reconstruct the past millennium significant hydrological events in the Arno River basin. The synthesis between land and marine archives reveal a close relationship between human activities and natural factors in the past 2000 years of the Arno River evolution

Holocene relative sea-level changes in west Wales: new results from Dyffryn Dysynni

Caitlin Nagle^{1,2}, Katherine Selby², Bob Johnston¹

¹University of Sheffield, Sheffield, United Kingdom. ²University of York, York, United Kingdom

Abstract

At present Holocene sea level changes in west Wales are poorly constrained with only 14 reliable sea level index points published (Shennan et al. 2018). This paucity of data, particularly for the Late Holocene, potentially results in lack of precision in predictions from glacio isostatic models for the region, and prevents changing coastal configuration and environment-human interactions to be fully explored. This research reconstructs Holocene sea level changes in west Wales and integrates these data with known archaeological sites to establish how patterns in settlement and land use were affected by coastal and sea-level changes. The Dysynni Valley in west Wales is a characteristic low lying coastal valley that contains well-preserved estuarine sediments and a rich archaeological record, from prehistory to the medieval period.

Fieldwork, including stratigraphic analysis, sampling, mapping and surveying was undertaken at two sites, Penllyn and Perfeddnant, approximately 6.5km apart, in order to establish the horizontal extent of marine inundation in the valley. The stratigraphy at Penllyn revealed a basal peat subsequently dated to between 7787-7665 cal BP, overlain by blue-grey clay, and then overlain by a woody peat dated to 6402-6297 cal BP. Laboratory work included loss on ignition, particle size and diatom analyses to establish the salinity and geophysical properties of the sediments that could be related to sea level fluctuations and changing sedimentary dynamics.

The diatom analysis at Penllyn revealed that the clay was dominated by marine and brackish species such as *Nitzschia navicularis*, *Diploneis interrupta*, *D. didmya* and *D. stroemi*. This evidence suggests that a marine-estuarine environment existed at this site during the mid-Holocene and this is likely to correlate to the Main Postglacial Transgression in the area. The loss on ignition and particle size analyses show high organic content in the peat, with low organic and carbonate content in the clay, and grain size dominated by silts, corroborating the relative sea level rise. At Perfeddnant ongoing analyses is revealing similar trends in relative sea level. Continuing research will enable accurate mapping of the extent and timing of marine inundation in the valley, which will have important implications for understanding environment-human interactions in Dyffryn Dysynni and more broadly within coastal zones.

Multiple Approaches to Investigating Human-Environment Interactions in the Coastal Zone: Lessons from Urban Coastal Communities from India

Shailendra K. Mandal

National Institute of Technology Patna, Patna, India

Abstract

Societies have lived with the vibrant nature of land and coastal environments for ages. Vulnerability of coastal areas to climate change is an important issue, which has gained attention recently. Faced with rising sea levels and the likelihood of increasing storminess, coastal communities are on the front line of climate change impacts. Coastal areas face multiple risks and stresses related to climate change and variability. Impacts of sea level rise are expected to have predominantly adverse effects on natural and human systems. Coastal communities are highly vulnerable to climate change impacts, mainly because of three main reasons, high resource dependency, high exposure and limited adaptive capacity. Coastal environments are also under pressure from increasing intensity of human activity. This raises concerns about coastal community's sustainability.

The Intergovernmental Panel for Climate Change Fourth Assessment Report has identified several low-lying deltas of Asia and Africa, which are highly urbanized and also vulnerable to climate change impacts. Thirteen of the world's twenty largest cities are located on the coast, and more than a third of the world's people live within 100 miles of a shoreline. Low-lying coastal areas represent about two per cent of the world's land area. This 2 per cent coastal land area contains 13 per cent of the urban population.

India has a 7,517 km long coastline with many low-lying and densely populated areas with nearly 260 million people living within 50 km of the seacoast. These highly vulnerable areas house a network of infrastructures. It is highly pertinent to start climate adaptive infrastructure and services, given the climate sensitive nature of the existing infrastructure systems in the coastal area. It could be maintained and managed in such a way that it is prepared to withstand sea level changes impacts.

This paper discusses on approaches that can increase resilience of infrastructure and the services in coastal urban areas of developing nations. It also explores the human-environment interactions in the coastal zone, including impacts of storms, inundation, coastal erosion and land use changes. It also highlights the Identification of vulnerable hot spots in the coastal areas, recommendations for climate proofing infrastructure and services and methodology for vulnerability assessment of coastal communities to climate variability and sea-level changes. It also recommends appropriate policy and institutional reform, capacity building and improved knowledge management towards increasing the resilience and adaptive capacity of these coastal communities to current and future sea level changes.

Abstract

The North Medoc Peninsula is bordered by the Atlantic Ocean to the west and the Gironde estuary to the east. The coast is formed by sandy beaches, dune barriers, estuarine marshes and intertidal mudflats. This sea-land interface experienced significant coastal changes during the Holocene.

During the last three decades, intense winter storms have unearthed vestigial sedimentary deposits containing numerous archaeological remains on the Amélie beach, located on the coastal side of the Gironde estuary. While threatening those nature/culture dialectic archives, this erosional context paradoxically provides an easy access for paleoenvironment analysis. The interdisciplinary project LITAQ aimed to reconstruct the Holocene and Pleistocene environments and related human settlements in this geographical area. Now ended, this program has initiated a long-lasting collaboration between archaeologists and natural scientists through survey campaigns at the Amélie.

Combination of topography, stratigraphy, and radiocarbon/relative dating of the beach and associated dune barrier sediments led to chronostratigraphic reconstructions. Thanks to sedimentological analysis, micropaleontology and geochemistry, depositional environment identification was achieved. In addition, several relative sea levels were produced, following the “sea-level index points” method.

The nearly complete Holocene sequence of the Amélie was recognized, infilling the paleochannel of Soulac, a tidal inlet of the Gironde estuary, allowing paleogeographic restitutions of this coastal area.

Concomitant with a sea level rise slowdown, the tidal channel infilled with marine and estuarine facies around 5000 BC. Protected by coastal dune barriers, two coastal marsh generations were recorded, between ca. 3000 BC to ca. 1500 BC and between ca. 800 BC to AD 300. Around ca. 1500 and ca. 1000 BC, an episode of marine erosion brought coastal dune ridge breach and enhanced wave penetration inside saltmarshes. From AD 300 to 700, the estuarine marsh was gradually buried by coastal dunes.

Systematic spatial and stratigraphic analysis of archaeological remains generated correlations between human settlement and supporting environments. From early Neolithic to Antiquity, our research has allowed a better understanding of the human adaptation to environmental changes through time.

Additional cores were performed inside the dune ridge and in the eastern marshes, located at the estuarine side of the channel. Coupled with a database of ancient drillings, this data allowed Soulac channel sequencing. The chronostratigraphic framework clarified the environments succession/expansion and erosion/aggradation phases rhythmicity controlled by interplay between marine, aeolian and fluvial processes with variable intensity within the channel.

To better specify climate forcing, regional and interregional analogies were made, using indexes such as CSP, coarse grained sedimentation pulses or aeolian activity/stability phases.

Moreover, the existence of high resolution marine cores collected during the program HAMOC in the Bay of Biscay, offshore of the Medoc littoral, gave the opportunity to directly correlate climate/marine changes and coastal responses.

Abstract

In the Patagonian archipelagos, marine hunter-gatherers based their subsistence mainly on the exploitation of marine resources. However, we can observe changes in their economy during the Holocene (San Román et al. 2016). Important transformations were seen in fishing strategies: during the period 6000 to 2000 years BP there was a strong tendency for the exploitation of demersal species (Torres et al. 2016). From 2000-1500 years BP onwards, exploitation shifted to taxa currently associated with kelp (*Macrocystis pyrifera*) forests and, in general, shallower waters. These shifts in target species may reflect cultural changes. Alternatively, they may reflect environmental change. Paleoceanographic studies show considerable dynamism in marine ecosystems during the Holocene, due to fluctuations in sea temperature, salinity change, meltwater and marine productivity (Aracena et al. 2015). Important inputs of meltwater occurred between 3250-2700 and 2000-1200 cal yr in the area, which affected marine productivity (op cit.) and could have had an impact on the prehistoric economy.

Our objective was to evaluate the changes in feeding mode, feeding behavior, and trophic level in these shallow-water fishes during the Late Holocene, in order to evaluate the responses of human populations. For this purpose, we undertook analyses of collagen $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ from benthic coastal and demersal fish remains found in archaeological sites of different dates within the Late Holocene was performed. The results were compared with similar taxa from the Intermediate Period (3200-2000 BP), Late Period (2000- 300 BP) and modern fish.

The analysis indicates that *C. gobio* had a similar core isotopic niche in both the late and intermediate periods. Modern *Patagonothen sp.* are considerably (ca. 4 ‰) ^{13}C depleted relative to the Intermediate Period, suggesting a shift to the consumption of prey fueled by pelagic-derived C relative to the ^{13}C enriched prey consumed in the Intermediate Period which were probably fueled by benthic-derived C (e.g. macroalgae).

The isotopic niche of *S. australis* differed in the Intermediate and Late Period, which could indicate that they fed in different environments. Conversely, modern *S. australis* are $\delta^{15}\text{N}$ enriched potentially indicating an increase in trophic position, or shifts at the base of the food web.

Effects of short-term climate oscillation on ecosystem of eutrophic lagoons in East Asia

Kota Katsuki¹, Koji Seto¹, Hiroyuki Takata², Takuroh Noguchi³, Akira Tsujimoto¹, Takeshi Sonoda⁴, Dong-Yoon Yang⁵
¹Shimane University, Matsue, Japan. ²Pusan National University, Busan, Korea, Republic of. ³Kochi University, Nankoku, Japan. ⁴Tokyo University of Agriculture, Abashiri, Japan. ⁵Korea Research Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

Abstract

Although it is a common knowledge that natural climate change affects impacts for aquatic environment and ecosystem of lagoon, the effects of decadal and hundred scales climate fluctuations have been comparatively less discussed. Most previous researches on fishery using lagoon mainly discussed the effects of human-induced eutrophication, because human impact generally gives clear influences on lagoon environment and ecosystem. Thus, we investigated the effects of short-term climate oscillations like as Arctic Oscillation (AO) and Pacific Decadal Oscillation (PDO) on lagoon environment and ecosystem in the East Asia as Hokkaido and west Honshu Japan and northeast South Korea based on lagoon sediment analysis. Lagoon sediments were obtained by hand pushing piston corer, and diatom remains and mineral components in the lagoon sediments were investigated for the paleo lake environmental reconstruction. In all lagoon sediments, some diatom taxa and mineral components in lake sediments were corresponding with AO and/or PDO phases. However, the reaction patterns for these climate oscillations were difference in each lagoon. For example, Lakes Notoro and Mokoto are adjacent seasonal frozen lagoons in Hokkaido, Japan. Ice-related diatom taxa in both lagoons showed clear relationship with AO. This is probably because the spring air temperature of this area is strongly controlled by AO phase. However, even foraminifera assemblage and primary production of Lake Notoro also followed in AO phase, the effect of AO was limited in the Lake Mokoto. The relative abundances of major diatom taxa are related more stronger with PDO phase. This difference is probably depended on their geomorphological setting. Lake Notoro is the large area and small catchment lagoon. In this lagoon, timing of lake ice melt and spring bloom type are important factors for primary ecosystem. On the other hand, in case of Lake Mokoto which is the small area and large catchment lagoon, autumn heavy precipitation and following land nutrient input probably affect stronger impact for primary ecosystem than the effect of spring temperature change. Such kind of relationship can be confirmed in other lagoon. Nutrient indicating diatom taxa and some mineral components in small lagoon, Lake Hwajinpo showed the good relationship with reconstructed PDO phase throughout the precipitation change. These results suggested the effect of short-term climate oscillations on lagoon ecosystem is complicatedly changed by surrounding environment. To understand the lagoon ecosystem, it is necessary to understand how the climate oscillation affect the impact for lagoon ecosystem.

Late Holocene paleoenvironmental history by High resolution analysis of clastic varves in the brackish Lake Mokoto, Hokkaido, Japan

Koji SETO¹, Kota KATSUKI², Takeshi SONODA³, Kazuyoshi YAMADA⁴

¹Shimane University, Matsue, Japan. ²Shimane University, Matsue, Isle of Man. ³Tokyo University of Agriculture, Abashiri, Japan. ⁴Museum of Natural and Environmental History, Shizuoka, Shizuoka, Japan

Abstract

In the coastal area of the Sea of Okhotsk in the east part of Hokkaido located to subarctic zone, many brackish-water lakes are distributed. Lake Mokoto has two-layer structure of polyhaline surface waters and mixoeuhaline bottom water. The bottom water shows the anoxic conditions in summer season. In this reason, the sediments of Lake Mokoto consist of organic mud with the lamination. The 09Mk-1C core collected from Lake Mokoto at 2009. In the soft X-ray photograph, the cyclic lamina set is observed in their core. According to the meteorological data in Abashiri region, the annually precipitation is high from August to September. Probably, the cyclic lamina set is formed by seasonal change of precipitation. After that, the cyclic lamina set was certified as varvesediments by the analysis of 15Mk-3C core, which is collected at 2015.

In February 2018, we collected 18Mk-8C, 18Mk-1B, 18Mk-2B cores from the central part of Lake Mokoto (water depth 4.5 m). The 18Mk-8C core is collected from the surface sediment, and the core length is 176 cm. The flood lamina set formed in 2015 and 2016 was confirmed, and one set of laminar set can be observed above it. For this reason, it seems that it is collected almost from the surface sediment. The 18Mk-1B and 2B cores were collected at 1 m interval from 5 m and 5.5m below the surface water of the lake. The length of each core is about 19 m. These cores were mostly muddy varvesediments, and lower 2 m were sediments with massive or Bioturbation. Though these cores have loss horizons, they can be correlated by the lamina level. It can be regarded as a continuous core by integrating them. Three tephra were observed in integrated cores. The top tephra is Ta-a tephra, volcanic ash which fell in AD1739. The middle part of tephra is Ko-c2 tephra in AD1694. 42 lamina sets were counted between the two tephra. The bottom tephra is Mb-a tephra in the 10th century.

CNS element analysis was carried out on the horizon of late Holocene in integrated cores. The total organic carbon (TOC) and total sulfur (TS) contents show the high values in middle parts, and decrease upward. However, the flux of TOC and TS increase upward. This suggests eutrophication by human impact. Ultra high resolution analysis (about 10 samples per year) was carried out at the top. TOC contents showed a value of 4 to 5%, but TS contents showed a low value (less than 1%). The TS contents and the apparent density show a high correlation, suggesting that a large amount of clastic material flows from the river. The clastic material contains TOC, suggesting an increase in organic load from the watershed.

Break-up of Neolithic cultural layers in the coastal Qiantang River, eastern China: pollen evidence

Jun-Wu SHU¹, Le-Ping JIANG²

¹Key Laboratory of Economic Stratigraphic and Palaeogeography, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China. ²Zhejiang Provincial Institute of Archaeology and Cultural Relics, Hangzhou, China

Abstract

With discoveries of early rice-based agricultures such as Kuahuqiao Culture (c. 8-7 cal. ka BP) and Shangshan Culture (c.10 cal. ka BP) in recent years, a breakthrough has been made for Neolithic archaeology as well as environmental archaeology in the Qiantang River drainage region, eastern China. Here we reconstruct vegetation in order to reveal environment change and human activities based on the AMS ¹⁴C chronology and pollen analyses of cultural layers of Loujiaqiao archaeological site after 6500 a BP. Such analyses have been focused on the interval sediment between cultural layers to **understand its formation**.

Our results show that: 1) a mixed evergreen and deciduous broad-leaved forest primarily composed of evergreen oaks (*Cyclobalanopsis*) and deciduous oaks (*Quercus*) flourished in the adjacent small hill during the early Hemudu Culture (6500-6300 cal. aBP). This forest suggests that the climate was warm and humid and favored local fishers, foragers and hunters to settle down. During this time, the forest vegetation remains closed with minor anthropogenic disturbance; 2) Subsequently, a visible natural interval layer occurred around 6100 cal. a BP overlaying the early cultural layers. It shows that pollen floral of this layer seems quite unusual: *Pinus* is dominant with first small occurrence of *Picea*, *Abies* and *Tsuga* which distribute in present subalpine mountains; moreover, marine algae such as *Spiniferites* and *Lingulodinium* made first appearance in abundance and fresh algae. Based on Holocene environmental evolution of Qiantang River, it is assumed that the Hangzhou estuary had been formed and then prompted strong tidal currents to migrate upward in long distance along the river valley to study site. Meanwhile, the river was blocked by the tidal currents and water level began to rise considerably. Thus, Loujiaqiao site **was completely inundated** leaving local people to abandon this site; 3) Afterward, Neolithic farmers came back to the study site probably due to the lowering the flood. A human-induced oak forest dominated in the surrounding hill and became an important economic nut forest for local people. The progressively opening of forest linked closely to local intensified rice farming.

Key words: Pollen analysis, Interval layer, rice farming, Sea tide, Archaeological site, Qiantang River

A Late Holocene record of environmental change from the east coast of New South Wales, Australia.

Lydia Mackenzie¹, Michael-Shawn Fletcher², Patricia Gadd³

¹Nanjing Institute of Geography and Limnology, Chinese Academy of Science, Nanjing, China. ²University of Melbourne, Melbourne, Australia. ³Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

A multi-proxy palaeoenvironmental record from a lake (36° 5'37.33"S; 150° 7'26.02"E) on the east coast of Australia provides a record of coastal development and vegetation succession over the last 3,800 cal. yr BP. Lead-210 and ¹⁴C dating built a robust age-depth chronology for the 61cm long core. Pollen, charcoal and x-ray fluorescence analysis provide records of vegetation change, fire regimes and catchment dynamics during the late Holocene. This study finds that an open coastal environment dominated by Amaranthaceae and *Eucalyptus* was present between 3,800 and 3,000 cal. yr BP when sea level on the east coast of Australia was ~1.7-1.5m higher than present. Rainforest indicators including *Cyathea*, *Pomaderris* and *Nothofagus* suggest a mixed wet Sclerophyll community was present either regionally or locally. Low pollen concentration and relatively high counts of Fe, S and Ca suggest iron sulfides and shell hash accumulated in a shallow or periodically exposed basin. Microscopic charcoal counts varied between 4,000 and 3,500 cal. yr BP and may indicate an increase in regional fire events. From 3,000 cal. yr BP Casuarinaceae and Poaceae increased and aquatic types *Typha* and Cyperaceae first appeared in the record suggesting the falling sea level allowed a barrier dune to form and a brackish to freshwater wetland to develop. Between 3,000 and 2,000 cal. yr BP Sr and Ti counts varied significantly, suggesting terrestrial and marine sediments may have periodically washed over the barrier dune and accumulated in the wetland during a period when sea level was ~1.1m higher than present.

Sclerophyll open forest dominated by Casuarinaceae expanded until 2,000 cal. yr BP and then remained constant until present. Local and regional fire indicators increased briefly at 2,000 cal. yr BP. The presence of European settlers in the region is clearly identified by the occurrence of *Pinus* and the significant increase in regional and local fire regimes from 1900 AD and 1920 AD respectively. This multi-proxy record from a coastal lake in eastern New South Wales identifies the impact of sea level change and coastal progradation on vegetation and fire regimes and investigates natural and anthropogenic driven environmental change during the late-Holocene.

Palaeoenvironmental evolution of Holocene–Modern back-barrier mangroves in the northern Mekong River delta, Vietnam

Daniel Collins¹, Toru Tamura¹, Van Lap Nguyen², Thi Kim Oanh Ta², Limi Mao³, Yuji Ishii¹, Hiroyuki Kitagawa⁴, Rei Nakashima¹

¹Geological Survey of Japan, Tsukuba, Japan. ²HCMC Institute of Resources Geography, VAST, Ho Chi Minh City, Vietnam. ³Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China. ⁴Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan

Abstract

Mangroves are sensitive to climate, sea level, intertidal elevation, salinity and the balance of river and marine processes. In the northern Mekong delta, mangroves inhabit a wave-protected, tide-influenced, back-barrier area (Can Gio) but their Holocene development is poorly constrained. This study combines sedimentary, stratigraphic and palynological analyses of Pleistocene–Modern sediment cores with radiocarbon and optically stimulated luminescence (OSL) dating to interpret the (1) local palaeo-environmental and geomorphological evolution and (2) regional controls on sedimentary dynamics impacting mangroves. Interpreted intertidal–upper subtidal facies comprise bioturbated carbonaceous mudstones with abundant mangrove organic fragments and palynomorphs. They gradationally overlie interpreted subtidal facies, which variably comprise bioturbated mudstones, sandy mudstones and heterolithic containing brackish-water shells. Radiocarbon dating indicates modern mangrove material occurs throughout the uppermost 3–4 m of sediment (c. <4 ka) suggesting root penetration and mixing by mangroves. The OSL dating suggests initial barrier formation by 3.21 ± 0.19 ka, which is earlier than adjacent barriers and consistent with the ages of sandier core sediments (c. 5–3 ka) and archaeological sites (c. 2 ka). Substantial thinning (>10 m) of the Holocene succession southwards towards the barrier suggests its development was influenced by bedrock topography. Sand supply from the active Mekong delta during barrier development was limited by the relatively lateral and distal position. Instead, the proposed model for barrier development involves the gradual supply of suspended sediment with a small fraction of silt–sand, deposition across shallower bedrock, and preferential winnowing of mud to form a sandier deposit. Suspended sediment was most likely supplied by south-westward alongshore currents from sandy shorelines to the north-east, and the Saigon River and local rivers eroding sandy Pleistocene outcrops. The proposed geomorphological model illustrates the interaction of topography, sediment supply and fluvial–marine processes on early barrier development and mangrove expansion in the northern Mekong River delta.

P-1023

Neolithic vegetation, environment and their relationship with human activities in the Baima Lake area, eastern China: Preliminary pollen result

Pan Haochen

Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China

Abstract

Relationship between human and nature during the early Neolithic in the eastern coastal areas of China remains problematic. Among them, the key issue that how ancient human initiated rice cultivation (*Oryza sativa*) has been hotly debated. Zong et al. (2007) suggested that prehistoric Kuahuqiao human removed the alder fen carrs (*Alnus*) by fire to start rice cultivation about 7700 years ago using “slash-and-burn” subsistence strategy, while Shu et al. (2010, 2012) presented more detailed research challenging the hypothesis.

However, previous studies focused on the Kuahuqiao site and other interesting subjects remain uncertain such as: What's the change in vegetation and environment around the site? How large is the scope of human activities? What is the extent of the marine transgression that caused the collapse of the Kuahuqiao site? We made a new core from the Lake Baimahu, less than 5km from Kuahuqiao site, trying to answer these questions.

Vegetation, environment were reconstructed based on AMS¹⁴C dating and sporo-pollen analyses. Three distinctive zones are well recognized: 1) **Zone I:** (8000-7750 cal. a BP), the period features the predominance of *Quercus*, *Pinus* and Poaceae. In this zone, *Cyclobalanopsis* and *Quercus* are abundant, Poaceae is prominent in the upper layers and increase visibly while *Pinus* experiences gradual decline. Charcoal increase slowly; 2) **Zone II:** (7750-7400 cal. a BP), this zone is dominated by *Pinus* and *Quercus* in percentage. *Quercus* showed a decreasing trend which is distinguished from Zone I, while *Cyclobalanopsis* have a slow rise. *Spinferites* begin to increase. Charcoal was almost stable, which is significantly reduced compared with the previous area; 3) **Zone III:** (7400-7150 cal. a BP), this zone is characterized by the gradual increase of *Quercus*, *Typha*, *Spinferites* and Poaceae, while the *Pinus* declined rapidly. At the same time, there are abundant Polypodiaceae-type and *Azolla* spores.

Dominance of *Quercus* and *Cyclobalanopsis* reflect the warm and humid climate; High content of Poaceae (<38 µm in diameter) indicate the grass distributed widespread in swampy wetlands. The expansion of Chenopodiaceae and Cyperaceae could be mainly encouraged by the rising sea level and the overwhelming marine transgression; In addition, the large amount of charcoal may indicate frequent human activities. However, there is no Poaceae (≥38µm) observed shows that rice cultivation was limited. These conclusion are similar with that at the Kuahuqiao site, so the ancient humans may have been reached and inflected the Baima Lake area.

Phytolith analysis will be incorporated in our study to better indicate the rice agriculture in the future.

Depositional process and provenance changes of the sediments in the East China Sea during the middle and late Holocene

Ke Wang¹, Ryuji Tada¹, Tomohisa Irino ², Hongbo Zheng³

¹The University of Tokyo , Tokyo , Japan. ²Hokkaido University , Sapporo, Japan. ³Yunnan University , Kunming, China

Abstract

Hydroclimate variations associated with the East Asian Summer Monsoon (EASM) precipitation exert significant impacts on lives of people inhabiting within the Yangtze River drainage and coastal zone. Seasonal shift of main precipitation area is attributable to the reposition of northern limit of summer monsoon, which would lead to provenance and composition changes of suspended materials transported by the Yangtze River. Therefore, the interannual to millennial time-scale variability of the position of rain belt mentioned above could be recorded in the long-term change in compositional variation of sediment originated from the suspended materials in the Yangtze River. The East China Sea(ECS) is of primary importance owing to massive inputs of terrestrial materials from the Yangtze River. The variation in the Yangtze River discharge and provenance could have been recorded in sediments of the Yangtze delta and ECS. Therefore, we could expect to recognize provenance changes in core sediments taken from the Yangtze subaqueous delta in association with EASM precipitation variability. In order to reconstruct the EASM precipitation and provenance variability during the middle and late Holocene from these sediment records, it is also necessary to examine the transportation mechanism of Yangtze-derived sediment including sediment reworking / re-deposition by coastal current, tide and local input, the migration of shoreline and estuary of the Yangtze River, as well as the change of depocenter in the Yangtze delta associated with the postglacial sea-level rise. Here, the sedimentary evolution, stratigraphy, age model and potential provenance change of MD06-3040 core covering the middle and late Holocene will be reported.

³Clinton Marine, Goteborg, Sweden

Abstract

Identifying sediment budgets with the potential to be mobilized in the next few decades is an important area of investigation for the coastal engineering community [1]. This includes characterizing sediment type (consolidated, unconsolidated, grain size) from the terrestrial cliff-dune system to around 20-30m water depth offshore. The main problem area here is the very shallow, always submerged region that is too shallow for survey boats to operate safely. This is the region where much of the sediment is mobilised and energy dissipated. Here we combine the passive seismic survey method to obtain thickness of inland deposits with a shallow offshore seismic survey, helping to bridge the gap between onshore and nearshore along the coast of the Isle of Sheppey, North Sea, reducing the uncertainty in this critical area.

Offshore data was collected in 2017 by Clinton Marine. The survey area is 50km², and comprises 1789km lines of 2D seismic data, acquired using Innomar's Medium SES-2000. Unconsolidated sediment is easily penetrated and imaged using this system, with resolution rapidly deteriorating once consolidated sediments are encountered. This is the basis upon which mobile sediments were interpreted and mapped. Offshore backscatter data processed and interpreted using Fledermaus FMGT reveal sediment grading from gravel to fine silts and muds, correlating with grab samples.

Onshore data was collected in February 2019 by the British Geological Survey using the passive seismic survey method. Passive seismic surveys measure background seismic noise to estimate the thickness of different lithologies through different time domains and spectral techniques. Passive seismic surveys consist of a series of single-station point recordings, generally arranged into linear transects or a grid pattern, the latter of which can be used to generate 3D surfaces of target horizons. We have used the Tromino ENGY-3G, a small, portable, broadband, three-component seismometer and the proprietary software Grilla (v7.0) that implements the Horizontal-to-Vertical Spectral Ratio (H/V) method [2, 3]. The reason behind using the spectral noise ratio is that seismic noise varies largely in amplitude as a function of the noise "strength" but the spectral ratio remains essentially unaffected and is tied to local subsoil structure [4]. The Grilla software also provides routines for quality control of the H/V analyses following the European SESAME project directives.

Estimates of carbon stocks in Swedish coastal areas of the Baltic Sea

Ann Elofsson, Karl Ljung, Helena Filipsson
Department of Geology, Lund University, Lund, Sweden

Abstract

Carbon storage in natural environments is an important factor for making both national and global carbon budgets. Presently, only carbon stocks in the terrestrial realm are systematically included in national carbon budgets. The large amount of carbon stored in coastal and marine sedimentary stocks are significant and may occur in the same order of magnitude as the terrestrial carbon stocks. Given the current rate of emissions and the pressing need for international agreements on reducing greenhouse gas emissions, a solid understanding of the different carbon stocks are of great importance for making realistic and useful assessments of national carbon budgets. Recently attention has been drawn to the carbon storage capacity of coastal sediments (Smith et al., 2015; Smeaton et al., 2016; Avelar et al., 2017). It has been shown that many coastal regions have high sediment carbon stocks, particularly in fjords (Smith, et al, 2015). Coastal sediment carbon stocks can also be significant when compared to terrestrial carbon stocks which are normally included in the assessments.

The aim of our project is to produce estimates of the marine carbon stocks in Sweden's Exclusive Economic Zone along the Swedish Baltic coast. We will present preliminary carbon-stock estimates based on published data and measurements on sediment cores. The sediment carbon stock estimates will be interpolated and spatially averaged using GIS and statistical tools. For coastal-marine settings we will develop a GIS model of basin shape and bottom type representing the Baltic coast. The purpose of including bottom type in our GIS averaging is to account for soft depositional bottoms with higher carbon accumulation and hard erosional bottoms with no or low accumulation. We aim to produce a data set that can show regional differences in carbon stocks along the Baltic coast as well as an estimate of the total carbon stock of the Baltic coast.

Vegetation history of Hyrcanian forest and the climate dynamics in northern Iran

Fang Gu, Kamaledin Alizadeh, Hermann Behling

University of Goettingen, Department of Palynology and Climate Dynamics, Göttingen, Germany

Abstract

The Caspian Hyrcanian forest region, mainly located at the narrow elongate belt between the southern shores of the Caspian Sea and northern slopes of Alborz mountain range in northern Iran, forms a unique hotspot of biodiversity with ancient mixed broadleaf forest. The Hyrcanian forest constitutes the most important refugia and the last relicts of broad-leaved deciduous forests covered the temperate zones of the northern hemisphere before the Quaternary, such as the Arcto-Tertiary relict species *Parrotia persica* (Persian iron), *Zelkova carpinifolia*, and *Pterocarya fraxinifolia*. Due to its special geographical location, this ecosystem is very sensitive to environmental changes, therefore the environmental records from this region can provide important archives for the past vegetation and climate changes as well as human impact.

In this study, we are using multi-proxy analysis to reconstruct past environmental changes using a ca. 550 years old sediment record by applying pollen/spore, Non-Pollen Palynomorphs (NPPs) and geochemistry analysis. The NPPs results indicate active erosion process of the catchment area between 540 and 450 cal yr BP. The pollen analysis indicate that *Alnus*, *Carpinus betulus*, *Fagus*, *Quercus*, *Ostrya*, *Zelkova* and *Pterocarya* are the most dominate taxa in the Caspian Hyrcanian forest since ca. 450 cal yr BP. Human impact was not so strong during the recorded period, but increased recently. This study contributes to an in-depth understanding of the dynamics of Hyrcanian forest, past climate changes, human activities and also provides suggestions for the conservation and management of the Hyrcanian forest in northern Iran.

Reconstruction of Palaeoenvironment of Chilka Lagoon, East coast of India using Benthic Foraminiferal Records

ANUPAM GHOSH¹, UTSHA DASGUPTA¹, Akira Tsujimoto², Ritsuo Nomura²

¹Jadavpur University, Kolkata, India. ²Shimane University, Shimane, Japan

Abstract

Anthropogenic impact on the water of Chilka lagoon (19°28'–19°54' N: 85°06'–85°35'E), the largest brackish lagoon of Asia, has been studied in details for the last few decades by using different environmental proxies. The present study is aimed to reconstruct the palaeoenvironmental and palaeoecological changes of the Chilka lagoon from a 70 cm long sediment core collected from the central section (19°39'41.40"N, 85°25'1.69"E) of Chilka lagoon by using biological proxy i.e benthic foraminifera.

In the present study, the 70 cm core was sliced into 1 cm and divided it into half ~ one for chronological analysis and another for microfossil analysis. The chronological data shows that the 15cm of the core is assign to 47 years from the present and the sedimentation rate of that area is 0.317cm/year. Hence from the sedimentation rate it can be concluded that bottom layer of the core (i.e. 70cm) is assigned to about 220 years from the present. For micropalaeontological analysis, the samples were wet sieved through 63 µm sieve and dried at 50°C. The sediment samples were split with the help of micro splitter and benthic foraminifera from 1gram of each split sediment sample was counted. The Total Foraminiferal Number (TFN) is very high in the upper part of the core and suddenly gets decreased from 14cm downwards. In the lower part of the core TFN slightly increases but not as much as upper part of the core. In the upper part of the core, the agglutinated species dominates (95-100%) and very few calcareous species (0-5%) are encountered there but in the lower part of the core, we find a vice versa scenario. The dominant agglutinated foraminiferal species are *Ammotium spp*, *Textularia agglutinans*, *Miliammina fusca*, *Trochammina spp*, and calcareous hyaline forms are *Ammonia parkinsoniana*, *Ammonia beccarii*, *Criboelphidium hispidulum*. In the first 11cm of the core, uniserial agglutinated species such as *Ammotium salsum*, *Ammobaculites sp.* and *Reophax sp.* dominates but from the 12 cm suddenly their percentage decreases. The presence of the highest percentage of uniserial agglutinated species indicates a typical anoxic stressed environment. The Murray's Ternary plot clearly shows two distinct cluster- one rich in agglutinated species in the upper and middle part of the core and another with a high percentage of calcareous hyaline species in the lower part of core indicating a stressed environment in the upper and middle part of the core. In the present study, the dominance of agglutinated species in the upper part of the core (up to 15cm which is assign to 47 years from the present) indicates a stressed environment that can be related to human interference in the lagoon in the past few decades.

Isotopic signature of ancient limpet shells as indicator of seasonal harvesting pattern in archaeological context

Jean-François Cudennec¹, Pierre Stephan¹, Yvan Pailler², Yves-Marie Paulet¹

¹University of Western Brittany, Brest, France. ²Institut National de Recherches Archéologiques Préventives, Brest, France

Abstract

Recent insight in *Patella vulgata* sclerochemistry and sclerochronology leads to the use of this species as a palaeo-environmental archive, mainly for the reconstruction of palaeo-SST through the study of $\delta^{18}\text{O}$ in shells. But high-resolution $\delta^{18}\text{O}$ profile can also be used to determine the season of death of the studied individuals. In archaeological context, it is possible to determine patterns of seasonal harvesting, as it has been achieved on several bivalve species.

For European Atlantic seashore, coastal shell middens hold high proportion of *Patella* shells, in particular in insular context, due to the abundance and the accessibility of these species for coastal populations. This archaeological material allows to study patterns of intertidal resources exploitation and insular site seasonal occupation. As a case study for this method, the site of Beniguet-2 (Le Conquet, Finistère, France), consists of three layers of shell middens interbedded in aeolian sand. These layers were radiocarbon dated back from Final Neolithic (2400 B.C.), Early Bronze Age (2000 B.C.) and Early Middle Age (650 A.D.). 10 shells from each occupation layers were studied, with two comparative methods.

Results show significant differences between the different shell layers, thus between the occupation periods. The Final Neolithic layer and the Early Middle age layer show year-long harvesting of *Patella*, while Bronze Age layer seems to contain only spring-collected shells. Interpretation of these results leads to several hypothesis, like seasonal or year-long occupation of insular sites, seasonal harvesting of particular resources, or single-meal shell pack. These results confirm the interest of *Patella vulgata* shells as palaeo-environmental and anthropological archive.

3D imaging of calcite microfossils – messengers of recent environmental changes

Helena L. Filipsson¹, Laurie M. Charrieau^{1,2}, Sha Ni¹, Karl Ljung¹, Dirk Mütter³

¹Department of Geology, Lund University, Lund, Sweden. ²Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan. ³Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Copenhagen, Denmark

Abstract

During the 21st century, the rising concentration of anthropogenic carbon dioxide in the atmosphere is likely to affect all marine calcifying organisms, and the ecosystems they inhabit, since the oceans act as a large sink for CO₂; a process referred to as ocean acidification. Furthermore, on a regional scale, a number of additional processes such as increased land run-off, erosion, and inorganic - and organic matter deposition will contribute to lower the pH and alkalinity in coastal waters. Concurrently other large environmental changes occur in coastal zones such as increasing seawater temperatures, eutrophication with resulting increased hypoxia, and pollution from industry and traffic. We have studied recent environmental changes in Skagerrak, NE Atlantic and in the entrance of the Baltic Sea (the Öresund) by sampling marine sediment cores and its content of benthic foraminifera fauna together with a range of environmental variables (grain-size distribution, content of organic carbon, nitrogen, heavy metals, and black carbon). Here we present data from high-resolution X-ray microtomography analyses, performed at SPring-8, Japan, on benthic calcareous foraminifera. We analysed three foraminiferal species with respect to shell structure, surface/volume ratio, size and density. The microtomographic results show considerable variability but a tendency towards lower shell thickness and concurrently higher shell surface/volume ratios in the last two decades compared with earlier part of the record, suggesting that substantial changes in shell preservation (and thereby water chemistry) have occurred.

The chronology and provenance of Holocene sediment in the Yangtze River (Changjiang) Delta, China: an OSL approach

Xiaomei Nian, Weiguo Zhang, Fengyue Qiu
East China Normal University, Shanghai, China

Abstract

Delta is formed under the interaction of climate, sea-level change, topography and sediment supply, which records the information of land-sea interaction. The Yangtze River Delta is home to China's largest coastal economic zone, and its evolution has drawn wide attentions. However, chronology framework of the Yangtze River Delta is a particularly troublesome problem due to the complicated sedimentary characteristics, and its provenance remains controversial. The development of optically stimulated luminescence (OSL) technique provides an opportunity to solve the above problems, since the luminescence signals of quartz or feldspar have widespread application in determining burial ages of Quaternary sediments. Meanwhile, it shows great potential in tracing the provenance of sediments.

In this study, the luminescence technique was used to determine the age of core HM and analyze its sediment provenance change. The single-aliquot regenerative-dose (SAR) protocol was applied to four different grain-size quartz fractions (4-11 μm , 45-63 μm , 63-90 μm , 90-125 μm). The results show that the ages of the samples obtained with four different grain-size fractions are generally consistent with each other within the limits of experimental errors and the stratigraphical order for early Holocene sediment. However, fine grain-size fractions yield the apparent overestimated ages for late Holocene sediment. In addition, three quartz fractions (45-63 μm , 63-90 μm , 90-125 μm) were subjected to quartz luminescence sensitivity measurements. High variable luminescence sensitivity was observed among the different grain-size fractions and different sedimentary units of the Yangtze River delta. By integrating chronology and sediment provenance analysis, we speculate that change of the sediment supply during late Holocene affect the accuracy of fine-grain OSL ages.

The postglacial development of Narva-Luga Klint Bay (eastern Gulf of Finland. Baltic Sea)

Alexander Sergeev¹, Darya Ryabchuk¹, Leonid Budanov¹, Vladimir Zhamoida¹, Margarita Kholkina¹, Dmitry Gerasimov², Igor Neevin¹, Anton Terekhov¹

¹Russian Geological Research Institute (VSEGEI), St.Petersburg, Russian Federation. ²Peter the Great Museum of Anthropology and Ethnography (Kunstkamera) Russian Academy of Sciences, St.Petersburg, Russian Federation

Abstract

The abstract presented new results of geophysical and geoarcheological studies of the formation of coastal marine sediments developed in the area of the Narva-Luga Klint Bay (lowland between the Narva and Luga rivers). A multiple depositional sequence represented here mainly by periglacial accumulative sandy landforms was formed during the last ice sheet degradation at the end of Pleistocene. According to the OSL dating the age of subsurface part of the extended presumably glaciofluvial landform named Kuzemkino Spit (a series of pebble-sandy clinofolds forming the glacial delta according to GPR data) is 13-10.8 thousand cal. yrs. BP. During the Holocene the lowland was substantially transformed by coastal-marine and alluvial processes. Geological and geomorphological studies show traces of at least two transgressions happened in the post-Ancylus Lake time (middle Holocene). Two erosion horizons indicating the sea level fluctuations of the Baltic Sea in the Holocene were distinguished using GPR profiling and OSL dating. The glaciofluvial deposits are covered by a thin sandy layer which was formed 8.1 ± 0.8 thousand cal. yrs. BP according to OSL dating of the sample collected at the height range from +11.8 to +12.3 m.s.l. The coastal scarp, the base of which is located at a height of +8.5 m, is developed hypsometrically lower in the same glaciofluvial complex. At the absolute level of 8.5 m, there was a relatively long-term stabilization of sea level. The beach and submarine sand ridges, subsequently not affected by marine transgressions and preserved as relict forms in the relief, were formed. According to archaeological data Kuzemkino landform was settled by ancient people after the Littorina transgression maximum. Earlier (Gerasimov et al., 2010) it was suggested that during the Early Neolithic time there were only short-term camp sites on the spits. The location of the archaeological sites is confined to the palaeo-beach line and confirms the formation of indentation in the second half of the Littorina Sea period. Geological and geophysical data analyses were carried out in frame of project № 17-77-20041 of Russian Science Foundation.

Monitoring and understanding geomorphological risks to coastal heritage: insights from contrasting sites in Wales and Ireland.

Hywel Griffiths¹, Louise Barker², Anthony Corns³, Kieran Craven⁴, Sarah Davies¹, Toby Driver², Daniel Hunt², Patrick Robson¹, Robert Shaw³

¹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom. ²Royal Commission on the Ancient and Historical Monuments of Wales, Aberystwyth, United Kingdom. ³The Discovery Programme, Dublin, Ireland. ⁴Geological Survey Ireland, Dublin, Ireland

Abstract

Projections of future climate change and sea level rise suggest that the effects of more frequent storm activity are likely to become more significant. This includes the geomorphological processes of coastal erosion and sand inundation, especially in exposed, remote and unprotected coastal locations. This means that the historic environments of these landscapes and the historically-, archaeologically- and culturally- important heritage sites located within them are at risk of being lost, damaged or buried. Effective management of these sites, including recording, interpretation and planning protection measures requires a better understanding of the nature and rate of geomorphological processes and the factors which control them. Placing recent, historical changes in a longer term context of environmental change may also aid stakeholder and public discussions on management options.

We present data from preliminary desk-based work (historical maps, reports) and fieldwork (dGPS, UAV and geophysical survey, rapid coastal zone assessment, palaeoenvironmental work) undertaken as part of the CHERISH project at three such sites – Bardsey Island and Dinas Dinlle hillfort in north west Wales and Dunbeg promontory fort, County Kerry, Ireland. These sites are all currently experiencing erosion, but due to site-specific characteristics (e.g. geology and sediment type) variations in erosion processes and rates are evident. Significant archaeological material has been, and continues to be exposed, damaged and lost at all sites including possibly prehistoric cremation burials and other archaeological material on Bardsey and structural damage and loss to the prehistoric and early medieval promontory fort at Dunbeg and the prehistoric hillfort of Dinas Dinlle. Previous work has shown that ~ 8m of erosion has occurred at some sites on Enlli (1918-2014) and recent surveys have shown that this has erosion is continuing. Rates of erosion through the glacial sediment underlying Dinas Dinlle fort are in the order of 0.2 m/yr (1889-2017). At Dunbeg, historical rates have been faster (e.g. ~ 0.5 m/yr 1897-1915) and recent storms in winter 2017-2018 caused the loss of 3000 m³ at this site. At Dinas Dinlle and Dunbeg, although wave action is the main erosive agent, the impact of overland flow pathways also appears to be significant.

These preliminary results suggest that erosion is likely to continue resulting in further exposure and/or loss of important archaeological material. Integration of these data with data from surveys of other sites on both sides of the Irish Sea will enable identification of areas of coastline to prioritise for targeted recording and management.

Linking lake level changes and surface deformation in the Dead Sea

Julius Jara-Muñoz¹, Amotz Agnon², Daniel Melnick³, Yannick Garcin⁴, Yaniv Darvasi², Manfred R. Strecker¹

¹University Potsdam, Potsdam, Germany. ²Hebrew University of Jerusalem, Jerusalem, Israel. ³Instituto de Ciencias de la Tierra, TAQUACH, , Universidad Austral de Chile, Campus Isla Teja, Valdivia, Chile. ⁴CEREGE, CNRS, IRD, INRA, Coll France, Aix Marseille Université, Aix-en-Provence, France

Abstract

Loading and unloading of the crust controlled by lake level changes may exert an important influence on the patterns of surface deformation, seismogenesis and fault activity. However, the relative contribution of climatic and tectonic factors on surface deformation at millennial time scales still remains poorly understood and quantified. The Dead Sea is the deepest continental basin on Earth; it is characterized by a complex history of abrupt lake level changes, active faulting, and variable seismic recurrence during the late Pleistocene and Holocene. Elucidating the interaction between climate and tectonics in this area is an extremely relevant topic in virtue of potential seismic scenarios associated with global climate change and anthropogenic impacts that may alter current lake levels. Here we study the outstanding exposure of fossil lacustrine shorelines along the coast of the Dead Sea, these geomorphic markers resemble past lake level positions and can be used to determine surface deformation rates. We study nine sites distributed along the eastern and western coasts of the Dead Sea, performing field topographic surveys, field observations and sampling for dating in each site. This study for first time provides chronological constraints for the lacustrine shorelines sequence, including 30 radiocarbon ages from fossil stromatolites. We map the distribution of fossil shorelines using high-resolution drone and LiDAR topography coupled with surface classification models. Our results suggest a sequence of up to 20 levels of fossil lacustrine shorelines between -150 and -380 m and with ages ranging between ~10 and ~40 ka. This sequence resembles the progressive drop of the lake Lisan (paleo Dead Sea). The shoreline elevations display a long wavelength deformation pattern decreasing in elevation northwards and southwards and are locally offset by faults at Ein Gedi, Ye'elim Creek, Ein Boquek, Metzkoque Dragot, along the western coast and by the Sehati, and Movenpick faults along the eastern coast. By comparing the elevation among shorelines of different sites we estimate a continuous deceleration of vertical deformation rates towards the present. Based on the comparison with previously published lake level curves, we suggest that isostatic rebound associated with lake-level drop may locally counteract tectonic subsidence. This study emphasizes the link between climate and surface deformation processes in the Dead Sea. This work is supported by the German Science Foundation (DFG) grant JA 2860/1-1 "LIFE - Linking lake level changes, surface deformation and seismogenesis in the Dead Sea" and the German-Israeli Foundation for Scientific Research and Development (GIF), grant I-1280-301.8/2014.

Early Holocene human-environmental interaction along the coast of Yoldia Sea and Ancylus Lake, Lithuania: multidisciplinary approach

Vladas Žulkus¹, Algirdas Girininkas¹, Gražyna Kluczynska², Vaida Šeirienė², Jonas Mažeika², Albertas Bitinas², Tomas Rimkus¹, Aldona Damušytė³, Miglė Stančikaitė^{1,2}

¹Institute of Baltic Region History and Archaeology, Klaipėda University, Klaipėda, Lithuania. ²Institute of Geology and Geography, Nature Research Centre, Vilnius, Lithuania. ³Geological Survey of Lithuania, Vilnius, Lithuania

Abstract

Traditionally, four main stages have been accepted describing the development of the Baltic Sea during the post-Glacial – Baltic Ice Lake, Yoldia Sea, Ancylus Lake and Litorina Sea. However, numerous questions related with the spatial-temporal resolution and ecological regime of the Yoldia Sea and Ancylus Lake still stays unsolved. And even less is known about the Late Palaeolithic-Mesolithic human groups that settled the area at that time. To explore these issues, a multidisciplinary approach that included both archaeological and geological investigations have been applied in Lithuanian' sector of the Baltic Sea.

To reconstruct the Early Holocene human-environmental interaction the data obtained from the bottom of the Baltic Sea and the coastal zone of the Lithuanian territory was studied involving palaeobotanical (pollen, diatom, plant macrofossil) survey, isotopic (¹⁴C) measurements and lithological (loss on ignition (LOI), grain-size and magnetic susceptibility (MS)) and archaeological investigations. Identified changes of the palaeoenvironmental regime and human history are discussed in the context of the circum-Baltic area.

Working on the reconstruction of the environmental history of the Early Holocene basins sediment cores of biogenic, limnic and marine sediments from the bottom (24 - 30 m b.s.l.) of the Baltic Sea were recovered. The part of the sequences, consisting of limnic and biogenic deposits and representing the Early Holocene, according to ¹⁴C data, are discussed.

The results obtained show the existence of a shallow transparent water basin surrounded by the birch-pine-predominating forest during the Early Holocene. Investigated basin was surrounded by wetland with *Menyanthes trifoliata* and Typhaceae. Beside that numerous trunks of the pine tree have been discovered laying at about 24–25 m. b.s.l. Dated back to about 11410–10170 cal. BP (9.640–8.220 cal. BC) these fossils prove the existence of the dry land in territory. One more stage of the biogenic sedimentation took place between 9.150–8.520 cal. BP (7.200–6.570 cal. BC). Investigated beds are laying at 29 m b.s.l. proving existence of the regressive coastal line below mentioned absolute height during the Early Litorina Sea stage. Based on the information obtained two phases of the Early Holocene basin development have been identified - the first corresponds to Yoldia Sea–Ancylus Lake period while the second one could be correlated with the Early Litorina Sea time.

Discussing the Early Holocene population history representatives of Early Mesolithic Kunda (Pulli) and Maglemose cultural groups should be mentioned. While mostly of the archaeological settlements have been discovered far inland from the present sea coast. Since the access to water bodies was of particular importance for survival of these communities, settling close to the sea coast, i.e. westward migration could explain this phenomenon. And this idea has been approved during the resent underwater archaeological investigations.

The search for the MIS 5e sea-level highstand from a slowly uplifting coastlines: lessons from the South Coast of England

Martin Bates¹, [Rebecca Briant](#)², Jenni Robertson², Jean-Luc Schwenninger³, John Whittaker⁴

¹University of Wales, Lampeter, United Kingdom. ²Birbeck College, London, United Kingdom. ³Oxford University, Oxford, United Kingdom. ⁴Natural History Museum, London, United Kingdom

Abstract

Global sea level reconstructions are dependent on clastic deposits to provide wider spatial coverage than can be achieved using marine or coral reef sequences. However, these deposits are more complicated to interpret, as their relationship with mean sea level is less clear. In addition, on slowly uplifting coastlines, there is the potential for overprinting of multiple highstand events at similar altitudes within the landscape. Here we report on 35 years of research in the Sussex / Hampshire Coastal Corridor (SHCC) which is thought to exhibit a uniquely complete record of deposition during multiple phases within the last interglacial (LIG), both within deposits of the 'Pagham Raised Beach' (PRB) and further west within the Solent seaway. We show that none of these sequences were deposited at mean sea level during the highstand part of the interglacial. Indeed, all are likely to have been deposited at a significant elevation below this datum. This is problematic because the PRB deposits have been used uncritically to represent mean sea level in a previous global sea level reconstruction. We apply the lessons learned from detailed study of this sequence to other sequences that have also been used for sea level reconstructions and show that very few of the clastic sequences used to augment other more continuous records from marine or subsiding settings are from geomorphological settings that convincingly correspond to sea level highstand conditions during the mid interglacial.

A multiproxy approach to investigate Late Holocene hurricane-fire interactions from a coastal lagoon near Manatee Bay, Jamaica

Romario Anderson¹, Michael Burn¹, S. Yoshi Maezumi^{1,2}, Suzanne Palmer¹, Dana MacDonald^{3,4}, Jeffrey P. Donnelly⁴
¹University of the West Indies, Kingston, Jamaica. ²University of Amsterdam, Amsterdam, Netherlands. ³University of Massachusetts, Amherst, USA. ⁴Woods Hole Oceanographic Institution, Woods Hole, USA

Abstract

Complex interactions exist between hurricane and fire activity that produce diverse ecological impacts on tropical coastal ecosystems. The Hellshire Hills lie within the Portland Bight Protected Area (PBPA) in southern Jamaica and are dominated by a continuous fire-adapted, semi-deciduous dry-limestone forest surrounded by coastal mangrove and lagoon communities. Archaeological evidence suggests that the Hellshire Hills were inhabited as early as 650 CE by different Ostionoid and subsequently Meillacan cultures (950 CE), suggesting a long-history of human land use in the surrounding landscape. Additionally, extended periods of drought, as well as the passage of tropical cyclones resulting in the accumulation of organic matter in the landscape, can affect the intensity and frequency of subsequent forest fires. Consequently, there exists the potential for the influence of both anthropogenic and natural drivers on the fire regime of the Hellshire Hills. Comparisons between charcoal and additional sediment proxies recovered from coastal lagoon cores within the PBPA, provide the opportunity to examine long-term natural and anthropogenic controls on local fire dynamics within this unique dry-forest community.

Here we present preliminary analyses of a 5m (~2000-year long) sediment record from a coastal lagoon north of Manatee Bay. The sediment stratigraphy is dominated by organic peats and authigenic marl sediments separated by distinct layers of coarse marine bioclastic sediments and charcoal. Loss-on-Ignition measurements at 550°C and 950°C utilized with grain-size analyses of the coarse sediment fraction (> 63µm) confirm the presence of multiple coarse carbonate sand layers within the stratigraphy. The composition of these coarse sediments (marine organisms including coral fragments, the alga *Halimeda sp.* and foraminifera) suggests they are allochthonous with a marine provenance and were most likely deposited during the passage of historical tropical cyclones; although deposition of washover during the earthquake-induced (M7.5W) tsunami of 1692 CE that generated a 1.8m wave that devastated nearby Port Royal cannot be fully discounted. Analysis of macroscopic charcoal suggests hurricane-fire linkages within the lagoon watershed were likely associated with changes in available fuel. Synthesis of these data with existing paleotempestological and archaeological records suggests the combined impact of human and hurricane activity on long-term fire activity in the Hellshire Hills during Pre-Columbian, Colonial and Industrial times.

P-1038

Anthropogenic effect or natural limit? Shoreline changes of a delta from accretion to destruction: A case from the Eastern Mediterranean

Emrah Özpolat¹, Tuncer Demir²

¹Eurasia Institute of Earth Sciences, Istanbul Technical University, Istanbul, Turkey. ²Faculty of Letters, Geography Department, Akdeniz University, Antalya, Turkey

Abstract

The construction of dams on rivers feeding deltas has caused to the sinking of world deltas. Especially due to anthropogenic effects over the last half-century delta shoreline retreat has attracted much scientific attention. However, most studies focus on shoreline retreat after dams are constructed. To clearly show the retreat of shorelines has been due to anthropogenic effects, it is very important to observe the natural shoreline changes before the anthropogenic effects on the delta. This study observed shoreline changes in the Seyhan Delta in the Eastern Mediterranean from 1950 to 2018 employing long-term Landsat MSS, TM and OLI time-series and aerial photographs. To identify shoreline changes, aerial photographs from 1950 and 1956 together with Landsat satellite images from 1972, 1985, 1998, 2009 and 2018 were employed. After extracting shorelines with MNDWI and NDWI index, the statistical analysis of the shoreline changes found with the Digital Shoreline Analysis System tool (DSAS) for different periods was undertaken.

The results indicated that the shoreline accreted nearly 131 meters nearly the river mouth with a maximum rate of 22.9 m yr⁻¹ from 1950 to 1956. In this period an area of 322,071 m² was added to the delta. Contrary to this, following the construction of the Seyhan Dam in 1956, the Seyhan Delta lost a total area of 4,039,251 m² from 1956 to 2018. The shoreline retreated 2293 meters at the river mouth, with a maximum rate of retreat of 37 m yr⁻¹. The major cause of this retreat is the trapping behind the Seyhan Dam of sediment brought down by the Seyhan River.

Comparing our data with different delta shorelines around the world showed the Seyhan Delta is the delta experiencing most rapid shoreline retreat in Turkey at a rate of 37 m yr⁻¹. Additionally, it is the delta with the third most rapid shoreline retreat in the Mediterranean, after the Nile and Ebro deltas. In conclusion, accreting under natural conditions, the Seyhan Delta witnessed dramatic shoreline retreat due to the effect of the dams constructed on its course. In the future, it is to be expected that the shoreline will retreat even more rapidly from causes such as the construction of further planned dams, land subsidence and rising of global sea level. This situation will have a great impact upon wetland areas and upon agricultural and tourism areas and structures in the delta. This study was supported by HÜBAK #14162 project.

Sea-land-man interactions revealed by the coastal vegetation history of the central Mediterranean during the Holocene

Federico Di Rita, Donatella Magri

Sapienza University of Rome, Department of Environmental Biology, Rome, Italy

Abstract

Mediterranean coasts are projected as one of the most vulnerable areas to climate change and impact of human activities, mainly due to sea level rise and the ever-increasing of human population. This process is particularly worrying in some areas of the central Mediterranean, where the risk of natural ecosystem loss is extremely high. In this context, palynology represents a fundamental tool to detect the past climate-man-environment interplays and provides outstanding examples of long-lasting processes of natural ecosystems loss and recovery, related to the combined action of human activity, climate change, and geomorphic processes. Here, we present a review of pollen records from coastal areas of central Mediterranean regions (including Malta, Sardinia, Corsica, Italian Peninsula, Sicily, Croatia, and Greece), in order to describe the general processes characterizing the environmental evolution of this region and to detect the main causes producing landscape change during the last thousands of years. An overview of the main vegetation types reveals a rather diverse composition and structure of the vegetational landscape, mostly depending on the interaction of diversified environmental forcings from a local to global scale, which make it impossible to define a pollen stratigraphical scheme valid for the entire area during the last thousands of years. Climate and geomorphic processes played a major role in shaping the vegetation features of the central Mediterranean. In some case, only one sector of the central Mediterranean Basin was involved (e.g. Tyrrhenian expansion of *Alnus* around 5200 cal. BP), while in other cases extensive geographical processes occurred (e.g. development of coastal wetlands around 7000 cal. BP). Besides, coastal pollen records substantially contribute in defining the effects of the relative sea level changes in coastal ecosystems, during both the Pleistocene/Holocene transition and the Holocene, so providing paradigmatic examples of ecological dynamics associated with the sea level rise. Concerning human impact, a general and progressive anthropization trend in the vegetational landscape is observed since the Neolithic, evolving with different times and modes from site to site. In many cases, human populations adapted their activities to the locally existing natural resources, for example by exploiting native mediterranean plant taxa (e.g., *Olea*, *Vitis*, and *Quercus suber*) or transforming natural coastal wetlands in saltworks, always determining deep landscape changes and depletion of the native biodiversity. This long-term environmental perspective indicates that the current coastal ecosystems of the central Mediterranean Basin represent an ephemeral snap-shot, destined to new, abrupt and dramatic future changes. Thus, palaeoenvironmental studies may prove of fundamental importance in estimating both the environmental instability typical of each geographical context and the degree of vulnerability of coastal ecosystems, so providing suggestions for appropriate conservation actions in coastal environments.

Using historical sources as proxies to study estuarine flood risk: the cases of Tagus (Portugal) and Shannon (Ireland) estuaries

Ana Rilo^{1,2}, Alexandre Tavares^{3,4}, Paula Freire⁵, José Luís Zêzere⁶

¹LNEC - National Civil Engineering Laboratory, Estuarine and Coastal Zones Unit, Lisbon, Portugal. ²Centre of Geographical Studies, Institute of Geography and Spatial Planning, Universidade de Lisboa, Lisbon, Portugal. ³Centre for Social Studies, Coimbra, Portugal. ⁴Earth Sciences Department, Coimbra University, Coimbra, Portugal. ⁵LNEC - National Civil Engineering Laboratory, Estuarine and Coastal Zones Unit, Lisbon, Portugal. ⁶Centre of Geographical Studies, Institute of Geography and Spatial Planning, Universidade de Lisboa, Lisbon, Portugal

Abstract

Estuarine margins are complex areas where multiple flood triggers interact such as tides, fluvial discharges and storm surge along with human presence. Additionally, the expected sea level rise and increasing storminess poses new challenges on how to manage properly for the future in a scenery of increased uncertainty. Therefore, historical information on past flood events can be of great value to better understand estuarine flooding and the related societal effects.

The use of historical sources to extract information on flood events has been widely used to improve the flood frequency estimation through the maximum level extraction, as well as to support the reconstruction of geomorphological evolution. Instruments as databases of flooding events (at local, regional, national and international levels) have been compiled with the aim of create a congregated knowledge and enable a better understanding of these events and related damages in order to support prevention and proper land use planning.

In this work we present and compare two estuarine flood damage databases built on written historical sources such as newspapers, reports, photographs and letters. The Tagus estuary database congregates 235 entries between 1865 e 2013. The database uses mostly daily newspapers with a wide and continuous temporal coverage, one geodatabase from the Portuguese National Protection Authority and photographs from Lisbon Port Authority, comprising a total of 106 historical sources. The Shannon estuary database congregates 230 entries and comprises the period between 1927 e 2013, although with gaps in the temporal coverage. It was built based on the diverse typology of documents extracted from the Irish Flood Hazard Mapping Website [<http://www.floodmaps.ie/>] property of The Office of Public Works (OPW). At total, 106 documents were analysed including reports, letters, photographs, newspapers and minute meetings.

To allow a comparison both databases have a similar structure, founded on four groups of information, namely: Basic information; Type of impacts; Flood characteristics and Triggering factors. The historical sources were analysed using content analysis techniques in order to maintain coherence in the information extraction and statistical techniques were applied to analyse the data gathered. The results highlight the differences and the similarities on what concerns flood damages and triggers between the two estuarine systems. The results also point out the different capacity of each source type to inform about the triggers and damages.

This work demonstrates the usefulness of historical sources as a proxy to better understand the complexity of flooding in estuarine systems, the applicability of databases as instruments to collate different typologies of sources and finally, it also highlights the vast amount of information that can be extracted from these types of sources and their utility for estuarine flood risk management.

LGM-to-recent sedimentary and high-resolution acoustic facies of a transgressed alluvial plain (Gulf of Trieste, northern Adriatic)

Ana Trobec¹, Andrej Šmuc¹, Sašo Poglajen², Marko Vrabc¹

¹University of Ljubljana, Faculty of Natural Sciences and Engineering, Department of Geology, Ljubljana, Slovenia.

²Sirio, Koper, Slovenia

Abstract

Post-LGM sea-level rise significantly affected sedimentary environments on low-gradient continental shelves. One such case is the present-day northern Adriatic where the vast LGM alluvial plain was rapidly transgressed and transformed into a shallow marine environment. One of the last areas which were affected by the Holocene transgression in the Adriatic Sea is the Gulf of Trieste located in its northeasternmost part. This area is particularly suited for investigations of the Late Pleistocene-Holocene transition due to its exceptionally well-preserved terrestrial record and shallow depths facilitating sediment sampling.

We used the Innomar SES-2000 sub-bottom sonar to acquire profiles from which we determine different acoustic facies units using the IHS Markit Kingdom software. We correlated the acoustic facies with sediment samples obtained with the Uwitek gravity corer. We performed granulometric analysis of the sediment samples with the Fritsch Analysette XX Laser Particle Sizer and the Gradistat software. AMS radiocarbon dating was used for absolute dating of the samples.

The sampled alluvial sediments were deposited between the onset of the LGM and the Early Holocene. Overlying Early Holocene transgressive sediments are buried by Early Holocene to recent shallow marine deposits. Our work provides a correlation of the high-resolution acoustic facies with the sedimentary facies on transgressed alluvial plains. The oldest sampled alluvial unit are cross-stratified sandy muds of fluvio-aeolian origin which show an acoustic facies with low-amplitude chaotic reflection geometries. This unit is topped by graded deposits (sandy mud and sandy clay grading into clay) expressed in the geophysical record by sub-horizontal high-amplitude and high-frequency reflections. These deposits are overlain by overbank fine-grained sediments which are expressed as a transparent acoustic facies containing individual discontinuous middle-to-low amplitude reflections. Transgressive deposits are represented by bioclastic sandy mud containing brackish mollusk assemblages and show middle-to-low amplitude reflections with onlapping and concordant reflection geometries. Marine sediment is composed of bioclastic sandy mud and silt with shallow marine mollusk assemblages and has a transparent acoustic facies.

Spatial variation of concentration and chemical fractionation of sedimentary phosphorus in Guanabara Bay, Rio de Janeiro - Brazil.

Carlos Marclei Arruda Rangel¹, José Antonio Baptista Neto², Estefan Monteiro da Fonseca², Priscilla Soares de Oliveira²

¹Universidade Federal Fluminense, Angra dos Reis, Brazil. ²Universidade Federal Fluminense, Niterói, Brazil

Abstract

The Anthropocene consists in the most recent period of the quaternary and the history of the Planet. It is at this time, that human activities begin to have a significant global impact on the Earth's climate and the functioning of its ecosystems. In this way, surface sediments absorb concentrations and chemical forms of pollutants caused by anthropic activities. Among the coastal aquatic ecosystems, the estuaries constitute a depositional environments and potencial reservoirs of several contaminants associated with recent sediments (Kucuksezgin et al., 2006). The Guanabara Bay system, located in Rio de Janeiro city, received a huge amount of untreated sewage produced by human activities. The aim of this study were, evaluate the seasonal variations of physic-chemical parameters and characterize the phosphorus fractionation in Guanabara Bay sediments (Gachter et al., 1998). In order to identify and quantify the different forms of phosphorus was used a SEDEX sequential extraction of 23 sediments samples. The total phosphorus (TP) in the sediments ranged between 1.4 and 80,2 $\mu\text{mol.g}^{-1}$ respectively. The highest concentrations of TP in this area are attributed to the input of untreated domestic sewage. P-Exchangeable showed a variation in ranged between minimum and maximum 0 and 6,5 $\mu\text{mol.g}^{-1}$, respectively. Through the obtained data in this study it is possible to observe in most of the stations, the significant occurrence of the P exchangeable fraction, which may also be associated with eutrophication existing in the system. The P-Fe fraction ranged between 0,22 and 19 $\mu\text{mol.g}^{-1}$. Phosphorus bound to metal has ranged between 0,70 and 6.40 $\mu\text{mol.g}^{-1}$. The eutrophication determines reducing environmental conditions, which are determinant in the predominance of the P-Fe and P-Me chemical fractions preferably linked to the organic phase. The P-Ca ranges from 0,21 to 12 $\mu\text{mol.g}^{-1}$. The intense degradation of the natural system releases the stable phosphorous phases to other P-exchangeable fractions, that characterizes contaminated aquatic systems (Harahan et al., 2005). The concentrations of residual phosphorous are unimpressive in both seasons with minimum and maximum values of 0.5 to 7 $\mu\text{mol.g}^{-1}$.

Seasonal distribution of organic matter in vertical and horizontal profiles of sheltered and exposed beaches on Polish coast

Katarzyna Bigus

Pomeranian University in Słupsk, Słupsk, Poland

Abstract

Sea coast is an extraordinary area which joins the elements of sea and land environment. It is an important zone both from environmental as well as economical point of view. Unique characteristics of sea coast cause that it is popular amongst of tourists and patients for recreational and rest purposes. Sea coasts are simultaneously very sensitive for any changes, both natural and anthropogenic. Many studies and observations indicate consecutive degradation of polish coast. It is caused by increased level of the sea and well as intensity and frequency of storms. Very often they are also modified by humans in an uncontrolled way in order to fulfill an increased economic expectations of tourists. Therefore, an important problem is the cleanliness and attractiveness of the beaches.

Sandy sediments coming from three beaches of the southern Baltic Sea were collected and analyzed. Investigated beaches were divided according to strength of anthropogenic impact and degree of sheltering. The first beach was situated in Ustka on the eastern side of the mouth of the Słupia River, second in Czołpino and the last one in Puck. Core sediment samples were collected seasonally, depending on the influence of the sea water on the examined sediments. At each station, surface sediments (0-5 cm) were collected as well as sediments at the depth of 10-15 cm. The general content of organic matter, proteins, lipids, carbohydrates, organic carbon and total bacterial number were determined.

The results of the conducted tests reveal, that anthropopressure, degree of sheltering, the depth where the collected sediments were taken and the direct influence of the sea water on the sediments have impact on the chemical composition of organic matter and bacterial number in beach sediments. Determination of the labile form of organic matter in the entire organic matter was a way of assessing the variability of the unformatted fraction of organic carbon. This fraction can not be used as a source of food for organisms living in the beach sediments. It is negative because the introduction of excessive organic matter causes the exploitation of oxygen resources in a given ecosystem. As a consequence, indigenous organisms can be replaced by allochthonous organisms, and even poisoning of existing organisms can occur.

The rise and fall of Los Buchillones: a Taino village on the north coast of central Cuba

Mercedes Liedtke¹, Matthew Peros²

¹University of Ottawa, Ottawa, Canada. ²Bishop's University, Sherbrooke, Canada

Abstract

Los Buchillones is a Taino village located on the north coast of central Cuba. Several dozen AMS dates indicate that it was occupied from approximately 1220 to 1640 CE. It is one of the largest and best preserved prehistoric settlements in the Caribbean, and consists of approximately 40 collapsed houses made of wood and palm thatch. This high level of preservation is due in part to the fact that the site is submerged under 1 m of water, partly in a lagoon. Geoarchaeological investigations in the late 1990s suggested that Los Buchillones was built over water and that the prehistoric houses that are preserved at the site were constructed on piles. More recent archaeological investigations focusing on house architecture also supported the idea of pile dwellings, possibly as a strategy to cope with sea level rise, coastal erosion, and episodic storm surges. Recent paleoenvironmental investigations in the region provide important new data with which to understand the evolution of Los Buchillones. Preliminary sedimentological findings from a nearby sinkhole show that a severe drought occurred just prior to the beginning of occupation of the settlement, whereas drying associated with the Little Ice Age roughly coincided with the abandonment of the site. This would suggest possible close climatic control on settlement occupation, possibly through its impact on marine resources and agriculture. In addition, paleotempestological data from the Bahamas shows that the period from 1220 to 1640 CE represented a time of relatively active hurricane activity, which may partly explain the presence of a stilt village. The archaeological and paleoenvironmental data that have emerged from this region of Cuba permit hypotheses concerning vulnerability and resilience in coastal zones to be tested in a prehistoric context.

Records of environmental change and sedimentation processes over the last century in a Baltic coastal inlet

Hanna Nilsson¹, Kotaro Hirose², Olof Berglund³, Anna Godhe⁴, Helena L. Filipsson¹

¹Department of Geology, Lund University, Lund, Sweden. ²Resources and Environmental Engineering, Waseda University, Tokyo, Japan. ³Dept. of Biology, Lund University, Lund, Sweden. ⁴Dept. of Marine Sciences, University of Gothenburg, Gothenburg, Sweden

Abstract

The marine ecosystem in the Baltic Sea is affected by multiple stress factors, such as eutrophication and deoxygenation, overfishing and heavy metal pollution. Human-induced environmental changes may occur during a range of timescales and marine organisms must adapt to the new conditions, or they will be locally extinct. This project aims to reconstruct one Baltic coastal environment, SE Sweden, which has experienced an increasing human impact over the last century and identify trends of both human-induced pollution and large-scale environmental changes. The study area is affected by eutrophication due to nutrient load from surrounding farmlands and large-scale nutrient inputs. The inlet is deoxygenated due to organic substances in suspension and slow water exchange.

Four undisturbed laminated sediment cores were collected in the inner and outer part of the coastal inlet, dated using ²¹⁰Pb and ¹³⁷Cs. We are using grain-size analysis, organic carbon and nitrogen content, biogenic silica and elemental analysis to reconstruct the coastal environment over the last 100 years.

The results from our analysis of these four cores of near-coast sediments will contribute to increased understanding of past environmental changes and sedimentation processes in near-coast sediments of the Baltic Sea.

Holocene shoreline displacement and Stone Age palaeogeography of the Pärnu Bay area, eastern Baltic Sea

Triine Nirgi¹, Alar Rosentau¹, Tõnno Jonuks², Tiit Hang¹, Jan Risberg³, Argo Jõelett¹, Hando-Laur Habicht¹, Sten Suuroja⁴, Aivar Kriiska⁵, Hannes Tõnisson⁶

¹Institute of Ecology and Earth Sciences, University of Tartu, Tartu, Estonia. ²Estonian Literary Museum, Tartu, Estonia. ³Department of Physical Geography, Stockholm University, Stockholm, Sweden. ⁴Geological Survey of Estonia, Rakvere, Estonia. ⁵Institute of History and Archaeology, University of Tartu, Tartu, Estonia. ⁶Institute of Ecology, Tallinn University, Tallinn, Estonia

Abstract

The shore displacement and palaeogeography of the Pärnu Bay area, eastern Baltic Sea, during the Stone Age, were reconstructed using dated sedimentological and archaeological proxies and GIS-based landscape modelling. We discovered and studied buried palaeovalley sediments on the coastal lowland and in shallow offshore of the Pärnu Bay and interpreted these data together with previously published shore displacement evidence. The reconstructed shore displacement curve is based on 82 previously published and 7 new radiocarbon dates from sediment sequences and archaeological sites. The new shore displacement curve displays regressive water levels at -5.5 m and -4 m a.s.l before the Ancylus Lake and Litorina Sea transgressions, respectively. The total water level rise during the Ancylus Lake transgression (10.7–10.2 cal. ka BP) was around 17.5 m, with the average rate of rise about 35 mm per annum, whilst during the Litorina Sea transgression (8.5–7.3 cal. ka BP) the water level rose around 14 m, with average rate about 12 mm per annum. The relative sea level increase rates around 7.8–7.6 cal. ka BP clearly exceeds the concurrent rate of the eustatic sea level rise similarly to slowly uplifting areas in Samsø (Denmark), Blekinge (Sweden) and Narva-Luga (NE Estonia-NW Russia). The palaeogeographic reconstructions show the settlement patterns of the coastal landscape since the Mesolithic and provides new perspective for looking hunter-fisher-gatherer settlement sites on the shores of the ca. 9000 years old submerged river valley in the bottom of the present-day Pärnu Bay.

P-1047

Reconstructing Estuarine Palaeo-Environments using 3D Ground Penetrating Radar Imaging

Luis Rees-Hughes¹, Dr Natasha Barlow¹, Dr Adam Booth¹, Dr Jared West¹, Dr George Tuckwell², Tim Grossey²
¹University of Leeds, Leeds, United Kingdom. ²RSK Geophysics, Hemel Hempstead, United Kingdom

Abstract

During the last two decades, geophysical method, specifically Ground-Penetrating Radar (GPR) have grown in popularity for acquiring high-resolution images of the buried stratigraphy, internal structure and wider context of geomorphological landscapes. GPR provides a practical complement to established methods, including in-field mapping of exposures and sediment core-logging which typically provide sparse 2D insight into subsurface architecture and morphology. In geomorphological settings, GPR surveys typically complement core sampling by linking borehole data along 2D transects but cannot reveal full subsurface morphology. More comprehensive GPR surveys offer rapid, non-invasive 3D characterisation of the shallow sub-surface (~10 m maximum depth), with data interpretable in terms of the thickness, lithology, structure and extent of subsurface depositional environments (e.g. coastal, fluvial and alluvial deposits).

The wider uptake of 3D GPR is enabled by recent advances in GPR systems technology – the development of robust equipment and GPS-coupled antennas being particularly advantageous. 3D methodologies and their dedicated processing algorithms are now commonplace within the engineering and archaeological sectors, and are able to reveal the full structure of complex targets. Equivalent advantages can now be realised for geomorphological characterisation, for assessing the true size and extent of buried coastal landscapes.

This poster highlights the potential of 3D GPR methodologies using a 500 MHz GPR dataset collected over a buried Holocene estuarine environment in Llanbedr, Gwyendd, North Wales, which has since been reclaimed for use as an airport. The complexity of the buried estuarine structures, including small, meandering, salt-marsh channels, motivates a 3D GPR survey, given that i) the channel geometry is too complex to appreciate from individual 2D transects and ii) their narrow size suggests they could easily be missed in a core logging programme. When viewed in a top-down “depth-slice” view, the 3D architecture of the subsurface is easily appraised, and can furthermore be interpreted as a palaeo-record of the evolution of the site. The deepest palaeo channels (2.9 m depth) are small and sparsely distributed (*Fig. 1a*), but are both more densely spaced and complex at shallower depth (1.4 m) (*Fig. 1b*). When combined with regional models of sea-level change and associated sedimentation, these data provide a valuable model for the evolution of Holocene estuarine environments and present-day analogues.

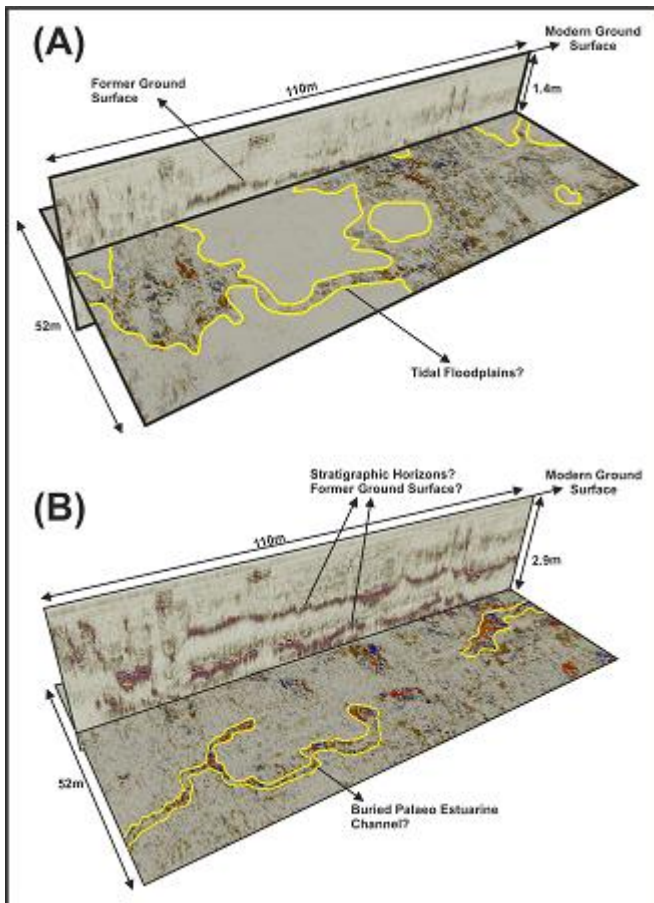

Figure 1: (A) 3D depth slice at 1.4m of the more densely spaced and complex palaeo estuarine channels. (B) 3D depth slice at 2.4m of the small and sparsely distributed palaeo estuarine channels.

Woodlands under the waves: Orcadian landscape change from the Mesolithic to Bronze Age

Scott Timpany¹, Michelle Farrell², Martin Bates³, Richard Bates⁴, Jane Bunting⁵, Steve Davis⁶, Sue Dawson⁷, Caroline Wickham-Jones⁸

¹University of the Highlands & Islands, Kirkwall, United Kingdom. ²Coventry University, Coventry, United Kingdom.

³University of Wales Trinity St David, Lampeter, United Kingdom. ⁴University of St Andrews, St Andrews, United Kingdom. ⁵University of Hull, Hull, United Kingdom. ⁶University College Dublin, Dublin, Ireland. ⁷University of Dundee, Dundee, United Kingdom. ⁸University of Aberdeen, Aberdeen, United Kingdom

Abstract

Coastal landscapes are vulnerable to both gradual and sudden, dramatic environmental change through the mechanisms of sea-level rise and extreme events such as storm surges and sand blow events. Coastal environments are also critical for resources, communication and living space, and arguably were even more important in prehistory. Here we present the results of a holistic investigation of coastal landscape change in Orkney over a 7000 year period, from the Mesolithic to Bronze Age; achieved by analysing a section of landscape incorporating dryland, intertidal and marine zones.

Offshore geophysical survey has provided information on seafloor sediments and inundated land surfaces; pollen, diatom, waterlogged plant remains, insect and sediment DNA analyses of radiocarbon dated sediment cores recovered from intertidal peats and freshwater lakes have enabled reconstruction of rising sea-levels, climate, and terrestrial landscape change including woodland decline and the introduction of agriculture. This study provides valuable contextual information for the periods before, during and after the use of the monuments making up the Heart of Neolithic Orkney World Heritage site, including the ongoing excavations at the Ness of Brodgar.

Pollen results show extensive woodland cover during the Mesolithic and into the Early Neolithic (c.7500-3800BC) that included pine, birch, hazel and to a lesser extent oak and alder. Submerged forest identified as largely willow with some birch has offered a glimpse into the character of wet woodland, dated to c. 4800-3350BC, with high levels of microscopic charcoal, including fragments of reed stomata and grasses provide evidence for wetland burning. While the discovery of a radially-split oak timber within the intertidal peat, (felling date of c.4200BC) demonstrates Later Mesolithic communities were not only present but manipulating the environment.

Woodland cover reduces significantly from c.4300-3800BC with evidence for agriculture beginning after this time; corresponding with the start of the Neolithic in Orkney. This landscape change occurs against a backdrop of sea-level rise, which in the intertidal zone led to the demise of carr-woodland and development of freshwater pools. Despite such extreme landscape change the occurrence of agriculture-related pollen and probable woodland clearance demonstrates that rather than abandoning these areas Neolithic people were actively modifying and monumentalising their landscape (e.g. the start of pier-architecture building at the Ness of Brodgar has been dated

to c.3000BC). A further extreme event (storm surge) is indicated by marine clays incorporated in intertidal peat between c.1600-1400BC. Pollen evidence suggests agricultural activity resumes immediately following this event showing continued resilience by Orcadian communities.

The results of this work have contributed significantly to our understanding of not only how this area of Orkney changed in prehistory as a response to wider environmental change but also more broadly as to how people adapted and reacted in the face of dramatic landscape change.

Searching for fingerprints of early 20th century ice melt in Australian salt marshes

Sophie Williams¹, Roland Gehrels¹, Patrick Moss², Sönke Dangendorf³, Andrew Sole⁴

¹University of York, York, United Kingdom. ²University of Queensland, Queensland, Australia. ³Universität Siegen, Siegen, Germany. ⁴University of Sheffield, Sheffield, United Kingdom

Abstract

Sophie Williams

Department of Environment and Geography, University of York, Wentworth Way, York, U.K., YO10 5NG.

Sea-level rise during the 20th century was faster than during any other century in the last 3000 years. Proxy evidence from salt marshes suggests that the magnitude of the sea-level acceleration from the 19th into the 20th century was greater in the Southern Hemisphere in comparison to the Northern. The cause of this sea-level acceleration remains unknown. Anthropogenic forcing was still weak; therefore, the rise must have been driven by natural processes. One potential source may have been melting of Arctic glaciers and the Greenland ice sheet (GrIS) during the Arctic Warm Period of the 1920s and 1930s. This melt produced a sea-level 'fingerprint', including high relative sea-level rise in far-field areas like South Africa, South America and the Pacific. In this study, we search for the fingerprint of ice melt in the salt marshes of southeastern Australia to test the hypothesis that Arctic and Greenland ice melt was responsible for the rapid rise in sea level in the early 20th century. Using microfossils, specifically benthic foraminifera preserved in sediment cores, changes in sea level will be reconstructed over the last ca. 500 years at cm-scale resolution at three sites in southeastern Australia including Bruny Island (Tasmania), Tarra River (Victoria) and Wapengo Lake (New South Wales). Core chronology will be established via a variety of dating tools including ITRAX-XRF, stable lead isotopes ($^{206}\text{Pb}/^{207}\text{Pb}$, $^{206}\text{Pb}/^{208}\text{Pb}$), radionuclides (^{137}Cs and ^{210}Pb), and AMS-bomb spike ^{14}C . Reconstructions will be compared to the sea-level fingerprint of historical changes in Arctic ice mass.

Reconstruction of post-glacial sea level fluctuations in the Baltic Sea: an integrated approach

Albertas Bitinas

Nature Research Centre, Akademijos g. 2, LT-08412 Vilnius, Lithuania. Klaipėda University, Marine Research Institute, Universiteto av. 17, LT-92294 Klaipėda, Lithuania

Abstract

There were many attempts to reconstruct the Baltic Sea water level changes by different investigators. As a result, several dozens of relative sea level (RSL) curves have been published; most of them are controversial to each other. Besides, a few others unsolved topics linked with the Baltic Sea development are still under discussion. The reason of such variety and incompatibility of RSL curves is that different authors were guided by different set of factual data, used different ways of data interpretation, etc. But the main problem is that separate parts of the Baltic Sea experience (or experienced before) different influence of glacioisostatic rebound: the absence of stable rafter ("zero" point) is the main obstacle for reliable reconstruction of sea level fluctuations starting from the Late Glacial until the present days.

The Lithuanian coast is the transit zone between the northern part of the Baltic Sea (that is still experiencing the glacioisostatic uplift), and the Southern Baltic (that is recently subsiding). Thus, it is the Lithuanian coast that could be the best "rafter" for the estimation of sea level fluctuations. The recent underwater archaeological investigations carried out by researches of Klaipėda University (V. Žulkus, A. Girininkas, etc.) show that large submerged landscapes with survived remnants of tree trunks and stumps, also sediments of relict lakes and bogs, are spread on the Lithuanian offshore. It serves as a good sea level indicator starting from the Yoldia Sea stage. A new reconstruction of sea level fluctuations at the Lithuanian coast is based on two principal moments: (1) strong selection of reliably dated objects indicating sea level position (key-indicators), and (2) an estimation of glacioisostatic rebound trend and amplitudes in the coastal zone. The rating of the latter factor allows to speak not only about RSL fluctuations, but also about eustatic sea level changes in the Baltic basin.

It is possible to conclude that the salinity of the different Baltic Sea basins (freshwater or brackish) and transitional situation between them (transgression or regression) depend on three main factors: (1) rate of the eustatic water level rise in the World Ocean (i.e. in the North Sea in our case), (2) water level in the Baltic Sea basin related to melting of the Scandinavian Ice Sheet and inflow of rivers, and (3) rate of glacioisostatic rebound in the Southern Sweden and in the region of the Danish Straits. The glacioisostatic model and eustatic curve of sea level fluctuations at the Lithuanian coastal zone, as well as integrated model of the Southern Baltic development during the entire post-glacial period are presented in the graphic form.

P-1051

Investigating the influence of the deglaciation of the Southern Alps icefield on Holocene sea-level change, South Island, New Zealand

Alastair Clement¹, Pippa Whitehouse²

¹Massey University, Palmerston North, New Zealand. ²Durham University, Durham, United Kingdom

Abstract

During the Last Glacial Maximum (LGM) New Zealand's Southern Alps were covered by the Southern Alps icefield, a 800-km long mountain icefield spanning $\sim 5^\circ$ latitude, feeding outlet glaciers extending 70-100 km onto the adjacent forelands, sometimes to sea level. Large-scale glacial retreat commenced c. 17,000 years BP; today, only mountain glaciers remain. Glacial isostatic rebound of the Southern Alps has previously been hypothesised but has not been substantively investigated. This ongoing project aims to identify the potential effects of glacial isostatic adjustment (GIA) – particularly in response to retreat of the Southern Alps icefield – on Holocene sea-level (SL) changes around the coast of the South Island.

There are two ongoing avenues to this investigation. Firstly, production of a high resolution time-series of the deglaciation of the Southern Alps icefield from c.17,000 years BP to c. 6,000 years BP (when the minimum extent of the icefield was reached). This will be achieved by scaling an existing model of the extent of the Southern Alps icefield during the LGM (Golledge et al., 2012, QSR 46) using reconstructions of temperature and equilibrium line altitude. This local ice history will be merged with components of the global ice history to correctly model the GIA process. The global ice history will influence SL change around the South Island, but variability in our study area is likely to reflect melt of the Southern Alps icefield.

Secondly, production of new records of Holocene SL changes for key tectonically-stable regions around the South Island: Nelson-Tasman Bay; Otago; and Southland. Existing Holocene SL reconstructions from Otago show a misfit with current GIA model predictions (which do not consider the effect of deglaciation across the Southern Alps), and continuous GPS measurements from the region indicate subsidence. We hypothesise that these observations reflect regional subsidence associated with the collapse of a glacial forebulge throughout much of the Holocene. The new SL reconstructions – obtained over the Southern Hemisphere summer 2018-2019 field season – will be used to validate model predictions of South Island Holocene SL change derived using the approach described in the first part of this study.

Sea-level rise in the Bristol Channel during the mid-late Holocene: new evidence from the Taw Estuary, southwest Britain.

Glenn Havelock¹, Tony Brown², Jason Jordan³, Jean-Luc Schwenninger⁴

¹University of York, York, United Kingdom. ²University of Southampton, Southampton, United Kingdom. ³Coventry University, Coventry, United Kingdom. ⁴University of Oxford, Oxford, United Kingdom

Abstract

This paper presents a new sea-level history for the Taw Estuary in southwest Britain. For the sea-level reconstruction, modern diatom samples were collected from two transects located across the intertidal marshes of the Taw Estuary, producing a local training set that related diatom species distribution to elevation in the tidal frame. A diatom-based transfer function was then developed and subsequently used to quantitatively reconstruct Holocene sea-level changes in two dated sediment cores, taken from the inner Taw Estuary. The transfer function model (WAPLS) indicates precise and accurate reconstructions are possible with an error estimate of ± 0.18 m, which is comparable to other diatom-based transfer functions.

11 sea-level index points (SLIP's) resulted from the reconstructions, producing a new mid-late Holocene sea-level record for south-west Britain, spanning the last -6,700 years. Importantly the new record includes 4 SLIP's from the last -2,300 years, a period where there is a paucity of SLIP's in this region, due to predominantly minerogenic deposition. The results show a history of steady sea-level rise from 6,700 cal. yr. BP to 2,300 cal. yr. BP. This is followed by a marked slow-down in sea-level rise and a subsequent highstand (close to modern elevation) that lasted from approx. 2,200 cal. yr. BP to 1,200 cal. yr. BP. The record then indicates a possible downward oscillation in sea level of c.0.5 m, followed by a rise of c.1.0 m since 800 cal. yr. BP. The reconstructed sea-level history is compared to the latest glacial isostatic adjustment models for the region, indicating some agreement.

One of the notable results of this reconstruction is the indication of a possible late Holocene sea-level highstand during the first millennia AD. This has not been shown in other reconstructions for the region (possibly due to a lack of SLIP's), but evidence for a Romano-British transgression and subsequent sea-level highstand has been indicated in the archaeological and historic record. Significantly, a separate comprehensive stratigraphic and palaeoecological investigation of the River Taw estuary and valley, that extends upstream of the current tidal limit, has revealed conclusive evidence of a major marine incursion that took place during the first half of the first millennia AD (the "Romano-British" period). Major valley incision took place at this time, followed by widespread deposition of shelly estuarine sands and silts upstream of the modern deposition of this facies. Fossil diatom assemblages from marsh sediments dated to the early centuries of the first millennia AD also contain significant numbers of brackish-marine mesohalobous and polyhalobous species upstream of their modern-day occurrence. In conclusion, this new evidence all points to a prolonged marine incursion into the estuaries of southwest Britain during the first millennia AD.

Inception of the World Atlas of Last Interglacial Shorelines (WALIS) – advancing knowledge of sea level changes in past warmer worlds.

Alessio Rovere¹, Deirdre Ryan¹, Thomas Lorscheid¹, Evan Gowan², Matteo Vacchi³

¹MARUM, University of Bremen, Bremen, Germany. ²Alfred Wegner Institute, Bremerhaven, Germany. ³University of Pisa, Pisa, Italy

Abstract

In the last century, nearly 1000 scientific papers have described the elevation, age or stratigraphic details of last interglacial shorelines (ca. 125 ka). This has resulted in thousands of sites reported globally, but with varying degrees of detail and scarce standardization between different datasets. In order to disentangle eustatic, isostatic, and other processes causing relative sea level changes in the Last Interglacial, the paleo sea level community is in need of a reliable global database of last interglacial sea-level proxies. Here, we present two tools designed to facilitate the compilation of the World Atlas of Last Interglacial Shorelines (WALIS). The first is a relational MySQL database, complete with a user-friendly interface of more than 100 different fields that allows the insertion of sea level data and metadata inclusive of sea level stratigraphy and multiple methods of radiometric age constraint. The second is a Wiki website designed to host the last interglacial sea-level information derived from the database and subdivided by national boundaries. The WALIS database and Wiki are being developed in the framework of the WARMCOASTS ERC Starting Grant, and will be improved and maintained in close collaboration with the PALSEA community (PAGES-INQUA).

P-1055

Improving mangrove radiocarbon chronologies for reconstructing late Holocene sea-level changes

Juliet Sefton¹, Sarah Woodroffe¹, Philippa Ascough²

¹Durham University, Durham, United Kingdom. ²Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom

Abstract

Mangrove sediments are an important archive of past sea-level changes in relatively under-sampled, low-latitude locations. These locations are important because they are far from the former and present polar ice sheets, and therefore records of sea-level changes are less dominated by glacial isostatic adjustment signatures. However, the utility of mangrove sediment is currently limited due to problems with poor fossil preservation and the difficulty of establishing accurate and precise radiocarbon chronologies. Mangrove-based sea-level reconstructions depend upon radiocarbon chronologies but obtaining samples which faithfully record down-core ages can be problematic due to bioturbation by roots and crabs, and potential inputs from many carbon sources that do not reflect deposition age. To confidently interpret mangrove sea-level records, we need a better understanding of how to obtain accurate age estimates for mangrove sediments. In settings with slow sedimentation rates during the late Holocene, this means being able to create high resolution chronologies based on closely spaced radiocarbon dates in short cores (often less than one metre long).

Here, we address the question of which components of the fossil mangrove record are most reliable for radiocarbon dating. Many mangrove sea-level studies have reported problems with out-of-sequence ages when bulk sediment samples are used for measurement. Additionally, mangrove roots can penetrate as much as two metres into underlying sedimentary sequences, and therefore ages from large root material will not be the same as *in situ* material from an equivalent stratigraphic depth. Similarly, fine roots which branch off from the main larger roots at depth also introduce younger carbon into the sedimentary sequence, but decompose more rapidly than larger roots. Where identifiable and present, above ground macrofossils (e.g. leaves, seeds) can provide the most accurate ages. Such macrofossils are short-lived, discrete plant material that represent up to 18 months mangrove tree growth, or a single flowering season, which overcomes the problem of inbuilt carbon ages. Previous work has targeted a specific organic concentrate size fraction (10-63 μm) in Holocene mangrove cores from Tanzania.

Here we compare radiocarbon dates derived from bulk sediments, organic concentrates (size fraction 10-63 μm), pollen concentrates and surface macrofossils (leaves and seeds), from short cores (<1 m) collected in Seychelles mangroves. We aim to identify which organic components provide the most accurate ages for short sequences of late Holocene mangrove sediments. These results will inform future mangrove dating strategies and allow more accurate and precise sea-level reconstructions.

Pre-industrial Sea-level Rise Hotspots in the Northwest Atlantic Ocean

Roland Gehrels¹, Soenke Dangendorf², Natasha Barlow³, Margot Saher⁴, Antony Long⁵, Philip Woodworth⁶

¹University of York, York, United Kingdom. ²University of Siegen, Siegen, Germany. ³University of Leeds, Leeds, United Kingdom. ⁴Bangor University, Menai Bridge, United Kingdom. ⁵Durham University, Durham, United Kingdom. ⁶National Oceanography Centre, Liverpool, United Kingdom

Abstract

The Northwest Atlantic is a region where hotspots of sea-level rise in the instrumental record have been linked to observed ocean-atmosphere climate variability. Here we test if these hotspots are present in pre-industrial sea-level records by reconstructing sea-level changes from three sites in the Northwest Atlantic (Nova Scotia, Maine, Connecticut) using foraminifera preserved in salt-marsh sediments as proxy indicators. We use training sets comprising contemporary foraminifera to develop transfer functions for sea-level reconstructions. The transfer functions quantify the vertical relationship between elevation and micro-biota and allow sea level to be expressed as a function of the microfossil assemblages preserved in sediments in cores. We collected the cores from the highest marsh zones, close to the upper limit of present tidal inundation and away from tidal creeks. We assess statistically the fit between modern and fossil foraminiferal datasets using the Modern Analogue Technique. We use a variety of dating methods, including AMS¹⁴C, ²¹⁰Pb, ¹³⁷Cs, ²⁰⁶Pb/²⁰⁷Pb, pollen markers and trace metal markers to develop robust chronologies for our records. We apply a Gaussian process regression approach that models relative sea-level (RSL) at each site by taking the corresponding vertical and chronological uncertainties into account, and therefore provides probabilistic estimates of past rate changes. We test the assumption that sediment compaction errors are insignificant in our sites by comparing our reconstructed sea levels with sea-level data reconstructed from basal sediments that are unaffected by the effects of compaction.

In all three sites the 20th century rates are unambiguously high compared to rates in preceding centuries. However, we also document evidence for sea-level rise in the late 18th century that was only slightly slower than rates in the 20th century. To our knowledge this represents the first clear proxy evidence for episodes of pre-industrial rapid sea-level rise along the North American East Coast in, broadly, the same region where sea-level rise hotspots have been documented in 20th century tide-gauge records. A comparison with other North Atlantic salt-marsh records reveals that centennial periods of sea-level acceleration along the US east coast coincide with periods of deceleration in Iceland and vice versa. This anti-phase relationship correlates significantly with centennial swings in the North Atlantic Oscillation and is physically linked to changes in the prevailing wind and pressure conditions along the two coasts. We conclude that sea-level rise hotspots are a persistent feature along the North American East Coast and not unique to the 20th century. Predictions of future sea-level rise for New York City, Boston and other population centres in New England and Atlantic Canada should account for fluctuating rates of background natural sea-level rise.

Reconstructing holocene sea levels using rock-encrusting oysters: case examples from peninsular Malaysia

Peter Parham^{1,2}, Timothy Shaw³, Keven Roy³, Jędrzej Majewski¹, Ibrahim Komoo^{4,2}, Benjamin Horton^{1,3}

¹Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore. ²Centre of Tropical Geoengineering, Universiti Teknologi Malaysia, Johor Bahru, Malaysia. ³Asian School of the Environment, Nanyang Technological University, Singapore, Singapore. ⁴Institute for Environment and Development, Universiti Kebangsaan Malaysia, Bangi, Malaysia

Abstract

We present a standardized methodology for using rock-encrusting oysters (REO) to reconstruct relative sea level (RSL) during the Holocene. REO are important sea-level indicators in tropical and subtropical areas where Holocene RSL was higher than present. Reconstruction of former sea-level is based on the altitudinal relationships between living and fossil REO at the same locality. We surveyed REO of *Saccostrea cucullata* from two Peninsular Malaysia field areas (Langkawi islands and NE Peninsular Malaysia) with differing glacial isostatic adjustment (GIA) histories. Living *S. cucullata* are confined to the intertidal zone between mean low water spring tide (MLWST) and mean high water spring tide (MHWST). We therefore are able for the first time to formally define the reference water level of *S. cucullata* as the mid-point of MHWST and MLWST and the indicative range as the altitudinal difference between MHWST and MLWST, which is ca. 1 m and 0.5 m for Langkawi and NE Peninsular Malaysia, respectively. The elevation of *S. cucullata* above their living counterparts represents the change in RSL between now and the time the fossil REO lived. We determine the chronology by radiocarbon dating the fossil *S. cucullata* and subsequently calibrate using marine reservoir effects of -121 ± 60 and -15 ± 38 for Langkawi and NE Peninsular Malaysia, respectively.

We reconstruct RSL at Langkawi and NE Peninsular Malaysia using 20 sea-level index points and radiocarbon dates for the fossil oysters. We compare these index points with site-specific RSL predictions based on GIA model ICE-7G_NA (VM7). Our index points from both study areas indicate highstand-to-falling-stage RSL from mid-Holocene onward. The consistency supports the reliability of our method, and provides constraints on the performance of our GIA model. Thus, we are confident that this standardized methodology is effective for reconstructing RSL over millennial time scales with 0.5 to 1 m precision in tropical and subtropical areas where Holocene RSL was higher than present.

Abstract

Kurile-Kamchatka and Aleutian island-arc systems are located along a zone of intense seismic and volcanic activity in the northwestern Pacific (NWP). Neotectonic vertical movements and the superposed effects of climate-controlled sea-level changes play a decisive role in the evolution of the coastal sectors of this region. To highlight similarities and differences in the paleoenvironmental history of the southern Kuriles we analyzed sediment records from Shikotan Island and compared our results with the available information from the adjacent areas in the NWP.

7.9-6.4 cal ka BP. This period corresponds to the warm and dry Holocene Climate Optimum (HCO), which had a coeval impact on the neighbouring Kurile, Kamchatka and Japanese islands. During the Holocene transgression the sea-level rose up to 3 m above PSL.

6.4-5.8 cal ka BP. During this interval a trend toward wetter and cooler conditions occurred. The lower sea level corresponds to the end of the Holocene transgression.

5.8-5.0 cal ka BP. Neoglacial cooling coincided with the most significant Middle to Late Holocene (Jomon) regression when sea level was 4–5 m below PSL. Landslides at this time could have been caused by the higher precipitation and/or strong earthquakes.

5.0 – 3.5 cal ka BP. An onset of a low-amplitude Late Holocene transgression. The higher sea level corresponded to the Late Jomon transgression, with an amplitude of approximately 1.2–2.5 m above PSL. The presence of tsunamigenic sands corresponded to strong paleo-earthquakes around ca 4.43 and 3.89 cal ka BP.

3.5 – 2.0 cal ka BP. Cool climate. Tephra deposition (2.5 cal ka BP, Tarumai Volcano, Hokkaido) altered the lake chemistry. Two sand layers may correspond to small tsunamis preceding the eruption.

2.0 – 1.07 cal ka BP. Cool conditions and slight regression that were also identified on Kunashir Island and in Central Kuriles corresponded the beginning of the Kofun cold stage of Japan. Fragments of *Coscinodiscus sp.* in a sand layer at 2.0 cal ka BP indicated a tsunami event.

1.07 – 0.4 cal ka BP. Gradual climate warming and transitions to a MWP in this interval could be correlated with a Nara-Heian-Kamakura warm stage. The impact of the MWP was not prominent on the Bering Islands, Central Kamchatka, and Central Kurile islands apart from the Semushir.

After 0.4 cal ka BP. The deposits of this interval were formed during the LIA, which was distinctly pronounced across Kuriles, on Japanese islands, and in Kamchatka. Fragments of oceanic diatoms indicate several tsunami events.

In summary, the general chronology of major Holocene climatic events in the southern Kuriles is in accordance with the climate records from the NWP region. The recognized spatial differences in timing and magnitude of the Late Holocene climatic episodes (LIA, MWP) in the study region needs further investigations.

P-1059

Glacial Isostatic Adjustment of the British Isles and North West Europe.

Sarah Louise Bradley^{1,2}, Jeremy Ely², Chris Clark², Robin Edwards³, Ian Shennan⁴, Benoit S. Lecavalier⁵, Richard C.A. Hindmarsh⁶

¹Department of Geoscience and Remote Sensing, Delft University of Technology, Delft, Netherlands. ²Department of Geography, University of Sheffield, Sheffield, United Kingdom. ³School of Natural Sciences, Trinity College, Dublin, Ireland. ⁴Sea-Level Research Unit, Department of Geography, Durham, United Kingdom. ⁵Department of Physics and Physical Oceanography, Memorial University, St. John's, Canada. ⁶British Antarctic Survey, Cambridge, United Kingdom

Abstract

The British and Irish Ice sheet (BIIS) was one of the smaller marine-based ice sheets that grew during the Last Glacial cycle, but it is by far the world's best empirically constrained with the completion of the BRITICE-CHRONO project. Despite its small size (contributing less than 2m to global sea level rise), the ongoing glacial-isostatic-adjustment- (GIA) driven crustal motion plays an important role in controlling rates of sea-level-rise across the North-West Coast of Europe. Unravelling this complex GIA signal is important not only for ongoing and future sea level projections, but also in understanding marine-based ice sheet dynamics.

The pattern of relative sea level (RSL) and GIA across this region is spatially variable and highly non-monotonic. This is due to the temporally varying interplay between the regional GIA signal, driven by the BIIS and the global signal which was driven by the deglaciation of the larger global ice sheets, such as Antarctica and Laurentide. Although many previous GIA modelling studies were relatively successful in capturing the broad pattern of regional RSL change, there are some major unresolved discrepancies and factors that were not considered, which this study will address. Firstly, the models were not able to capture both the elevated RSL during the Late Devensian and the timing and magnitude of the Holocene highstand. Secondly, new evidence shows that the BIIS is more dynamic and spatially extensive than previously thought. Finally, the deglaciation of the grounded ice sheet from the offshore continental shelf and resultant RSL was largely overlooked in previous studies, due to a lack of observational data.

In this study, we utilise the recently updated regional sea-level database, which contains over 2100 data points, recording relative sea level (RSL) from 86 unique regions in Great Britain (GB) and Ireland for the last 20 kyr. We will present an ensemble of simulations of the BIIS and Scandinavian ice sheet (SIS), constrained by the new geomorphological and geochronological data collated by the BRITICE-CHRONO consortium and the DATED -1 project, combined with different global GIA models. By comparing the predicted RSL with the updated sea-level database, we will outline the interplay between the regional (BIIS and SIS) and global ice sheets (Laurentide and Antarctica) in driving the pattern of RSL in GB and Ireland over the last 20 ka.

P-1060

Reconnaissance of Early-Middle Pleistocene Bridgewater Formation and implications for long-term landscape development of the northern Coorong Coastal Plain, South Australia

Deirdre D. Ryan¹, Robert P. Bourman², Brian G. Jones², Colin V. Murray-Wallace²

¹University of Bremen, MARUM Center for Marine Environmental Sciences, Bremen, Germany. ²University of Wollongong, School of Earth, Atmospheric and Life Sciences, Wollongong, Australia

Abstract

Located on the southern margin of Australia, the Coorong Coastal Plain retains one of the longest terrestrial records of Quaternary sea-level highstands recognized in the Bridgewater Formation carbonate aeolianites and associated lagoonal sediments. Quaternary uplift in the southern coastal plain has allowed the discernment of barriers of different ages through the generation of physical space resulting in the identification of thirteen 'dune ranges'. Additional ranges farther inland extend the record through the Middle Pleistocene Transition and into the Early Pleistocene. The northern coastal plain record is less well defined due to decreasing rates of uplift northward and eventually subsidence in the Murray Lakes region. However, this region remains important due to the presence of the River Murray, the largest exhoreic river of Australia, and for improving our understanding of the Quaternary development of the landscape. Investigation of the Bridgewater Formation in the northern part of the coastal plain has allowed the identification of Early and Middle Pleistocene beach barriers and assisted in the identification of multiple drivers of regional landscape evolution.

Other than the potential for paleomagnetic analysis, the ranges are beyond the current capabilities of other geochronological methods. The tentative ages were determined through correlation with the marine isotope record and their counterparts in the south using geographic and morphostratigraphic interpretations assisted by topographic transects derived from SRTM data. The deposition of the Bridgewater Formation in the northern coastal plain, and therefore, to some extent, the position and orientation of successive coastlines has been influenced since the Early Pleistocene by the Padthaway Ridge, a Late Cambrian-Ordovician basement feature. Ranges deposited upon and landward of the Padthaway Ridge have typically formed composite structures and form topographic highs in the landscape. The composite nature of these features may also be in part due to shorter cycles of sea-level change prior to establishment of eccentricity-dominated cyclicity. Preservation of these ranges indicates the River Murray has always discharged to the west, supporting not only the premise of long-term subsidence of the Murray Lakes region, but also suggesting dominant longshore drift northwest along the coastline during sea-level highstands throughout much of the Pleistocene. Ranges deposited seaward of the Padthaway Ridge have subsided and have been susceptible to erosion by the River Murray and sea-level transgressions and highstands. In summary, in addition to eustatic sea-level fluctuations, the distribution and preservation of the Pleistocene Bridgewater Formation within the Coorong Coastal Plain has been influenced by the presence of the Padthaway Ridge basement structure, differential rates of uplift experienced across and along the Coorong Coastal Plain, a dominant northwest direction of longshore drift during sea-level highstands, and susceptibility to erosion by the River Murray.

P-1061

Inception of a global atlas of Holocene sea levels

Nicole Khan¹, Erica Ashe², Robert Kopp², Benjamin Horton¹

¹Nanyang Technological University, Singapore, Singapore. ²Rutgers University, Piscataway, USA

Abstract

Determining the rates, mechanisms and geographic variability of sea-level change is a priority science question for the next decade of ocean research. The HOlocene SEA-level variability (HOLSEA) working group is developing the first standardized global synthesis of Holocene relative sea-level that incorporates full consideration of vertical and temporal uncertainty for each sea-level index point, including uncertainties associated with the relationship of each indicator to past sea level and the methods used to date each indicator. HOLSEA aims to: (1) estimate the magnitudes and rates of global mean sea-level change during the Holocene; and (2) identify trends in spatial variability and decipher the processes responsible for geographic differences in relative sea-level change.

The global atlas includes over 12,000 sea-level index points and limiting data from a range of different indicators across seven continents from the Last Glacial Maximum to present. The global atlas will be made available in a special issue of Quaternary Science Reviews and archived on NOAA's National Centers for Environmental Information (NCEI). The global atlas now includes sea-level data from:

1. Near-field regions (Atlantic Canada, Greenland, the British Isles, the Russian Arctic, Antarctica);
2. Intermediate-field regions (Pacific, Gulf, Atlantic and Caribbean coasts of North America, western Europe, the Mediterranean, New Zealand);
3. Far-field regions (Atlantic South America, South Africa, India, Sri Lanka, the Maldives, Southeast Asia, China, Australia)

Here we combine near-, intermediate-, and far-field data along a pole-to-pole transect (Greenland, North American Atlantic coast, Caribbean, South American Atlantic coast and Antarctica) to illustrate the advantages of applying a spatio-temporal empirical hierarchical statistical model to describe the spatial variability in relative sea level and its rates of change. By comparing these records across a transect that spans a range of 'fingerprints' from land-based ice sheets, we have the potential to isolate ice-sheet contributions to Holocene RSL changes.

Early to mid-Holocene relative sea-level changes in the Ningbo Plain, southern Yangtze River Delta, Eastern China

Long Wang¹, Zhanghua Wang¹, Timothy Shaw², Nicole Khan^{2,3}, Keven Roy², Jędrzej MAJEWSKI⁴, Benjamin Horton^{4,2}
¹State key laboratory of Estuarine and Coastal research, East China Normal University, Shanghai, China. ²Asian School of the Environment, Nanyang Technological University, Singapore, Singapore. ³Department of Geological Sciences, University of Hong Kong, Hongkong, Hong Kong. ⁴Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore

Abstract

Holocene relative sea-level (RSL) records from far-field locations provide important constraints on the timing of the deglaciation of the large northern hemisphere ice sheets and on the viscosity profile used in Glacial Isostatic Adjustment (GIA) model predictions. Here, we reconstruct RSL changes during the early to mid-Holocene in the Ningbo Plain, southern Yangtze River Delta (YRD), eastern China. Previously published RSL curves for the YRD were hampered by dating and vertical constraint uncertainties. Using 25 newly obtained boreholes, we provide a detailed RSL record using new radiocarbon ages coupled with multi-proxy lithological and sedimentary evidence that constrains the timing and position of past RSL. Furthermore, we applied an Errors-In-Variables Integrated Gaussian Process (EIV-IGP) model to assess magnitudes and rates of RSL change and compare the RSL reconstruction with GIA model predictions.

Our reconstruction provides 38 new sea-level index points and 5 limiting data points. During the early Holocene, RSL rose from ~ -34 m at ~ 10 ka BP to ~ -3 m at 7 ka BP. The millennial-scale rate of RSL rise decreased during the early Holocene from 13.6 mm/yr (10 – 9 ka) to 10.9 mm/yr (9 – 8 ka) to 3.6 mm/yr (8 – 7 ka). During the mid-Holocene, RSL rose to ~ -1 m at 5.5 ka BP at a rate of 1 mm/yr (6 – 5 ka). Comparison of GIA predictions with the new data show GIA is the main driving force of Holocene RSL change in southern Yangtze. However, obvious misfits exist in comparison to different GIA models. Our results demonstrate the need for new high-quality far-field RSL data to tune the next generation of GIA models.

P-1063

A limpet's-eye view of post-glacial isostasy

Michael J. Simms¹, Paula Reimer²

¹National Museums Northern Ireland, Belfast, United Kingdom. ²Queen's University, Belfast, Belfast, United Kingdom

Abstract

The altitude of intertidal marine platforms is determined by a combination of intrinsic and extrinsic factors of which mean sea level is just one. Hence it can be difficult to accurately determine relative sea level during formation of so-called 'raised beaches'. Many Sea Level Index Point (SLIPs) rely for dating on supratidal or subtidal organic material (terrestrial vegetation or marine shells) whose exact relationship to mean sea level is imprecise, and so it can also be difficult to establish an accurate chronology.

The '25 Foot Raised Beach' in Northern Ireland is a distinctive erosional feature formed during a brief period when Holocene eustasy and isostasy were rising at the same rate. The date and relative elevation of this 'mid-Holocene highstand' has been established as part of a broader Relative Sea Level (RSL) curve using conventional SLIPs which indicate a RSL in north-eastern Ireland of c.+6 metres at c.6 ka B.P.

Bioerosional marks of Limpets (*Patella*), and other intertidal and subtidal organisms, have been observed on limestone cliffs >10 metres above present LWM at a site in Co. Antrim, Northern Ireland. The vertical distribution of modern limpets relative to HWM and LWM is well documented and hence these sub-fossil limpet marks accurately constrain upper and lower tidal limits in this region at some point during the Holocene. Remarkably, sub-fossil shells of Limpets (*Patella*), with an associated fauna of Winkles (*Littorina*), Dog Whelks (*Nucellus*) and encrusting annelids (*Spirorbis*) have been recovered from the base of fissures around 1-2 metres directly below the limpet marks. C-14 analysis of this shell material gives various dates between 4ka and 6ka cal B.P., the oldest of which matches closely with previous dates for the mid-Holocene highstand and formation of the '25 Foot Raised Beach'. Marine shells have been used previously to date the raised beach, but never from a context where they can be tied in so precisely to tidal range.

These limpet marks represent a uniquely precise SLIP for the Holocene. Significantly, they indicate a vertical error of ~40% for previously published Holocene RSL curves for the region. Furthermore, the vertical distribution of associated bioerosional taxa at this site has implications for the rate of decoupling of isostasy and eustasy following the mid-Holocene highstand and, indeed, for the very nature (gradual vs. episodic) of isostatic uplift here.

P-1064

Sea-level research on the North Sea and in Greater Rotterdam, The Netherlands

Marc Hijma¹, Kim Cohen^{2,1}, Freek Busschers³, Paolo Stocchi⁴, Natasha Barlow⁵

¹Deltares, Utrecht, Netherlands. ²Utrecht University, Utrecht, Netherlands. ³TNO-Geological Survey of The Netherlands, Utrecht, Netherlands. ⁴NIOZ, 't Horntje, Netherlands. ⁵Leeds University, Leeds, United Kingdom

Abstract

The Netherlands has a long tradition of sea-level research from which vast amounts of data accumulated over the last 60 years. The results, however, are scattered across large numbers of papers and reports, were obtained using different sampling and dating techniques, have been in part revised, and as a whole had not been uniformly scrutinized on quality and usability today. We present new results for Greater Rotterdam (including record of the pre-8.2 sea-level jump) and from offshore regions within the southern and central North Sea (Rhine-Thames land, Doggerland).

For the Rhine-Meuse delta and transgressed palaeovalley below 'Greater Rotterdam' (RMD), we have recently re-assessed the sea-level reconstruction data. Following documented protocols, index points tied to radiocarbon dates from peat beds were selected (catalogued), then documented and screened individually in a database, and then further screened in ensemble on quantified age-depth position and inshore palaeotidal setting. The RMD database holds 50 sea-level index points (SLIPs) and 56 upper limiting data points. The SLIPs cover an age-range of 8.8-3.0 ka, beginning at -21 m O.D. in the RMD near offshore. For upper limiting data points, the coverage reaches further offshore tracing the Rhine palaeovalley, back to 11 ka BP and down to -34 m O.D.

Between 8.0 and 4.5 ka, relative sea-level rise gradually decelerated from 0.9 to 0.2 m/cy. Between 9.0 and 8.0 ka, rates of rise were much higher. They averaged 1 m/cy, and were briefly higher (~2m/cy) during a superimposed 'sea-level jump'. For this jump, the RMD resolves a magnitude of 1.7 ± 0.6 m for the first phase (starting 8.45 ka), and a few more decimetres in a second phase (8.3-8.25 ka). This corresponds to globally-averaged jump components of 2.5 ± 0.9 m (1σ) and 0.1-0.4 m respectively, caused by drainage of Lake Agassiz-Ojibway also known from the 8.2-ka cold event.

For the pre-9 ka BP period, for which data is to be sampled offshore, SLIPs are rare and not currently available from the Rhine palaeovalley. More to the north (Oyster Grounds and Doggerbank regions), a few SLIPs exist, that have considerable uncertainties with respect to their sampled elevation, their indicative meaning and their age. Resampling for SLIPs, aiming to densify the vertical series from subregions offshore is an ongoing effort, with two cruises with the vessel Pelagia (NIOZ, Royal Netherlands Institute for Sea Research) completed in 2017 and 2018. These sampled peat beds between -60 and -25 m O.D. (completed) to obtain sea-level index points (in preparation).

In our presentation we will show both the results from the database effort in the Rotterdam area and the preliminary results from our North Sea palaeo sea-level campaigns.

A Holocene sea level record for the far-field region of Singapore

Stephen Chua^{1,2,3}, Adam Switzer^{2,3}, Benjamin Horton^{2,3}, Nicole Khan², Michael Bird^{4,5}, Cassandra Rowe^{4,5}

¹Interdisciplinary Graduate School, Nanyang Technological University, Singapore, Singapore. ²Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore. ³Asian School of the Environment, Nanyang Technological University, Singapore, Singapore. ⁴ARC Centre of Excellence for Australian Biodiversity and Heritage, James Cook University, Cairns, Australia. ⁵College of Science and Engineering, James Cook University, Cairns, Australia

Abstract

The early Holocene (11.6 – 7.0 ka BP) was a period of dramatic environmental change coincident with rapid relative sea-level (RSL) rise that provides a valuable analogue for the future. However, this critical time period remains inadequately studied, especially in far-field regions that experience hydro-isostasy but minimal land-level change due to glacio-isostatic adjustment.

Singapore lies near within the tectonically stable Sundaland, and here we obtained new sea level index points (SLIPs) from a ~40 m sediment core in Singapore, that augment and extend existing records. We dated wood and charcoal samples from a basal mangrove peat unit to produce 4 new SLIPs spanning ~9.5 – 9.2 ka BP, which provide the earliest record of post-Last Glacial Maximum marine transgression in the region. Additionally, we recalibrated 57 published SLIPs and 20 marine-limiting points, and used a Bayesian modelling approach to produce a revised Holocene sea-level record for Singapore.

The new record reveals a period of rapid RSL rise in the early Holocene from -20.5 m at ~9.5 ka BP to -4.5 m at 8 ka with a rate of 10.9 mm/yr. The rate of RSL significantly slowed to ~4 mm/yr between 8 and 6 ka BP when RSL was ~2.5 m. The maximum RSL of 5 m was reached at ~5.1 ka BP. RSL sea-level fell from the highstand although there are only 2 index points both at ~2.3 ka BP to constrain the reconstruction. The resolution of the revised RSL record does not illustrate any inflections in the rate of sea-level rise during the Holocene. Our results provide new early Holocene data that may inform glacio-isostatic adjustment (GIA) models and projections of future sea level for Singapore and the region.

P-1066

Leveraging preservation bias in Last Interglacial coral sea-level records to refine global ice volumes over the ice age

Rebecca Cleveland Stout¹, Tamara Pico¹, Jacqueline Austermann², Peter Huybers¹, Jerry Mitrovica¹

¹Harvard University, Cambridge, USA. ²Lamont-Doherty Earth Observatory, Palisades, USA

Abstract

Accurately reconstructing sea level during the Last Interglacial (~125 ka) will improve our understanding of how ice sheets have reacted to warm temperatures in the past, and this insight can aid in refining estimates of future sea level rise in a warming world. Past sea levels have been reconstructed using biologic and geologic shoreline features, such as fossil coral reefs, marine terraces, and erosional notches. Amongst these sea level indicators, fossil coral reefs are the most widely used, as their chronology can often be tightly constrained using U-Th dating. Today's record of existing sea-level markers are a result of systematic preservation biases, which to-date have not been directly considered in reconstructions of Last Interglacial global mean sea level. Tectonic uplift, sea level change, accretion rates, and erosion rates dictate whether a coral reef forms and its subsequent probability of preservation, resulting in preferential preservation of proxies reflecting relative sea level highstands.

We explore the observed distribution of Last Interglacial coral reef sea-level markers using a statistical model that accounts for the growth and destruction of coral reefs over the last glacial cycle. We force this model with sea-level predictions from a large ensemble of glacial isostatic adjustment simulations sampling a range of possible ice volume change scenarios across the last ice age, and identify spatial signatures in model-produced coral distributions, to show how regional sea level patterns produce distinct records of coral reef preservation. We show that predicted elevation distributions of preserved corals in the Bahamas and western Australia are strongly imprinted by local sea level histories. We find that this modeling yields an improved understanding of indicative meaning, which is essential in constraining global mean sea-level values across the Last Interglacial and the subsequent glacial cycle, because only a certain subset of ice histories predict a present-day distribution of sea-level markers consistent with the observed dataset of Last Interglacial coral reef records. This reveals the potential to leverage the observed elevation distribution of Last Interglacial corals to constrain past relative sea level, and thereby global ice volumes, across the last glacial cycle.

Drivers of sea-level changes in eastern Canada

Robert L. Barnett^{1,2}, Pascal Bernatchez², Michelle Garneau³, Dan J. Charman¹

¹University of Exeter, Exeter, United Kingdom. ²Université du Québec à Rimouski, Rimouski, Canada. ³Université du Québec à Montréal, Montreal, Canada

Abstract

Coastal management and planning is needed for adaptation strategies against climate change risks associated with sea-level rise and storm surges. To be effective, policies rely on accurate forecasting of future sea-level changes at regional scales. Recent progress in climate modelling has closed the global sea-level budget for the twentieth century to within uncertainty and modelled sea-level estimates capture regional variability observed within instrumental datasets (tide gauge and satellite) since 1900 CE. Despite this good agreement, it can be argued that sea-level projections from climate models should be validated against datasets spanning beyond the twentieth century if they are to be considered robust estimators of long term (centennial to millennial) future sea-level changes. Natural variability remains a significant source of uncertainty in modelling sea-level change and proxy-based records of pre-industrial sea-level trends will be key for defining scales of multi-decadal to millennial variability prior to the onset of instrumental data collection and anthropogenic warming. Next-generation sea-level projection models that are capable of accurately hindcasting observed regional sea-level trends for recent centuries and millennia will be more robust at predicting sea-level changes further into the future.

Regional sea-level trends in eastern Canada differ significantly from the global mean due to, predominantly, gradients of vertical land motion that remain following the deglaciation of the former ice masses (the Laurentide Ice Sheet and the Appalachian Glacier Complex) that occupied this region during the Last Glacial Maximum. Areas undergoing glacio-isostatic subsidence along Atlantic Canada and within the Gulf of St. Lawrence currently experience rates of local relative sea-level rise that exceed the mean rate of global sea-level rise. We present an analysis of new and published high-resolution sea-level reconstructions from Quebec and eastern Canada that have been developed using foraminifera and testate amoebae from salt-marsh sediments. These records of Common Era sea-level changes reveal multidecadal variability that is superimposed upon the near-linear background trends of glacio-isostatic adjustment. This sea-level variability is attributable to mass flux between the cryosphere and the oceans during climatic shifts during the late Holocene (the Medieval Climate Anomaly and the Little Ice Age) and to dynamic ocean mass redistribution during phases of ocean-atmosphere modes. Distinguishing the roles of these different drivers and replicating their contributions in climate models is a necessary first step towards developing accurate long-term projections of future sea-level changes throughout eastern Canada.

P-1068

Mapping of tunnel valleys in the UK and Norwegian North Sea

Dag Ottesen¹, Margaret Stewart², Marco Brønner¹

¹Geological Survey of Norway, Trondheim, Norway. ²British Geological Survey, Edinburgh, United Kingdom

Abstract

The use of 3D-seismic reflection data sets with regional coverage (180 000 km²) has enabled the mapping of large complexes of buried tunnel valleys in the North Sea. In addition, high-resolution airborne magnetic data were applied to complement the mapping of tunnel valleys where 3D-seismic data were not on hand.

Here we present the results of a regional mapping study for tunnel valleys for large parts of the North Sea, north of 56°N. The mapping reveals thousands of buried tunnel valleys with at least four valley generations, probably linked to the last few glaciations during the last 500 000 years. The tunnel valleys can reach lengths of more than 150 km, can be up to 5 km wide and 500 m deep.

The Quaternary North Sea Basin comprises relatively soft and generally poorly consolidated, fine-grained sediments which have provided an ideal substrate for the development of tunnel valleys. A eustatic low sea level has been a prerequisite for developing of such valleys and led to dry land on the North Sea Plateau with a generally passive ice sheet during deglaciation periods. The tunnel valleys are formed on the North Sea Plateau areas west and south of the much deeper Norwegian Channel. They seem to be less common in the northern North Sea, probably related to generally deeper water. Reconstruction of the ice sheet configuration during the formation of the tunnel valley is challenging, but it is inferred from our results that the water draining under the ice sheet has been generally flowing towards the Norwegian Channel.

Glacitectonic evidence of ice lobe interaction across Dogger Bank (southern central North Sea) during the Last Glacial Maximum

Emrys Phillips¹, Kirstin Johnson¹, Rachael Ellen¹, Carol Cotterill¹, Leo James²

¹British Geological Survey, Edinburgh, United Kingdom. ²RPS Energy, Woking, United Kingdom

Abstract

High-resolution seismic data from the Dogger Bank in the central southern North Sea has revealed that the Dogger Bank Formation records a complex history of sedimentation and penecontemporaneous, large-scale, ice-marginal to proglacial glacitectonic deformation. These processes led to the development of a complex assemblage of glacial landforms and sediments which record the interplay between two lobes of the Weichselian ice sheet which occupied the North Sea basin during the Late Glacial Maximum. The “Dogger Bank lobe” advanced from the N/NW with its subsequent active northward retreat resulting in the development of a complex assemblage of arcuate thrust-block moraines (“Dogger Bank moraine”) composed of highly folded and thrust lower Dogger Bank sediments (c. 40-50m thick). These large glacitectonic landforms (200m-15km across; >30km long) are separated by low-lying sedimentary basins and meltwater channels filled by upper Dogger Bank outwash sediments. The impact of the second lobe was restricted to the western margin of Dogger Bank where it led to the construction of a large (5-20km wide) thrust-complex (“western moraine”) composed of a thick sequence (c. 100-150m thick) of glacitectonised sediments. The geometry of the structures within this deep-seated moraine are consistent with ice-push driven by ice advancing from the west. The boundary zone between the two moraine systems is structurally complex and overlain by an elongate basin (up to 7-8km wide) filled by upper Dogger Bank sediments (10-40m thick) which were primarily derived from the northeast. This sedimentary basin formed as the two ice lobes unstitched and retreated from Dogger Bank. However the exact timing of the “decoupling” of the two ice masses remains uncertain. Initial results indicate that the two ice masses were still in close proximity resulting in the interleaving of the glacitectonised sediments within the moraines, with the unstitching of the two ice lobes occurring during the early stages of the deglaciation of Dogger Bank.

P-1070

Deposition of proglacial sediments along an active ice margin during the Last Glacial Maximum, Dogger Bank, southern central North Sea

Kirstin Johnson¹, Emrys Phillips¹, Rachael Ellen¹, Carol Cotterill¹, Leo James²

¹British Geological Survey, Edinburgh, United Kingdom. ²RPS Energy Ltd, Surrey, United Kingdom

Abstract

High-resolution seismic data from the Dogger Bank in the southern central North Sea has revealed that the Dogger Bank Formation records a complex history of ice-marginal to proglacial sedimentation and penecontemporaneous, large-scale, glacitectonic deformation during the Last Glacial Maximum. The study site presented here is located along the margin of the Weichselian aged British and Irish Ice Sheet and Fennoscandian Ice Sheet, within the Dogger Bank area.

The resulting glacial system and sedimentary sequences reveal the presence of a number of sedimentological features including meltwater channels, outwash fans and plains, desiccation surfaces and lacustrine systems, as well as a plethora of glacitectonic arcuate thrust-block moraines.

Here we focus on the development of the meltwater channel systems, outwash flood sheets and fan systems which formed during the northward retreat of the ice sheet across Dogger Bank. The fans are up to 2.5km wide and comprise sediment packages (up to 50m thick) with inclined reflectors. They are interpreted as forming an ice marginal apron system occupying a low lying sedimentary basin formed between the larger, higher relief moraines located within the southern margin of the Dogger Bank. Large channels up to 1km wide and between 30m and 70m deep have been identified incised into a thick (up to 40m thick) sequence of outwash sediments. These sediments exhibit varying degrees of deformation, linked to a history of active retreat of the ice margin. The complex internal architecture of the channels indicate that they record several periods of sedimentation separated by prominent erosive surfaces. Desiccation surfaces are preserved within both the channels and laterally extensive outwash plains, indicating several periods of intense periglacial weathering (drying, alteration) occurred during deglaciation. This sedimentary assemblage therefore records a complex history of deposition, meltwater release and channel incision separated by phases of periglacial weathering and glacitectonic deformation during the deglaciation of the Dogger Bank towards the end of the Weichselian glaciation.

Remains of arctic and boreal plants and animals from the Danish North Sea

Ole Bennike, Jørn Bo Jensen, Jørgen Leth, Niels Nørgaard-Pedersen
GEUS, Aarhus, Denmark

Abstract

The North Sea is a large shallow epicontinental sea dominated by sandy bottom that reflects a high energy environment. Little is known about the late Quaternary history of the Danish part that was probably dry land during long time periods of the last ice age.

In connection with mapping of raw material in the Danish part of the North Sea, a number of 6 m long vibro-cores were collected by the Geological Survey of Denmark and Greenland. During description of the sediment cores, remains of plants were noted, but most of them were early Holocene. However, a few samples from two sediment cores contained macrofossils of cold-adapted plants, such as the dwarf shrubs *Dryas octopetala*, *Salix herbecea* and *Betula nana*. Herbaceous plants were represented by *Carex* sp., *Ranunculus* sp. and *Juncus* sp. The samples also contained remains of plants and animals living in fresh water, such as *Potamogeton filiformis*, the bryozoan *Cristatella mucedo* and larvae of caddis flies.

Two samples were dated by AMS radiocarbon age determination. One sample gave an age of ca. 12.6 cal. ka BP, corresponding to the Younger Dryas cold period. The other sample was dated to ca. 35 cal. ka BP, corresponding to marine isotope stage 3, prior to the last glacial maximum. The floras and faunas are not rich in species, but they provide some of the first information about the biotas of the last glacial stage.

Previous remains of arctic species from the Danish North Sea are confined to a few records of walrus. One of these finds was also dated to ca. 35 cal. ka BP, whereas two others finds gave somewhat younger ages. In some areas of the Dutch sector of the North Sea, bones of arctic mammals are common. The fauna includes terrestrial species such as mammoth and reindeer and marine species such as walrus and white whale.

Pre-Holocene shells of marine molluscs have been reported from Jyske Rev and dating of three samples gave finite radiocarbon ages of 43–45 cal. ka BP. The fossil assemblages include warm-adapted bivalve species such as *Donax vittatus*, *Spisula subtruncata*, *Arctica islandica* and *Cerastoderma edule*. These species are well known from interglacial deposits in the region, but not from interstadial deposits and we suggest that the deposits are of Eemian age.

P-1072

Palaeoenvironmental change within the southern North Sea following the Last Glacial Maximum.

Stephen Eaton, David Hodgson, Natasha Barlow, Estelle Mortimer
University of Leeds, Leeds, United Kingdom

Abstract

The Last Glacial Maximum (LGM) to Early Holocene period is characterised by considerable global climatic instability. During this time the landscape of the southern North Sea evolved from an aerially exposed periglacial environment to shallow marine conditions. The stratigraphic record for the period covering the LGM up to the onset of the marine transgression in the Holocene can be documented using recently acquired high resolution seismic, core and geotechnical data from the offshore renewable energy industry, offshore East Anglia, England. These integrated data form a valuable archive of mid-latitude palaeoenvironmental change and landscape evolution during marine inundation of low-lying coastal areas.

Overlying sediments of LGM age are extensive peats and fluvial channel-fills that have been mapped in seismic profiles and calibrated to borehole records. These peats record the establishment of terrestrial landscape, intersected by a network of fluvial channels, as climate warmed during the Early Holocene. The nature of the seismic facies and tributive channel-network pattern indicate a palaeoflow direction towards the southwest. Average channel widths are 150 m (maximum 1.4 km) and <3 m deep and have variable fill character, ranging from dipping foresets to draped to chaotic fill. In the north of the survey area, isolated incisional fills are common and display both dipping (foresets) and draped fill characters. These may represent previous channels that have subsequently been eroded leaving isolated, disconnected fills. The peats are highly amorphous in character, suggesting high levels of decay. Overlying the peats is a transgressive surface of marine sands. The top peat-contact shallows towards the northwest indicating an approximately NE-SW trending shoreline, with marine transgression from the southeast. The patchy, laterally discontinuous distribution of the peats suggest that much of the organic material was eroded and reworked during transgression. These erosive processes during marine transgression are further supported by the contact between peat and the overlying marine sediments, whereby peat fragments (rip-up) are often incorporated into the overlying marine sediments.

The interpretation of LGM to Early Holocene stratigraphy reveal palaeoenvironmental evolution under rising relative sea level on a much larger scale than previously recorded in onshore archives, allowing development of kilometre-scale landscape response models. The ability to map subsurface organic material allows us to calculate both the amount of carbon stored in offshore environments, as well as furthering understanding of the erosion of coastal and freshwater peatlands under models of sea level rise.

Pockmarks within a stratigraphic framework from the Witch Ground Basin, central North Sea

Christoph Böttner¹, Christian Berndt¹, Benedict Reinardy^{2,3}, Jens Karstens¹

¹GEOMAR, Kiel, Germany. ²Stockholm University, Stockholm, Sweden. ³Bolin Centre for Climate Research, Stockholm, Sweden

Abstract

One manifestation of focused fluid migration at the seafloor are circular to semi-circular depressions known as pockmarks, which form in response to vigorous venting of fluids from the seafloor. Here, we use 2-D and 3-D seismic reflection, multibeam bathymetric and sedimentological data to map and describe pockmarks in the Witch Ground Basin (central North Sea) and characterize associated sedimentological and fluid migration structures. More than 1500 pockmarks of two distinct morphological classes spread over an area of 225 km². Large pockmarks (> 6 m deep, > 250 m long, and > 75 m wide), show active venting, and are located above vertical fluid conduits that hydraulically connect the seafloor with deep methane sources. Smaller pockmarks (0.9-3.1 m deep, 26-140 m long, and 14-57 m wide) are limited to the soft, fine-grained sediments of the Witch Ground Formation. The larger pockmarks are sourced by biogenic methane through seismic pipe structures which hydraulically connect deeper strata with the surface. The smaller pockmarks are independently formed by another source of fluids. Paleo-pockmarks within the Witch Ground Formation document distinct phases of pockmark formation, likely triggered by externally-induced pressure and temperature changes.

Mid-Pleistocene thin-skinned glaciotectonic thrusting of the Aberdeen Ground Formation, Central Graben region, central North Sea

David Vaughan¹, Emrys Phillips²

¹Fugro Survey Limited, Aberdeen, United Kingdom. ²British Geological Survey, Edinburgh, United Kingdom

Abstract

This paper presents the results of a high-resolution 2D seismic survey of Mid-Pleistocene glaciogenic sediments in the Central Graben region of the central North Sea. The survey has revealed that these sediments, which were originally interpreted as possessing a simple layercake stratigraphy, have in fact undergone major glaciotectonic thrusting and folding associated with the repeated southerly advance of an ice sheet across the region during the Mid-Pleistocene.

The total observed length of the thrust-stacked section is approximately 5 to 6 km, comprising a series of discrete thrust slices, which range in length from < 300 m to > 700 m. The basal detachment of the thrust complex occurs at a depth of c. 220 m below sea bed within the upper Aberdeen Ground Formation. The ice-proximal limit of thrusting is marked by a large depression (>100 m deep, >1600 m wide) infilled by a sequence comprising at its base acoustically chaotic deposits, overlain by a well-bedded unit, passing upwards into tectonically deformed sediments.

A thin-skinned glaciectonic model involving proglacial to ice-marginal glaciectonic thrusting followed by post-tectonic deposition is proposed. Initial ice advance led to the over-pressurising of groundwater within a laterally extensive sand sheet in the upper Aberdeen Ground Formation, promoting the formation of a major décollement surface at the base of the developing thrust stack. Detachment and transport of the thrustsediments led to the contemporaneous formation of a “glaciectonic hollow” beneath the ice margin. Dewatering of the basal décollement, possibly due to water escaping from the thrusts which propagated upwards through the Aberdeen Ground, led to the cessation of forward propagation of the leading-edge of the thrust stack accompanied by extensive shortening and deformation at its ice-proximal end. Subsequent retreat of the ice exposed the tectonic hollow which became infilled with glacial outwash. This glaci-fluvial sequence was itself deformed during later readvance of the ice from the north. The proposed model provides clear evidence that Mid-Pleistocene ice sheet dynamics within the Central Graben of the North Sea was far more complex than previously thought.

3D visualisation of the glacetectonic decollement surface throughout the survey area. Thrust slices are labelled as individual T-numbers, and the depth scale is in meters below sea bed.

Abstract

We used shotgun DNA sequencing of the full metagenome preserved in an ancient lake sediment from southern Sweden to investigate the whole diversity of taxonomic groups present. We combine sedimentary aDNA, pollen and macrofossil studies and tested if it was possible to correlate the relative abundances of plant taxa to distinct climatic shifts that occurred between 14 and 10.5 ka BP.

Metagenomic DNA provides a stronger signal of plant community changes than plant micro- and plant macrofossil analyses alone and a larger number of new taxa were recorded in Younger Dryas samples. A comparison between the three proxies highlights differences and similarities and supports earlier findings that plants growing close to or within a lake are recorded by DNA. Plant macrofossil remains moreover show that tree birch was present close to the ancient lake since Allerød; together with the DNA results, this indicates that boreal to subarctic climatic conditions also prevailed during the cold Younger Dryas interval.

Increasing DNA reference libraries and enrichment strategies prior to sequencing are necessary to improve the potential and accuracy of plant identification using the metagenomic approach.

Abstract

Insights derived from ancient DNA are revolutionizing our knowledge of biotic dispersals and population histories. Ancient DNA from lake sediments (*sedaDNA*) has been shown to provide finer temporal resolution than the hard tissue record, and so has great potential to refine insights into the speed and dynamics of biotic changes, such as the appearance of agriculture or the immigration of key taxa to a region. However, unlike the mature methodologies for hard tissues, the extraction of *sedaDNA* can be problematic, due to the complex and variable geo- and biochemical composition of sediments, which currently constrain the type of sediments amenable to analysis. In this study, we compare *sedaDNA* extraction protocols across a variety of sediment types. Although protocol chemistry impacts metabarcoding-inferred plant taxonomic diversity, sediment types with high organic content often yielded near-unusable results regardless of the protocol used. However, slight modification of an existing protocol greatly improved the results for some of these problematic sediment types. Together with other *sedaDNA* methodologies currently in development, this work brings us closer to unlocking the full potential of this underexploited ancient DNA source.

Holocene vegetation changes in the Alps, as inferred from lake sedimentary ancient DNA

Sandra Garcés Pastor¹, Peter D. Heintzman¹, Kevin Walsh², Charline Giguet Covex³, Willy Tinner⁴, Christoph Schwörer⁴, Oliver Heiri⁵, Inger G. Alsos¹

¹Tromsø University Museum, Tromsø, Norway. ²Department of Archaeology, University of York, York, United Kingdom. ³CNRS, Université Savoie Mont Blanc, Le Bourget-du-Lac, France. ⁴Palaeoecology, Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ⁵Geoecology, Department of Environmental Sciences, University of Basel, Basel, Switzerland

Abstract

Ongoing climate change is rapidly transforming ecosystems. Considering the range of projected climate change scenarios and the relatively short length of instrumental records, how species and ecosystems will respond to the effects of future human impact and climate changes is poorly understood. Palaeoecology can be used to better understand the dynamics of past ecosystem changes and composition of plant communities, allowing researchers to infer the extent of vegetation changes predicted by models of future climate.

High-mountain lakes of the Alps are suitable ecosystems for studying local environmental shifts driven by large-scale climate changes, giving a long-term perspective of environmental change. These mountain ecosystems are also expected to be severely affected by future changes in climate (prompting an upward shift in vegetation distribution, as well as elevated replacement rates and species losses).

Previous palaeobotanical studies in the Alps have used biotic proxies such as pollen or microfossils to infer past vegetation dynamics. However, microscopic morphological determinations are time-consuming and, in some cases, they might be limited by low taxonomic resolution and the preservation of identifiable remains. However, ancient DNA from organisms is also preserved in the sediment (*sedaDNA*), which can be detected and analysed through metabarcoding. By using the modern DNA sequence database PhyloAlps for the alpine flora of the Alps (4500 species and sub-species), we can bypass the morphological limitations and refine the taxonomic resolution, often to the species level. The *sedaDNA* also reflects the local vegetation surrounding the lake compared to the regional vegetal information provided by long-distance transported pollen. This proxy will allow the inference of more complete species occurrences, and thus, better assessments of vegetation shifts in past ecosystems.

To investigate the origin and impact of past environmental changes in alpine ecosystems along the Holocene, we performed a multi-proxy reconstruction using sediment cores from lakes of the Western Alps with different anthropogenic pressures. Using *sedaDNA*, elemental analysis, magnetic susceptibility, and loss-on-ignition data, we reconstructed the plant community composition and lacustrine dynamics during the Holocene.

We will present the major findings from these analysed records and the general trends inferred from them, and pay special attention to the anthropogenic pressure in lakes located close to archaeological settlements.

Abstract

For paleosols and similar horizons, the provenance of ancient DNA retrieved directly from sediments (sedaDNA) is such that local floristics are accurate but under-represent taxonomic richness. Sediment samples function like 1-2m² quadrats regarding the spatial distributions of plant taxa they record. Frozen silt deposits in NE Siberia (yedoma) often provide taxonomically rich sedaDNA records, but most samples are restricted to vertical sequences with little horizontal coverage at any given site. To test for spatial variation in paleo-vegetation, we sampled a series of horizons (five within a 1-m height range) across ca. 35 m of the face of a large yedoma exposure at Duvanny Yar, Yakutia (DY). The samples fell into five physical clusters related to the sampling design; they were individually radiocarbon-dated. Dating and detailed stratigraphy revealed a gently dipping palaeosol across the deposit. Samples of the same height above datum were thus not contemporaneous, but some ages clustered quite tightly within a total age range ca. 30-39 cal ka BP. A metabarcoding approach identified plant taxa (molecular taxonomic units: MOTUs) in DNA extracts from frozen sediment samples. For the main primer set (chloroplast trnL intron, P6 loop) we used four amplifications per sample; singletons with low reads (<100) and taxa occurring at high values in negative controls were filtered out. This meant exclusion of two widespread taxa that should have occurred, based on ecological expectation: Salicaceae and *Equisetum*. The number of MOTUs per sample ranged from 4 to 23 (mean 13.4, total 101); virtually all MOTUs were biogeographically reasonable. Of the major functional types: grasses, sedges, forbs and woody taxa, forb DNA dominates (except in three samples dominated by bryophyte DNA). This matches patterns observed at other late-Pleistocene localities across the Eurasian North.

Log-transformed data were examined with ordination (DCA, NMDS). While sample composition varies considerably, differentiation that might relate to a local-scale vegetation mosaic or gradient is poorly defined. This result is not dissimilar from observations of sedaDNA taken from modern tundra soils; it probably reflects a small suite of dominant taxa masking more subtle indications of vegetation composition shown by minor taxa. Overall, the data indicate predominantly herbaceous vegetation adapted to cold, dry conditions (NB excluded Salicaceae has low importance). Assuming that the dominant taxa correctly characterize the zonal vegetation, regional environmental conditions are probably the major control of sedaDNA assemblages from deposits such as these, but local-scale environmental variation may be difficult to identify.

Extraction of ancient DNA from macrofossils of different tree species preserved in European Alpine lake sediments

Christoph Schwörer¹, Nadir Alvarez², Felix Gugerli³, Willy Tinner¹, Christoph Sperisen³

¹Institute of Plant Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland.

²Natural History Museum Geneva, Geneva, Switzerland. ³Swiss Federal Institute for Forest, Snow and Landscape Research, Birmensdorf, Switzerland

Abstract

Lake sediment represent archives that capture the environmental history of their surroundings and provide ideal conditions for the preservation of ancient DNA (aDNA). The extraction and analysis of environmental aDNA directly from bulk sediment (i.e. exogenous aDNA, also known as sedimentary aDNA or *seDaDNA*) has recently been established as a new method in palaeoecology to infer past plant occurrences around these natural archives that can provide data complementary to traditional optical approaches such as pollen and macrofossil analysis. However, aDNA analysis has the potential to open up even more avenues of research in palaeoecology by directly studying population genetic processes through time. Endogenous aDNA from macrofossils preserved in lake sediments can be used to infer intra-specific changes in the genetic diversity and possibly adaptive potential of a species as well as tracking population dynamics in space and time. However, due to technical difficulties in sample preparation and aDNA extraction, only few studies have successfully extracted endogenous aDNA from macrofossils to answer population genetic research questions.

Here, we provide results of a pilot study that aimed to extract endogenous aDNA from different macroscopic plant remains of four conifer species from two lakes in the European Alps over the Holocene. We selected 25 macrofossils from *Picea abies*, *Pinus cembra*, *Abies alba* and *Larix decidua* that date to ca. 10 – 3.5 ka cal. BP. Most of the macrofossils are needles or needle fragments in various states of preservation, but we also used seeds, twigs and bud scales to test if successful aDNA extraction is dependent on the source material used.

We extracted aDNA from the samples in a dedicated aDNA facility under clean room conditions. To evaluate the identity of the species and estimate the proportion of endogenous aDNA and ancient and modern contaminants in each sample, we used an amplicon-sequencing approach (based on amplification of a short universal plant barcode, i.e. chloroplast *trnL* P6 loop) on a next generation sequencing platform. We also checked the amplicons for authenticity by analyzing diagnostic deamination patterns typical for post-mortem degradation of DNA: We considered the aDNA to be authentic if the PCR replicates contained sequence reads of the respective macrofossil species and if the cytosine to thymine and guanine to adenine misincorporation rates were significantly higher than a modern reference sample.

The results of our pilot study provide valuable information about the preservation and the potential for extraction and amplification of aDNA from a variety of source materials. Our results can be used to improve sampling strategies and extraction protocols to maximize genotyping success in future intra-specific aDNA studies.

Pleistocene extinction of megaherbivores from eastern Beringia using multiproxy palaeoenvironmental records from central Yukon lake sediments: first results

Scott Cocker¹, Tyler Murchie², Jordan Harvey³, Britta Jensen³, Hendrik Poinar², Michael Pisaric¹, Duane Froese³
¹Brock University, St Catharines, Canada. ²McMaster University, Hamilton, Canada. ³University of Alberta, Edmonton, Canada

Abstract

Here we present preliminary multiproxy palaeoenvironmental records from Gravel Lake, central Yukon Territory, to investigate the environmental response associated with the disappearance of megaherbivores at the end of the Pleistocene. Lake sediment cores were recovered in 2017 then subsampled and stored at the University of Alberta. Chronology for the cores is based on radiocarbon and cryptotephra analyses and 1 cm loss-on-ignition record of the sediments spanning the Pleistocene-Holocene transition. High resolution loss-on-ignition, coupled with a basal radiocarbon date of ca. 14,000 cal yr BP, allows identification of Bølling-Allerød warming and the Pleistocene-Holocene transition, and has guided subsequent sampling near the expected timing of megaherbivore extinctions in eastern Beringia. Palynological analyses of pollen and coprophilous fungi are in progress at the Brock University Water and Environment Laboratory alongside magnetic susceptibility (MS). We have identified pollen in standardised counts of 300 per sample with further identification of pigmented fungal spores, particularly those known to be obligate coprophilous genera. Coprophilous fungal spores have become increasingly utilised as proxies for megaherbivore abundance in Late Quaternary samples and appear throughout the samples from Gravel Lake. *Sporormiella*, *Cercophora*, *Podospora* and *Sordaria* appear to be the most common taxa. We aim to combine results of abundance and disappearance of obligate coprophilous spores, sedimentary ancient DNA, and an established chronology to identify the timing of local megaherbivore extirpation. At the McMaster Ancient DNA Centre, we are extracting sedaDNA using a recently optimized approach to maximize DNA recovery from environmental samples prone to the carryover of prolific enzymatic inhibitors. These sedaDNA extracts are being analysed with an enrichment approach targeting diagnostic genetic loci from the plant chloroplast animal mitochondrial genomes. By enriching the ecologically informative fraction of these sedaDNA libraries, we can more efficiently high-throughput sequence taxonomically diagnostic biomolecules in order to reconstruct palaeoecological change through time in central Yukon with our complementary set of environmental proxy data. Core chronology and LOI are being established at the University of Alberta allowing the sedaDNA, palynological data and MS to firstly be compared temporally, but similarly against previous studies from the region. The Arctic is currently undergoing dramatic changes that directly impact the stability of ecosystems and northern landscapes. Rapid climate change during the Late Quaternary caused numerous ecosystem responses, including altering vegetation assemblages and possibly contributing to the mass extinction of numerous megaherbivore taxa. This study aims to highlight the direct impact of climatic amelioration on megaherbivore populations with intentions to provide another dataset of biodiversity alteration from which analogues of modern ecological responses to current and future anthropogenic warming can be based.

Bacterial palEnDNA of Pleistocene sediments reveal paleoclimate changes

Senthil Kumar Sadasivam

Geobiotechnology Laboratory, National College (Autonomous), Tiruchirapalli, India

Abstract

The palEnDNA based reconstruction of bacterial community structure of three sediment layers from the Vettaikaraniruppu paleo-beach ridge core, clearly indicated that sediment bacterial communities reflected the depositional environment. Reconstruction of bacterial community structure was possible even from 146,000-year-old samples using V3 hypervariable region of bacterial 16S rDNA targeted Illumina sequencing. The bacterial community dynamics between and among the sediment layers showed that marine transgression caused a mix up of environments and resulted in the increase of taxonomical diversity and altered the functional diversity of the native community. After marine transgression, the bacterial communities had attempted to regain its original structure. These attempts erased the changes in biogeographic patterns, although the bacterial communities contained the impressions of marine transgression even after 3000 years. The difference in the recovery of palEnDNA from the three sediment layers reflected stratigraphic reliability. The taxonomic diversity observed in three samples revealed no intermixing of modern and ancient genetic signals and DNA leaching/migration through water, active bacteria, bioturbation or during the act of coring sampling itself. All these append the value to bacterial palEnDNA to be employed as a tool for paleoenvironmental reconstruction.

Abstract

Sedimentary ancient DNA (*sedaDNA*) has been proven to be a useful tool for paleoenvironmental studies, but only a handful exist for tropical regions. We here present *sedaDNA* analyses dating back to 1800 AD on two sediment cores from two crater lakes from the Kenyan Rift Valley. These alkaline-saline lakes have experienced different climatic and anthropogenic influences. New data were retrieved from a sediment core from Lake Kageinya (formerly known as Lake Eight), located in the remote, non-influenced anthropogenically, hot and hyper-arid Suguta Valley. In this study we used *sedaDNA* to study the temporal succession of *Brachionus* spp. rotifer haplotypes. The results are compared to previously published data from Lake Sonachi, a well-studied lake in the humid and colder mountainous region of Kenya near Naivasha town, now supported by a ²¹⁰Pb age chronology. Both records expand well beyond the onset of substantial anthropogenic impact on the regions. The results revealed that climate is the main driver for haplotype changes in both lakes rather than an anthropogenic impact. During prolonged dry periods haplotype composition remained constant and at low diversity such as from 1910 to the late 1960s. Sudden changes and the emergence of new haplotypes are observed when climate became more humid, but also more variable (before 1910 and from 1960s onwards). Progressive changes in haplotype composition during such variable climates could reflect local adaptation and/or is the result of immigration of new haplotypes after the eradication of previous populations during extreme environmental conditions. These results imply that *sedaDNA* in tropical lake sediments, despite of adverse chemical conditions, is preserved at least back to 1800 AD and its analysis provides a good complementary paleoenvironmental proxy for paleo-limnological reconstructions.

Abstract

Past changes in vegetation have typically been assessed using pollen and macrofossils as proxies. In recent years, these proxies have been supplemented by lake sedimentary DNA (*sedDNA*), which has a higher taxonomic resolution. However, the degree to which metabarcoding-derived *sedDNA* data quantitatively reflects actual species abundance in the vegetation surrounding lakes, is less clear due to various potential biological and technical biases. A large-scale direct comparison of contemporary vegetation data to that of *sedDNA* is therefore required, to determine if any correlation exists between these quantitative measures in spite of these biases. In this study, we assess how the vegetation in the catchment area of a lake predicts contemporary lake *sedDNA*. More specifically, we hypothesized that the dominant taxa of the most abundant habitat types in the catchment area of a lake will be the most abundant taxa, in terms of amplicon representation, in the *sedDNA* data. Furthermore, we hypothesized that species abundance distribution in the contributing area will be reflected in the *sedDNA*. In addition, we also considered distance from the lakeshore as one of the determinants of *sedDNA* deposition in a lake. To test this, we hypothesized that the vegetation in the area in closest proximity to the lake has the most resemblance to that inferred from *sedDNA*. To address these hypotheses, we described the catchment area of 23 lakes in Northern Norway, mapping vegetation types and performing point-intercept surveys to quantify the biomass of common species and functional groups. Then, also for each lake, we extracted *sedDNA* from top sediments, performed metabarcoding, and identified taxa based on available reference databases, to provide the number and proportion of reads as abundance estimates of common species and functional groups in the *sedDNA* data. Results from comparisons of species dominance and abundance relations between vegetation and *sedDNA* has the potential for opening avenues to more quantitative palaeoecological inference from ancient *sedDNA*, which is essential for a more nuanced understanding of past ecology.

Abstract

Between 14,000 and 5,000 years ago, on the cusp of major environmental shifts that affected the distribution of animals, vegetation cover and hydrology, humans entered interior Alaska and presumably witnessed these changes. Analysis of sedimentary ancient DNA (*sedaDNA*) from loess deposits that contain archaeological remains has the potential to revolutionise our understanding of how these early people responded to this changing environment and adapted their use of natural resources. Loessic sediments at these archaeological sites present particular challenges to *sedaDNA* studies, including anthropogenic disturbance of the matrix by ancient humans and unfrozen conditions for around four months of the year that may accelerate bacterial degradation and fragmentation of DNA.

Our objectives are i) to extract *sedaDNA* derived from vascular plant, mammal and fish taxa, from both cultural and non-cultural layers of two archaeological sites with well-preserved animal bones in interior Alaska and ii) compare the results with contemporaneous samples from a nearby lake, which will provide baseline data on the local biota spanning over 15,000 years.

Universal primers were used to amplify a short locus of the plant chloroplast genome. Species-specific primers were designed to amplify a short locus of the mitochondrial genome of key mammal and fish taxa species and were first tested on modern tissue samples from a museum collection prior to use on ancient material. Preliminary results from a series of pilot samples indicate good *sedaDNA* preservation and high taxonomic resolution of plant identifications with 121 plant taxa identified, of which 44 % were identified to species level, 42 % to genus and 14 % to family level.

eDNA analysis of mid-latitude sites for paleoenvironmental reconstruction

Caroline Kisielinski, Justin Tackney, Dennis O'Rourke, Rolfe Mandel
University of Kansas, Lawrence, KS, USA

Abstract

Recovery of ancient nucleic acids has been successful at identifying taxa in samples derived from permafrost, lake cores, cave sediments, and other protected and climatically stable environments (eDNA). The greatest success has been in high latitudes or at high elevations. There have been few reports of ancient eDNA analyses from open air, mid-latitude contexts. To evaluate the feasibility of routine use of eDNA approaches to paleoenvironmental reconstruction in mid-latitudes, we selected three stratified, well-dated archaeological sites on an east-west transect across Kansas, USA. Cultural deposits at the three sites are associated with buried soils.

The study sites occur in three different bioclimatic zones, and vary in age from ca. 13,000 to 1 ka. The Kanorado site is on the High Plains of western Kansas, a semi-arid region with short-grass prairie, low annual precipitation and humidity, and seasonal extremes of temperature. Stratified cultural deposits at Kanorado are in a well-developed buried soil and yielded radiocarbon ages ranging from ca. 13,000 to 10,400 ka. The Alum Creek site is in the dry sub-humid mixed-grass prairie of north-central Kansas and has cultural deposits dating to ca. 1000 ka in an overthickened A horizon of a buried soil. The Claussen site is in the moist sub-humid tallgrass prairie of northeastern Kansas and has stratified cultural deposits dating from ca. 10,400 to 10,000 ka in a deeply buried soil. We expected that ancient nucleic acids would yield different profiles of microbial, plant and/or animal species present in the buried soils at the three sites. The goal was to see if methodological resolution was adequate to test this assumption in semi-arid to moist sub-humid mid-latitude environmental contexts. For comparison, we also analyzed eDNA recovered from a ~1000 year-old archaeological site in subarctic coastal Alaska.

At all three sites, soil samples were taken from the surface of the buried soil, 5-10 cm above and below the soil surface, and from the modern surface in order to test for movement of nucleic acids through the stratigraphic column. We also tested several extraction and sequencing protocols to identify an optimal method for DNA recovery from these contexts. A subset of samples was shotgun sequenced on an Illumina MiSeq platform to ensure viability. After initial sequencing success, all samples were prepared for metagenomic sequencing and shotgun sequenced on an Illumina NextSeq to generate more reads for greater taxonomic resolution. Ancient nucleic acids were distinguished from modern DNA by the presence of distinctive damage patterns associated with degraded DNA. Preliminary analyses indicate that even at Kanorado, the oldest of the three sites, ancient nucleic acids were recovered from the soil surface. Bioinformatic analyses are ongoing to identify species present and to distinguish them, if possible, from modern forms.

Aquatic plant dynamic and fishes over the last 1800 years in the Lake Aiguebelette (Northern French Alps)

Charline Giguet-covex¹, Erwan Messenger¹, Florent Arthaud², Ludovic Gielly³

¹EDYTEM, CNRS, Université Savoie Mont Blanc, Le Bourget du Lac, France. ²CARTELE, INRA, Université Savoie Mont Blanc, Le Bourget du Lac, France. ³LECA, CNRS, Université Grenoble Alpes, Grenoble, France

Abstract

Watersheds of large peri-alpine lakes have undergone substantial demographic and urban developments (leading to the release of waste waters, containing nitrates and phosphates), as well as agricultural activities intensification (use of fertilizers) during the 20th century. The seasonal fluctuations of their water levels is often reduced and controlled to generate hydroelectric power or to reduce flooded areas. Furthermore, these lakes host fishing activities, often for commercial purpose. These pressures, combined with global warming, significantly impacted the aquatic ecosystems especially through the eutrophication process and modifications of the trophic web.

In order to understand such limnological changes, several peri-alpine lakes are monitored for several decades. However, this instrumental monitoring does not allow the assessment of the ecosystem state before the anthropisation acceleration. Lake sediment cores represent relevant archives to fill this gap. Geochemical analyses and biotic remains preserved in lake sediments can be used to reconstruct the past long-term trajectories of aquatic ecosystems.

However, up to now, palaeoecological studies undertaken on lake sediments were only focused on phytoplankton, zooplankton, chironomids or microbial communities, but nor on aquatic plant community, nor on fishes. For fishes, this lack is explained by the absence (or rare presence) of fossils preserved in the sediments and for aquatic plants by a limited detection by pollen analyses. Environmental DNA preserved in the sediment offers a unique opportunity to address these challenges.

In this paper, the DNA metabarcoding approach is used to identify past aquatic plants and fishes living over the last 1800 years in the Lake Aiguebelette (390 m a.s.l., 5.45 km² lake surface area, 70 km² catchment area, 73m deep). The most significant result is the evidence of interactions between aquatic plants and fishes. Roach, a fish species which has a preference for aquatic grass habitats, appears from 1000 years AD, i.e. when the diversity and biomass of aquatic plants highly increase. This change also corresponds to the development of mesotrophic conditions due to the intensification of the livestock farming.

Ancient DNA (aDNA) of bacteria from 146,000 year Late Quaternary sediments: a potential proxy for unearthing the “paleo sea-level reconstruction”

Senthil Kumar Sadasivam¹, Bhavatharini Shanmuganathan¹, Shan Thomas¹, Sivakumar Krishnan¹, Kartika Goswami², Maha Dev², Manoj Kumar Jaiswal², Anbarasu Kumaresan¹

¹National College, Tiruchirappalli, India. ²IISER, Kolkata, India

Abstract

Ancient DNA (aDNA) is prudent in unearthing the paleoenvironments. A Geobiotechnological approach to unearth aDNA of bacteria for paleo sea-level reconstruction had been attempted. A 25m sediment core had been excavated from the two beach ridges Vettaikaraniruppu (VKI: 10.572514 N, 79.835111 E) and Korukkai (KUI: 10.535717 N, 79.711936 E) located 2.6Km and 16.6Km inland respectively, along the Cauvery Delta, Tamil Nadu, South East Coast of India. aDNA isolated from four sediment samples from each core VKI-2 (2.8m), VKI-5 (7.2m), VKI-12 (21.0m) and VKI-14 (24.5m); KUI-3 (3.2m), KUI-7 (9.0m), KUI-11 (14.5m) and KUI-16 (24.2m) revealed highest aDNA yield in VKI-12 and KUI-16 paleosols and were least in VKI-5 and KUI-11 paleosols among their respective core samples. V3 hypervariable region targeted 16S rDNA metabarcoding and the taxonomic annotation revealed highest species richness and species evenness in VKI-5 and KUI-16 samples. Marine bacterial signatures at each taxonomic level viz., the marine signature phyla *AC1*, *Aminicenants Chlorobi*, *Lentisphaerae*, *Tenericutes*, and *WS3* were abundant in VKI-5 sample. At class level, *Deltaproteobacteria* with sulphate reducers *Desulfotomaculum* and *Desulfovibrio* were present in VKI-5, VKI-12 and KUI-11 proving that these sediments were formed under marine environment. At genus level, *Prevotella copri* which is an inhabitant of coastal environments was present in all four VKI paleosols, yet was abundant in VKI-5 sample. *Pseudomonas alcaligenes* was present in all the samples of KUI core, yet was abundant in KUI-7 and KUI-11 samples. Further, terrestrial and aerobic bacterial proxies were found to be the highest in VKI-2, VKI-14, KUI-3 and KUI-16 paleosols. Micropaleontological studies in VKI core revealed highest benthic and planktic foraminiferal species at 7.2m; least planktic to benthic foraminiferal ratio at 21.0m. In KUI core, abundant benthic foraminiferal species was observed at both 9.0m and 14.5m. Optically Stimulated Luminescence (OSL) dating revealed the age of VKI-2, VKI-5, VKI-12 and VKI-14 to be 3.36 ± 0.42 , 6.04 ± 1.25 , 122.10 ± 39.00 and 146.64 ± 36.81 kaBP respectively. KUI-3, KUI-7, KUI-11, and KUI-16 were dated to 19.22 ± 8.65 , 42.30 ± 14.67 , 67.63 ± 44.25 and 145.51 ± 27.92 kaBP respectively. The aDNA metabarcoding analysis of bacteria of VKI and KUI paleosols alongside the conventional foraminiferal proxies and OSL dating revealed marine environments at VKI-5 and VKI-12 which coincided with Mid Holocene Transgression and Last Interglacial Transgression respectively; KUI-7 and KUI-11 were formed under marine environment which was confirmed by the presence of foraminifers. The diversity of both marine and terrestrial bacterial proxies at various depths of both VKI and KUI paleorecords confirmed marine transgressions and regressions. The Geobiotechnological study revealed that bacterial DNA sustain activity even 146,000 years after burial and also reflected stratigraphic reliability and proved aDNA of bacteria to be an efficient proxy for paleo sea-level reconstruction.

Abstract

Along the last two millennia, peri-alpine lakes have been subject to complex human impacts, mixing agriculture, pastoralism, urban development... The current mosaic landscape of their watershed is the result of the long-term interactions between vegetation and the socio-economic history. In this paper, we propose to focus on one of the main peri-alpine lakes: Aiguebelette (373 m a.s.l., 5.45 km² area, 70 km² catchment area, 70 m max depth).

By crossing environmental DNA with pollen and coprophilous fungi analyses, we propose to address a more detailed reconstruction of past vegetation dynamic and land use history.

In this region, several pollen records already exist. They provide similar vegetation histories than Aiguebelette for the last millennia. Is that the result of a regional pollen rain, or a regional trend of the evolution of the socio-ecosystems? Because the plant DNA in lake sediments has a local origin (i.e. the watershed or less), it represents a key proxy to decipher the different pollen origins (regional / local) and to better reconstruct the spatial vegetation distribution in the Aiguebelette watershed.

The past vegetation dynamic and land use history can be summed up as follows:

- Along the 1850 years spanned by the sequence, pollen well-reflects the two main deforestation phases associated with crop increasing ([500-700], [1000-1850] cal. AD).
- From 500 AD, pollen and DNA evidence the onset of fruit tree cultivation (vines, chestnuts and walnuts).
- From 1000 to 1850 AD, pollen, DNA and coprophilous fungi spores, indicate an expansion of crop, fruit trees, hemp and pastoral activities. The DNA highlight the importance of orchards (plums or cherries, apples) in that economy.
- The last century is characterised by the decline of most of agricultural activities, except the development of vegetable gardens, similar to the ones that we can see today, with for instance celery, green beans or beetroots.

Past treeline dynamics at Bol'shoy Lyakhovsky Island (New Siberian Archipelago) since the last interglacial inferred from sedimentary ancient DNA

Heike H. Zimmermann¹, Elena Raschke¹, Laura S. Epp², Kathleen R. Stoof-Leichsenring¹, Georg Schwamborn¹, Lutz Schirrmeister¹, Ulrike Herzschuh^{1,3,4}

¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Research Unit Potsdam, Polar Terrestrial Environmental Systems, Potsdam, Germany. ²University of Konstanz, Konstanz, Germany. ³University of Potsdam, Institute of Geosciences, Potsdam, Germany. ⁴University of Potsdam, Institute of Biochemistry and Biology, Potsdam, Germany

Abstract

Permafrost deposits at Bol'shoy Lyakhovsky Island are natural archives dating back to the Eemian (Krest Yuryakh Suite, ~125 kyr BP) with excellent conditions to preserve ancient DNA. The today treeless island is located between the Laptev and East Siberian Seas, but during the last glacial it was part of the Western Beringian landmass due to the marine regression, which exposed the shallow Siberian shelf. Our aim was to reconstruct vegetation changes driven by the strong climatic oscillations from the last interglacial until today. Permafrost coring took place west of the Zimov'e River where four terrestrial permafrost cores were drilled. In total we collected 72 sediment samples and combined pollen analysis with sedimentary ancient DNA metabarcoding for which we amplified the short vascular plant specific P6-loop of the plastid trnL (UAA) intron. Furthermore, we applied two newly developed larch-specific chloroplast SNP markers to assess their suitability in identifying past population dynamics from environmental samples. The new markers were re-sequenced and displayed both SNP variants of each marker in last interglacial samples. Highest diversity and a vegetation containing trees (*Picea*, *Larix*, *Populus*) were inferred covering the island during the last interglacial. During the Mid Weichselian interstadial and the Bølling-Allerød interstadial complex only *Larix* was detected among trees but disappeared along with most shrub taxa during the Holocene. This suggests that the northern extent of the Siberian treeline was further north than previously inferred from pollen analyses, and that modern larch taiga is differently composed than the taiga during the last interglacial.

P-1216

Survival profiles from linear models versus Weibull models: Estimating stable and stationary population structures for Pleistocene large mammals

Guillermo Rodríguez-Gómez¹, Jesús A. Martín-González², Paul Palmqvist¹

¹Universidad de Málaga, Málaga, Spain. ²Universidad de Burgos, Burgos, Spain

Abstract

Survival and mortality profiles of mammalian species can provide information on the environmental context of Pleistocene archaeopaleontological localities as well as on the agents involved in the site formation process (e.g., the role played by the bone-accumulating agents, including their patterns of food procurement and carcass consumption, or the strategies of space use by carnivores and humans). Environmental context (i.e., climate and vegetational cover) and meat availability were both relevant factors for determining human settlements in Europe during the Pleistocene. For this reason, to gain deeper insights on the paleoecology of the large mammals communities can provide key information on human evolution and dispersal patterns. In this study we compare two mathematical approaches that allow reconstructing survival and mortality profiles of large mammals and their age-structured populations: the linear model and the Weibull model. Both approaches provide similar results for all species of large mammals analyzed. The lowest correlation coefficient was for *Bison bison* (0.789), but the difference in biomass estimates between the models decreases to <2%. When both methodologies were compared at the community level in the Orce sites, the ecological indexes used to compare paleocommunities showed also differences of <2%. Given the similarities in the output data derived from both models, we suggest a preferential use of the Weibull model due to its strength of results and easier computation compared to the linear model. Moreover, the λ and k parameters of the Weibull model supply information on the fertility and maturity of the age-structured populations, which are useful for differentiating among the reproductive strategies of the species compared. Therefore, our results suggest that the Weibull model is a valuable tool for investigating the availability of meat resources and the level of competition among carnivores in the Pleistocene communities of large mammals that inhabited Europe during the Pleistocene.

The vulnerable giant; establishing a window of extinction for the ultimate non-adapting - *Gigantopithecus blacki*

Kira Westaway¹, Renaud Joannes-Boyau², Yingqi Zhang³, Simon Haberle⁴, Russell Ciochon⁵

¹Macquarie University, Sydney, Australia. ²Southern Cross University, Lismore, Australia. ³Institute of Vertebrate Paleontology and Paleoanthropology (IVPP) Chinese Academy of Sciences, Beijing, China. ⁴Australian National University, Canberra, Australia. ⁵Iowa University, Iowa, USA

Abstract

The infamous giant ape *Gigantopithecus blacki*, the king of all Asian megafauna, was the largest ever primate and the only ape to go extinct in the Quaternary. Its abrupt disappearance from the fossil record is significant and has implications for other extinct megafauna and for understanding the adaptation and survival capabilities of the surviving species, including humans. This ape is shrouded in mystery as it is only known by teeth and mandibles and the cause of its extinction has remained elusive since its discovery in a Hong Kong drugstore in the 1930's. Some have argued that Giganto was vulnerable to changing climates and environments as it could not adapt when its preferred forested habitat deteriorated. But before the true cause of this giant's demise can be determined an accurate window of extinction must be established to pinpoint exactly when this ape dropped out of the fossil record. The precision in this timeline is essential as it will represent a vital tipping point on which palaeoenvironmental combined with palaeobehavioural evidence can be interpreted. This will allow an assessment of the vulnerability of the giant ape within the prevailing environmental conditions.

In this talk we will outline a new Bayesian modelling approach to establishing the extinction window of Giganto using luminescence, U-series, ESR and cosmogenic dating techniques applied to 19 caves sites in southern China. Using both a fossil and sedimentary context for dating and sampling both Giganto-bearing and non-Giganto bearing caves we have reconstructed a point in time when giants ceased to roam this region.

P-1219

Rise of the giant deers in China and the related palaeoenvironmental issues

Haowen TONG

Key Laboratory of Vertebrate Evolution and Human Origins of Chinese Academy of Sciences, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China

Abstract

One million years ago, the giant ruminant guilds of continental Eurasia were dominated by cervids rather than by bovids as that of today. The Villafranchian giant deer taxa include *Arvernoceros*, *Eucladoceros*, *Libralces*, *Cervalces*, *Sinomegaceros*, *Praemegaceros* and *Megaloceros*, all of which have body weights over 300 kg, and some of them even reached 870 kg. In East Asia, the pre-Villafranchian cervid guilds were usually dominated by small- to medium-sized three-tined deers of Cervinae and Muntiacinae. How the giant deers rose so abruptly and how they spread so quickly are still unsolved scientific questions. Among the Villafranchian giant deers, the comb-antlered deer *Eucladoceros* is the most peculiar taxon, which inhabited Eurasia in the middle and high latitudes during most part of the Villafranchian, and the most striking evidence is that it appeared in East Asia and West Europe almost at the same time. Although the species of *Eucladoceros* in China is prominently different from the co-generic species in Europe in morphology, the recent recoveries support a close relationship between them. The quick communications or migrations of mammalian fauna can be attributed to the spreading of the open habitats in Eurasia.

Abstract

Multiproxy data obtained from lakes and shallow marine sediments in NW Iberia allowed a more complete approach to the climate and the ecosystems dynamics in this region during the Late Pleistocene. Pollen evidence reveals that several types of coniferous, heath communities and broadleaved forests persisted between ca. 60-10 kcal. yr BP in different coastal valleys of NW Iberia. Particularly, the Galician *Rías Baixas* hosted quite different types of cryoxeric vegetation, among them: a) xerophilous communities with pine and juniper that likely inhabited coastal dunes; b) coastal wet/dry heathlands and c) cryophilous birch forests on coastal lowlands that were directly affected by the frontal systems and the coastal upwelling. Besides, we also found evidence of more mesic vegetation like: c) beech forests existing on oceanic slopes of some coastal highlands, where they probably found a humid atmosphere, with precipitation well distributed throughout the year, and a well-drained soil; and d) different mesophytic deciduous forests including hornbeam that might be comparable to the oak-ash, ravine and hardwood floodplain forests currently existing in other Atlantic and Continental regions of Europe. Therefore, a complex mosaic of woody habitats existed in this relatively small area, formed by species able to adapt and take advantage of different types of mesoclimates derived from the interaction between the regional climate, the upwelling cells and the coastal morphology. At the end of the Lateglacial period the climate become more oceanic in this region and the sea-level rose. Thus, at the beginning of the Holocene large areas of these coastal ecosystems were submerged by the sea and disappeared, while other upland zones were transformed, firstly covered by saltmarshes and then replaced by heathlands and oak deciduous forests.

A palaeoecological investigation of Scots pine (*Pinus sylvestris*) refugia in north-east Wales and Shropshire.

Dael Sassoon¹, William Fletcher¹, Alastair Hotchkiss²

¹University of Manchester, Manchester, United Kingdom. ²Woodland Trust, Grantham, United Kingdom

Abstract

Since its arrival in the British Isles around 10,000 cal yr BP, native *Pinus sylvestris* was widely distributed throughout the region and reached its maximum extent ~4500 cal yr BP. Around 4000 cal yr BP, it suffered a widespread and sudden demise, which is attributed to various factors such as climatic deterioration, competition with other tree species, anthropogenic effects, pathogens and volcanic activity. Currently, populations of native Scots pine are geographically isolated to the Scottish Highlands, while in the rest of the British Isles they exist only as plantations after being re-introduced as non-natives in the 1800s. This has caused significant debate regarding the presence of native Scots pine outside this recognised range. This study, undertaken in the framework of an MSc dissertation submitted to the University of Manchester, and in collaboration with the Woodland Trust for Wales, aims to understand the ecological history of present-day Scots pine populations found on the steep crags of Nesscliffe Hill, Shropshire. A 3m sediment record dating from 7000 cal yrs BP was extracted from Lin Can Moss (LM18), a small raised ombrotrophic bog adjacent to Nesscliffe hill. A basal radiocarbon date and palynological evidence of the elm (*Ulmus*) decline and the arrival of beech (*Fagus sylvatica*) help constrain the timeframe of the record. The record reveals a pine decline around ~3500 cal yr BP, but also suggests that Scots pine may have survived and persisted locally until at least ~2000 cal yr BP. This suggests that the area may have acted as a refugium, protecting Scots pine from climatic deterioration and human pressures. A novel approach using morphological analysis traced the size of fossil *Pinus* pollen grains throughout the LM18 record, and compared with fossil material of comparable age from Bennachie (BEN), Scotland, for both Mid-Holocene and sub-recent samples. For both age ranges, LM18 pine grains are significantly larger than in the BEN samples. This analysis supports that pollen at LM18 was deposited locally and was not derived from populations further north. The difference in grain size between LM18 and BEN may be caused by the different prevailing temperatures at the sites. Overall, the pollen record and morphological analysis point towards the persistence of small locally native Scots pine populations on the steep crags of Nesscliffe Hill, although the search for “smoking-gun” macrofossil, stomatal and DNA evidence continues. The findings have significant implications for the restoration of ancient woodlands and suggest that more focus should be directed towards the conservation of potentially native Scots pine in this area. Protecting locally native Scots pine will help mitigate the effects of climate change and promote adaptation of the species.

Last deglacial warming improving snail species diversity in fragile ecological region of East Asia

Yajie Dong¹, Naiqin Wu¹, Fengjiang Li¹, Linpei Huang², Wenwen Wen²

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²College of Tourism and Geography, Yunnan Normal University, Kunming, China

Abstract

Global warming poses increasing threats to terrestrial ecosystems, the recognition of which is leading to concerns that a wave of species extinctions may be imminent. Understanding how organisms adapt to past climatic warming is important for assessing potential biotic responses to future climate change. Terrestrial mollusks are an important component of terrestrial ecosystems mainly because of their key role as a trophic link between animals and plants. However, our knowledge how the structure and diversity of mollusk communities respond to past climate warming in fragile ecosystems is limited. Here, we present three well-dated high-resolution terrestrial mollusk records spanning the last 25,000 years from the Chinese Loess Plateau (CLP) and examine their past response to natural climatic warming since the last deglacial. Our fossil records show a low-diversity mollusk fauna in the Last Glacial Maximum, a significantly more diverse early to middle Holocene fauna exceeding today levels, and a decline in diversity in the late Holocene. The net gain in species diversity during the last deglaciation, consistent with the rise in northern hemisphere temperature, is more significant in northerwestern sites than in southeastern sites. However, in spatial no matter what the substages, the species diversity in southern sites (~10 species) is always higher than that in the northern sites (~4 species). These results suggest that the natural warming of ~2°C higher than today is beneficial for the increase of mollusk species diversity, particularly in the species-poor communities of fragile ecological region in East Asian monsoon.

Holocene paleoenvironmental changes in Upo Wetland of Korea and their link to flooding event

Hoil Lee¹, Jin-Young Lee¹, Jaesoo Lim¹, Sujeong Park¹, Sang Deuk Lee², Suk Min Yun²

¹Korea Institute of Geoscience and Mineral Resources (KIGAM), Daejeon, Korea, Republic of. ²Nakdonggang National Institute of Biological Resources (NN IBR), Sangju, Korea, Republic of

Abstract

Upo Wetland is the largest riverine wetland in Korea which has been inscribed on the Ramsar List of Wetlands of International Importance in 1998. In this study, sedimentological study was carried out in order to understand the environmental changes in Upo Wetland during the Holocene. The drilling work for recovering the Quaternary sediments was conducted on the inner part (UPW01, UPW02, UPW03) and the outer part (UPL01, UPL02) of the present Upo Wetland. The recovered sediments are commonly characterized by gravel-dominated deposits in the lower part and silty clay-dominated deposits in the middle to upper parts respectively, which are seemed to be changed from fluvial to palustrine/lacustrine environments around 4,000 cal yr BP. The abundant benthic and epipelagic diatom species are interpreted this area lasted for 4,000 years as a low flow velocity and water discharge. In particular, while the palustrine/lacustrine environments were maintained, the increasing diatom abundance, organic matters and high sedimentation rate in the sand-dominated deposits at the altitude of about 6-7 m are likely to be associated with flooding event around 1,300 cal yr BP. The commonly change from clay-dominated deposit to sand-dominated deposit since 1,500 years in the cores DSR09 and STP18-05 around the Nakdong River indicates the flooding event of the Nakdong River affected to Upo Wetland.

P-1224

Can we infer humidity gradients across the Ural Mountains during the Late Quaternary using arvicoline rodents as a paleoclimate proxy?

Evgenia Markova¹, Tatiana Strukova¹, Aleksandr Borodin^{1,2}

¹Institute of Plant & Animal Ecology UrB RAS, Ekaterinburg, Russian Federation. ²Ural Federal University, Ekaterinburg, Russian Federation

Abstract

Nowadays, the large-scale humidity gradients in the central part of Northern Eurasia are primarily determined by the latitudinal insolation gradient inducing the southward increase of evaporation, and the barrier role of the Ural Mountains against the Atlantic warm and humid air masses. The present-day climatic gradients are clearly reflected in the spatial spread of natural landscape zones and in the distribution patterns of particular plant and animal species. Here, we consider arvicoline rodents, the most widespread and abundant mammalian group in the Quaternary paleo-archives of the Northern Eurasia, as direct indicators of particular habitat characteristics, and as indirect proxies for climatic reconstructions. We classify 15 native arvicoline species known in the central part of Northern Eurasia since the Late Pleistocene into 5 groups based on the vegetation type and moisture balance of the breeding and survival habitats of their extant representatives. We identify the species groups of the hygro-, mesohygro-, meso-, mesoxero-, and xerophytic habitats and calculate the occurrence of each group in the micromammal assemblages from 32 multi-layer localities situated on the western and eastern macroslopes of the Northern, Middle, and Southern Urals. Based on the absolute and relative dating methods, the dataset is divided into the Late Pleistocene, Early, Mid-, and Late Holocene subsets. An analysis over the large-scale latitude-longitude grid reveals the significant southeastward increase in the frequency of occurrence of the species confined to xerophytic habitats in each of the temporal subsets. This result indirectly confirms the stable role of the Ural Mountains in shaping the west-east precipitation gradient during the Late Pleistocene – Holocene. However, the biogeographic barrier role of the Ural Mountains was changeable. In the Late Pleistocene, the environmental gradients favored 1) the uniformity of the arvicoline faunas on both western and eastern slopes of the Northern Urals, and 2) the distinctiveness between the faunas on the opposite slopes of the Southern Urals. During the Holocene, the differences between the slopes of the Southern Urals were leveled off whereas the faunas of the Northern Urals acquired significant differences between the slopes. The results suggest that arvicoline rodents may be successfully used for reconstruction of the environmental gradients across large spatial scales. The approach based on arvicolines appears to be especially important for the paleo-archives comprising no reliable paleobotanic data (e.g., the numerous karst caves of the Ural Mountains). When considering responses by individual species to climate change, all types of response might be referred to as 'species-specific habitat-related movements'. Two patterns of range contraction leading to the degradation of the Late Pleistocene non-analogous arvicoline communities are identified, including 1) gradual species declines, and 2) patchy extinctions. The study is supported by RFBR, grant № 19-04-00966.

The fight for survival; Pleistocene faunal contexts before, during, and after *Gigantopithecus blacki*'s extinction

Yingqi Zhang^{1,2}, Changzhu Jin¹, Kira Westaway³, Terry Harrison⁴

¹Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China. ³Department of Environmental Sciences, Macquarie University, Sydney, Australia. ⁴Department of Anthropology, New York University, New York, USA

Abstract

Gigantopithecus blacki is the largest hominoid that ever lived. It is known primarily from Early and Middle Pleistocene cave sites in southern China, dating from 2.0 Ma to ~300 ka, when it drops out of the fossil record. The cause of its extinction in the late Middle Pleistocene is unknown. Ecological change may have been the contributing factor. There was a progressive increase in dental size from the Early Pleistocene to the Middle Pleistocene, and possibly a shift towards greater complexity of the cheek teeth. These microevolutionary morphological changes may be evidence of adaptations to survive.

Here we report chronologically successive Pleistocene mammalian faunas from four cave sites in Chongzuo, Guangxi ZAR, China to establish the faunal contexts before, during and after *Gigantopithecus blacki*'s extinction. The four cave sites are Early Pleistocene Baikong Cave, Middle Pleistocene Yixiantian Cave and Hejiang Cave, and late Middle Pleistocene Baxian Cave. The faunas from these caves are represented mainly by dental remains of the *Stegodon-Ailuropoda* fauna (*sensu lato*), which set the stage for the rise and fall of *Gigantopithecus blacki*. In an attempt to establish the role played by *Gigantopithecus blacki* in this faunal assemblage the cause of its extinction, the compositional dynamics and chronological transitions of the *Stegodon-Ailuropoda* fauna are analyzed based solely on the taxonomic and morphological studies of the newly found dental remains.

Abstract

An increasing number of studies are evidencing the significant changes that mountain ecosystems are experiencing in relation to global change. For instance, changes in plant communities occurring across altitudinal gradients are affecting biodiversity. Palaeoenvironmental approaches may provide significant insights into long-term vegetation changes to manage these new scenarios in a proper spatio-temporal context. Lacustrine sequences are the most common deposits recording vegetation change on long timescales but other archives, such as sub-superficial ice, can be key for accurate reconstructions in mountain landscapes.

We present here a pioneer study from the Armeña-A294 Ice Cave (2238 m a.s.l.), located in the Cotiella massif (Spanish Central Pyrenees) with the first pollen and plant macrofossil record from an ice cave ever studied in the Iberian Peninsula.

The ice deposit contains several detrital layers with plenty of plant remains, which provide detailed palaeoecological information and allow obtaining an accurate chronology based on replicated ¹⁴C dates on terrestrial plant macrofossils. The period recorded spans the mid to late Holocene, with ages ranging from 5700 to 2200 cal yr BP, making it the oldest known firn ice cave worldwide.

This extraordinary archive preserves frozen pollen and plant macrofossils and is therefore ideal to assess the processes that controlled both local and extra-local plant species dynamics over time, and to infer the long-term vegetation and treeline fluctuations in the area (DOI:10.1111/1365-2745.13077).

The ice record shows that altitudinal treeline changes were closely linked to summer temperature changes. Thus, 5700 years ago mountain pines (*Pinus uncinata*) were dominating with birches (*Betula* spp.) in the surroundings of the ice cave at ca. 2250 m a.s.l., significantly higher up than today's maximum altitude reached by trees (2000 m a.s.l.). Approximately 4600 years ago, a progressive lowering of the treeline occurred together with the establishment of alpine meadows dominated by *Dryas octopetala* in response to the Neoglacial cooling trend. The treeline shifted upwards again ca. 3200 years ago, but did not reach its uppermost positions (before 4600 cal. BP), as documented by the persistence of alpine meadows. This treeline ecotone persisted near the cave until the end of the record 2200 years ago, when the ice sequence ends. The current landscape is very different to that of 2000 years

ago as currently only alpine meadows are present, suggesting that during the last two millennia large disturbances, either climatic or human, might have led to a depression of both treeline and timberline resulting in their current positions in the Armeña cirque.

The long-term sensitivity detected in these subalpine Pyrenean ecosystems is essential to assess future ecosystem dynamics under global change conditions. Ice archives are, however, severely endangered by rising temperatures and more scientific attention is needed in order to rescue their untapped information.

Reconstructing Pleistocene plant community shifts from the La Brea Tar Pits, and implications for regional plant response to climate change

Jessie George¹, Aisling B. Farrell², Emily Lindsey², Glen MacDonald¹

¹University of California, Los Angeles, Los Angeles, USA. ²La Brea Tar Pits and Museum, Los Angeles, USA

Abstract

Today, generalized patterns in the shift of plant species' distributions can be observed, or are anticipated, across the globe in response anthropogenic climate change. While similar larger-scale shifts are also observed in the Quaternary palaeobotanical record, evidence can be found for diverging patterns of individual species' responses on smaller spatial scales. How such individualist responses play out at regional scales is an important question. Understanding how and why these spatial dissimilarities in the response of terrestrial life occur is necessary to the management of changing terrestrial ecosystems in the future. This study uses plant macrofossils excavated from the La Brea Tar Pits in Los Angeles California to reconstruct past plant communities from the past 55,000 years - ranging from the Late Pleistocene and into the Holocene. Macrofossils are identified to species or genus using morphological traits and comparative modern specimens. Identified fossils are then radiocarbon dated using accelerator mass spectrometry. Thus far a total of 136 macrofossils have been identified and dated. Preliminary findings indicate significant range extensions southward and westward by genera such as *Pinus* and *Juniperus* during MIS 2 and 3. The macrofossils also suggest development of communities with no clear analogue today. The replacement of cypress and pine species with juniper and oak during MIS 3 is a possible indication of a drier climate during this mild interglacial than previously thought.

Palynological record for Holocene vegetation and environmental history on the southern coast of South Korea

Eunmi Lee^{1,2}, Sangheon Yi^{1,3}, Jaesoo Lim¹, Yongmi Kim^{1,3}, Kyoung-nam Jo²

¹Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of. ²Kangwon National University, Chuncheon, Korea, Republic of. ³Korea University of Science and Technology, Daejeon, Korea, Republic of

Abstract

Age-constrained high resolution palynomorph analysis of the STP16-20 sediment core obtained from the southern coastal region of the Korean Peninsula (KP) was carried out to clarify paleoclimate history during the Holocene. Palynological record shows the obvious environmental and vegetation changes against the relative sea level change and East Asian summer monsoon (EASM) oscillation, respectively. Our multi-proxy data (palynomorph, mean grain size, TOC, TS, C/N ratios, and $\delta^{13}\text{C}_{\text{TOC}}$) indicate that the depositional environment has changed at about 7500 cal yr BP from fluvio-coast to subtidal zone by sea level rise. At that time, sudden increasing of AP (arboreal pollen) and *Alnus* pollen profiles may reflect the abrupt depositional environmental change and local humid conditions near the coast environment, respectively. In addition, the critical pollen taxa suggest a significant shift in vegetation community at about 8000 cal yr BP; sharp decline in cold taxa (*Abies*, *Betula*, *Picea*, and *Pinus-Haploxyton*) and, in contrast, predominance of *Quercus-Lepidobalanus* and *Pinus-Diploxyton* (= Japanese black pine) together with the high proportion of freshwater discharge indicators (fern spores and *Pseudoschizaea*). These pollen assemblages refer that a mixed of deciduous and conifer forest flourished under the warm and humid conditions by enhanced EASM and sea level rise during about 8000-5900 cal yr BP. Since about 5900 cal yr BP, *Pinus* (*Haploxyton* and *Diploxyton*) were predominant, whereas *Quercus* was in decline due to weakened EASM. Our pollen record is well accordance with previous pollen studies of the other coast area in the KP. The Holocene climate changes on the southern coast of the KP might be controlled by activity of the East Asian monsoon. Noteworthy, the two dominant taxa of *Quercus* and *Pinus* display the opposite spectrum in their occurrence, and also it markedly has quasi-Periodicity at Centennial timescale during the early- to mid-Holocene (between approximately 7500 and 4000 cal yr BP). The mutual work with other cores in future is required to interpret more detailed the Holocene paleoclimate and paleoenvironment.

P-1229

The $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ record of the world's last woolly mammoths (*Mammuthus primigenius*): thriving or surviving?

Laura Arppe¹, Hervé Bocherens^{2,3}, Dorothee G. Drucker², Juha A. Karhu⁴, Sergey Vartanyan⁵

¹Finnish Museum of Natural History, University of Helsinki, Helsinki, Finland. ²Department of Geosciences, University of Tübingen, Tübingen, Germany. ³Senckenberg Center for Human Evolution and Palaeoenvironment, University of Tübingen, Tübingen, Germany. ⁴Department of Geosciences and Geography, University of Helsinki, Helsinki, Finland. ⁵North-East Interdisciplinary Scientific Research Institute FEB RAS, Magadan, Russian Federation

Abstract

The last woolly mammoths (*Mammuthus primigenius*) persisted on arctic islands several thousands of years into the Holocene, and finally became extinct at ca. 4,000 cal BP following a dramatic contraction of range size during a period of major climatic changes. Mammoths had survived similar climatic changes in earlier Pleistocene, reducing and confining their range to the north during warming episodes and expanding again during colder times.

To examine the level of ecological flexibility of woolly mammoths and their response to regional climatic warming, we analyzed collagen $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values in subfossil bones and teeth of the last population of woolly mammoths on Wrangel Island, and

specimens collected from the Bykovsky peninsula in Siberia. These new records were compared to a compilation of corresponding previously published data from the last representatives of the species in Europe, Siberia and northwestern North America. Altogether, we present new data for > 70 mammoth specimens on Wrangel Island and Siberia, most of them directly radiocarbon dated.

During their peak occurrence times, woolly mammoths all over northern Eurasia showed a consistent pattern of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values compared to sympatric large herbivores, with relatively low $\delta^{13}\text{C}$ values and conspicuously high $\delta^{15}\text{N}$ values reflecting a specific dietary niche. The gathered isotopic data for Europe and Siberia suggest alteration or disappearance of this niche towards the end of the record. Some populations maintained their accustomed specific isotopic niche, but were overlapping with coeval horses, a situation suggesting a reduction of mammoth population. In contrast, the mammoth population from Wrangel Island does not exhibit any clear ecological change from 10 to 4 kyr BP as judged by their $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values, and are comparable to their earlier, "full ice-age" counterparts in mainland Siberia. Compared with sympatric ungulates, it appears that the Wrangel Island mammoths were able to maintain a position in the $\delta^{13}\text{C}$ - $\delta^{15}\text{N}$ isospace similar to that of the late Pleistocene populations in continental Eurasia.

Most likely a combination of cold high arctic conditions, low competition and predation, as well as the impact of the mammoths themselves on maintaining the plant community, allowed this insular population to survive despite climatic change. The final extinction of the Wrangel Island woolly mammoths is not reflected in their $\delta^{13}\text{C}$ - $\delta^{15}\text{N}$ values, and appears to have caught the population at a time of stable climate, range size and dietary status. There is no evidence of mammoth hunting by modern humans on the island, but it is conceivable that their actions probably increased the stress level of the population to a level beyond survival capabilities and contributed to the final extinction.

This study was supported by the DAAD, Project # 54751123 and by the Academy of Finland, grant #SA259548.

Un-extirpating pine in western Ireland – it didn't die, it was just hiding.

Fraser Mitchell¹, Alwynne McGeever¹, Jenni Roche²

¹Trinity College, Dublin, Ireland. ²National Parks and Wildlife Service, Dublin, Ireland

Abstract

Pinus sylvestris was a dominant tree across northwest Europe during the early Holocene. Competition from other tree species, habitat loss and human exploitation all contributed to its asynchronous decline and apparent extirpation across much of its former range, including in Ireland, England, Wales, the Netherlands, Belgium and Denmark. *Pinus sylvestris* has been widely planted over recent centuries and now forms semi-natural forest stands across most of its former range. Palaeoecological analyses in western Ireland have identified a putative native stand of *Pinus sylvestris* that has continuity with prehistoric populations. The environmental setting and history of this site provides guides for exploring the continuity of *Pinus sylvestris* elsewhere in its former European range.

Abstract

The feeding habit of cave bear complex that went extinct around the Last Glacial Maximum (LGM), the period with the coolest and harsh climate condition during the late Pleistocene, has been intensely debated based on tooth and jaw morphologies, stable isotope analysis, etc. While many cave bears in Europe exhibit relatively low $\delta^{15}\text{N}$ values of bulk bone collagen that suggest dominant if not exclusive herbivory, some specimens from Romanian sites exhibit relatively high $\delta^{15}\text{N}$ values. Such values have been interpreted by some authors as reflecting omnivory or carnivory for these cave bear populations. However, without knowing the isotopic baseline represented in plants at the start of food-webs, a value that can be spatiotemporally variable, a herbivorous diet based on plants with high $\delta^{15}\text{N}$ values cannot be ruled out. Here we use a new approach based on $\delta^{15}\text{N}$ values of individual amino acids from collagen that offset the baseline $\delta^{15}\text{N}$ variation among environments. Our analysis performed on cave bears with high variability of $\delta^{15}\text{N}$ in their bulk collagen, from the Romanian sites of Măgura, Cioclovina and Răsuflătoarei caves, yielded strongly herbivorous signals that can be seen especially in the $\delta^{15}\text{N}$ values of glutamate and phenylalanine. Therefore, these results support the claim that the high $\delta^{15}\text{N}$ value of collagen observed for cave bears in Romanian region were most likely caused by their local plant diets with high $\delta^{15}\text{N}$ values, rather than by an omnivorous feeding behaviour of this species. Since both types of herbivorous cave bears inhabited the same caves at the same time or over a relatively short time span of about 2,000 years, some with low collagen $\delta^{15}\text{N}$ values and others with high $\delta^{15}\text{N}$ values, further research is needed to understand which types of plants with high $\delta^{15}\text{N}$ values were involved in this dietary difference and which factors drove the niche partitioning among coeval cave bears in Romania, but not in other areas of Europe.

P-1232

Pre- and postcolonial vegetation and settlement history in the North Pare Mountains derived from the Umbwane swamp pollen record

Lisa Schüler¹, Andreas Hemp², Hermann Behling¹

¹University of Goettingen, Goettingen, Germany. ²University of Bayreuth, Bayreuth, Germany

Abstract

Umbwane swamp is located at 1300 m in the North Pare Mts., Tanzania. The pollen archive spans the past ca. 1120 to 1960 yr AD/BC and allows the detailed reconstruction of the progressive human settlement of the area.

The first 200 yrs until ~ 1350 yr AD/BC abundant Cyperaceae and montane forest suggest that the Umbwane swamp was a small, more closed forest swamp surrounded by dense montane forest with a diverse understory dominated by Poaceae and ferns. Dry woodland was probably present at the lower slopes in the transition to savanna in the colline zone as where it can also be found today. After 1350 yr AD/BC, the strong reduction of montane forest indicates the begin of deforestation, most likely due to the need for firewood for iron smelting activities which are known to have taken place in the Ugweno area since that time (12). 1440 yr AD/BC marks a first opening of the swamp area as indicated by the increase of the fern *Cyclosurus interruptus*. Simultaneously, the forest abundance reaches a minimum suggesting intensified iron smelting and related activities took place close to the study site. After 1640 yr AD/BC, the pollen record shows an opening and expansion of the swamp area most likely due to permanent settlements. The first local maize cultivation around 1820 yr AD/BC precedes the first silviculture of exotic tree taxa (*Eucalyptus*, *Cupressus*, *Pinus*) roughly 50 yrs later introduced as part of the German colonialism (1881-1963). Simultaneously to the silvi- and agricultural activities, the swamp area becomes very open. The abundance of woodland and montane forest remains low as the largely opened area is heavily used for agricultural. The sudden decline in anthropogenic indicators and swamp vegetation at the end of the 19th century might represent the beginning of the climatic drought, causing a devastating famine in the North Pare which resulted in the collapse of the political and economic system debilitated by epidemics and warfare. After about 1940 yr AD/BC the swamp area is strongly reduced again due to drainage for the creation of arable land. This trend seems to have continued until today. This unique late Holocene pollen record gives detailed insight into the pre- and postcolonial vegetation and settlement history of the North Pare and complements very well the numerous archaeological sites - mostly associated with iron smelting – that were recorded throughout North and South Pare as well as in the Usambara Mountains.

Assessing the significance of testate amoeba shell morphology as an indicator of nutrient status in lakes

Helen Roe¹, Andrew Macumber¹, Stephen Prentice¹, Carl Sayer², Dave Emson²

¹Queen's University Belfast, Belfast, United Kingdom. ²University College London, London, United Kingdom

Abstract

There has been an unprecedented growth in recent years in the measurement of functional traits (FT) in many biological groups, particularly plants. These are measured characteristics that define species in terms of their ecological roles, i.e. how they interact with the environment and with other species. Traits have been used, for example, to study the fundamental constraints on plant evolution, to explain community assembly and to understand ecosystem function. Traits-based approaches have, however, been used comparatively rarely in Quaternary palaeoecological studies, as many biological groups are limited by issues of poor preservation and incomplete records. Traits-based approaches have nevertheless been applied to some fossil groups, e.g. Pleistocene mammal remains, which in turn have been compared with other palaeoecological datasets (e.g. pollen) to examine trait-environment relationships.

There is considerable potential to apply traits-based approaches to the subfossil remains of shell-forming micro-organisms like testate amoebae that are abundant and diverse, and whose short generation times make it possible to achieve high temporal resolution in palaeoecological studies. This has been highlighted in recent work with peatland testate amoebae that showed that traits can be used to reconstruct water table depth changes independently of species data (e.g. Lamentowicz et al., 2015). In this paper we review the potential for applying traits-based approaches to arcellinid testate amoebae (Arcellinida), a diverse group that dominate testate amoeba communities in lakes. In particular, we describe results from the 'ECOTRAIT' project, which is employing interdisciplinary methodologies to examine the utility of trait-based approaches for lacustrine Arcellinida. Specific project objectives include: to examine the character and causes of FT variability in modern and palaeo-limnological settings; to develop novel biometric approaches to aid in trait delimitation; and to evaluate the significance of trait-based approaches for understanding temporal changes in species composition. In this paper we describe the methodologies that can be applied to delimit traits, review some of the challenges associated with trait characterisation and measurement, and present traits-based data from sediment cores from lakes in Scotland and Norfolk. These both have a history of eutrophication related to catchment disturbance that has been inferred from other fossil groups (including plant macrofossils, diatoms, invertebrates). They thus form important test sites to examine the relationship between arcellinid test morphologies and trophic status.

Deconstructing biodiversity and ecosystem loss in Southern Europe during the Pleistocene

Donatella Magri¹, Maria Rita Palombo²

¹Sapienza University of Rome, Department of Environmental Biology, Rome, Italy. ²CNR-IGAG c/o Department of Earth Sciences, Sapienza University of Rome, Rome, Italy

Abstract

The multifaceted evolutionary history of fauna and flora leading to the modern biodiversity and biogeographical setting mingles with palaeogeographical, climatic and environmental changes. However, the actual role of climate in driving flora and fauna dynamics, geographical range dispersal, configuration, originations and extinctions along geographical gradients is a still highly debated topic in palaeobiology and palaeoecology.

The biotic response of individuals, species and communities to climate change, including warming and cooling events/periods, as well as changes in seasonality and precipitation regime, and occurring on different time scales, from glacial/interglacial cycles to a few decades, is a decidedly complex phenomenon. For example, an unexpected result is that some organisms seem to have remained “unchanged” over thousands to perhaps millions of years in the face of environmental perturbations and species invasions. The Quaternary period, recording the most dramatic change in the Earth climate system, is of particular interest for deciphering the actual relationships between climate changes and ecosystem evolution.

With the aim of scrutinizing the causal factors leading to the progressive changes in biodiversity, species demise, and reconstruction of plant and mammalian communities during the Pleistocene, we have analysed and compared the trends shown by South European plants and large mammals at local (Spain, France, Italy, and Greece) and regional (North Mediterranean) scale. Evidence from past vegetation shows a Quaternary-long persistence of some tree taxa. Other taxa undergo a progressive disappearance that in some cases may be related to long-term climate changes, for example at the transition Gelasian/Calabrian and Early/Middle Pleistocene, and in other cases may reflect long-term tree population dynamics. Evidence resulting from the analysis of SE mammalian fauna strongly supports the hypothesis of a climatic driven displacement of a number of taxa. Each species enlarged, displaced or contracted its geographic range as the environmental conditions were suitable or not for it. Other biotic and abiotic factors contribute to differentiate time and mode of dispersion from species to species, merging new species in the previously existing communities, leading to new competition dynamics that contribute to shape the progressive change of SE Pleistocene fauna at a different pace and rate in different territories.

All in all, the comparison among the general trends of vegetation and large mammal fauna in SW Europe during the Pleistocene shows that the dynamics of plant and animal communities significantly varied during time at a different pace and extent. Plant communities, for instance show a remarkable persistence, while a number of new and last appearances are found in mammals, so that there is no substantial loss of richness. Some hypotheses are discussed to explain this complex, intriguing pattern.

Palynological evidence of *Picea omorika*-type dominated forests in the classical interglacial site of the Hötting Breccia (Northern Calcareous Alps, Austria)

Roberta Pini¹, Cesare Ravazzi¹, Giulia Furlanetto², Lorena Garozzo¹, Michael Meyer³, Diethard Sanders³, Christoph Spötl³, Andrea Tramelli¹

¹CNR-IDPA, Laboratory of Palynology and Palaeoecology, Milano, Italy. ²University of Milano Bicocca, Dept. of Environmental and Earth Sciences, Milano, Italy. ³University of Innsbruck, Institute of Geology, Innsbruck, Austria

Abstract

While deposits of the Last Glacial Maximum are widespread in the Alps, sediments pre-dating the Last Glacial Maximum are rare, mainly due to repeated overprint by glacial ice streams. An exception is the Hötting Breccia, a thick and complex succession of Pleistocene slope- and alluvial fan deposits preserved on the south-facing slope of the Nordkette range near Innsbruck (Austria). Since the 19th century, geologists and botanists have been fascinated by this site, famed for its spectacular record of macrofossil imprints including woody taxa extinct from the Alps today (e.g. leaf imprints identified as *Rhododendron ponticum* var. *sebinense* Sordelli).

We carried out a re-appraisal of this classical interglacial alpine site focussing on the fossiliferous lacustrine sediments in the basal part of the Hötting Breccia at Rossfall-Lahner and using the slabs that bear fossil plant imprints. All studied samples (calclutites, calcisiltites, calcilithic arenites) contain fossil palynomorphs and, to our surprise, some of them provide palynological evidence of *Picea omorika*-type dominated forests, with minor contributions of *Picea abies*-type and by other evergreen and deciduous trees. The taxonomical assessment of fossil pollen of spruce was analyzed at the population level by comparing fossil pollen grain populations of 11 samples from the Hötting Breccia with 18 living populations of several W-European, Asian and Canadian spruces. We set up practical criteria for the specific diagnosis for light- and scanning electron microscope, and evaluated their functional and phylogenetic value. The recent discovery of functional traits in *Picea* pollen morphology allowed to define new pollen types of phylogenetic importance in Eurasian *Picea*.

The results support the presence of a spruce forest – at times dominated by Serbian spruce – in the upper montane to subalpine belt of the Northern Calcareous Alps during an interglacial younger than Marine Isotope Stage 22. Geochronological age constraints of the Rossfall-Lahner interval using optical dating techniques suggest that this site, whose flora has been traditionally considered as typical of the Riss-Würm interglacial, is early Middle Pleistocene in age, consistent with U-Th-dated (minimum) age constraints provided by vein-filling calcite.

Did brown bear expanded from Iberia to Scandinavia after the LGM? A cryptic Atlantic refugium out of the Iberian Peninsula

Ana García-Vázquez¹, Gloria González-Fortes^{1,2,3}, Ana Cristina Pinto Llona⁴, Aurora Grandal-d'Anglade¹

⁴Museo Arqueológico Regional, Research Associate, Alcalá de Henares, Spain

Abstract

During Pleistocene glacial phases, southern European peninsulas were the refugia for temperate species that followed a model of contraction-expansion forced by climatic oscillations. The European brown bear (*Ursus arctos* L.) phylogeography was used to illustrate this model because of the relationship between modern Iberian and Southern Scandinavian populations.

Recent studies indicate that this generally accepted paradigm of the southern peninsulas as glacial refugia has exceptions that indicate an existence of cryptic refugia for some species further north. After an exhaustive compilation of available genetic and radiometric data from Western European brown bears, and adding new sequences of current bears from the Iberian Peninsula, we try to reconstruct the postglacial dynamics of this species in West Europe, mainly in the Iberian Peninsula.

For the model of the Iberian Peninsula as a refugium to be fulfilled, the Iberian Pleistocene brown bears, glacial and pre-glacial, would have to be the direct ancestors of the rest of the Atlantic post-glacial bears. Both data, genetics and chronology, show that the Iberian Pleistocene lineages were not the direct ancestors of the Holocene brown bears of western Europe. However, there is no continuity in any of the Pleistocene lineages in the Holocene of the Iberian Peninsula. All defined haplotypes were extirpated during the LGM at least in the North. After a gap in the record that coincides with the LGM, radiometric dating shows a sudden abundance of Cantabrian bears that we interpret as a late recolonization of the Peninsula. In Britain the same pattern of sudden abundance is observed coinciding with the melting of the glacier caps, about 15,000 years BP. In Iberia, this expansion occurred after the Younger Dryas.

So, the first area of Atlantic Europe to be recolonized after the ice retreatment was the British Isles. Brown bears entered Iberian Peninsula belatedly (around 10,000 years BP), and finally Southern Scandinavia was the last place to be colonized (9,500 – 7,500 years BP) when a land bridge were suitable. We therefore propose the existence of a cryptic refugium in continental Atlantic Europe, from where the bears would expand as the ice receded. The delay in the recolonization of the Iberian Peninsula could be due to the orographic characteristics of the Pyrenean-Cantabrian region and to the abundant presence of humans in the natural entrance to the Peninsula.

The Iberian Peninsula was considered traditionally as a glacial refugium for large mammals and humans, but with the available data, neither the 14C ages nor the mtDNA data support an Iberian refugium for the brown bears during the LGM, at least for those that recolonized the British Isles and the south of Scandinavia.

The late Pleistocene and Holocene Thecamoebians from lake Stará Jímka in the Šumava Mts.

Vladimír Suchánek, Katarína Holcová
Faculty of Science Charles University, Prague, Czech Republic

Abstract

At the end of the last glacial period after glacier retreat the today defunct lake Stará Jímka was created (Břízová et Mentlík, 2005a; Mentlík et al. 2010). Its sedimentary record captures the climate changes in the last 15 000 years (periods bøling, allerød, younger dryas and early holocene), during recent it was buried (Mentlík et Břízová, 2005). For the study of the paleoenvironment of Šumava lake we can use testate amoebae alternatively Thecamoebians (Arcellinida), whose species composition is preserved in the sediment of the defunct Šumava lake Stará Jímka (Břízová et Mentlík, 2005a; Mentlík et al. 2010).

In the past few years, dr. Lorencová and doc. Holcová were studying Thecamoebians from Šumava Mts. in the Czech Republic. Within the project GA AVČR „Actuoeology of freshwater Thecamoebians from the Šumava Mts“ they observed hydrological changes in the recent sediment of Lipno Dam. (Holcová et Lorencová, 2004b). After that Lorencová (2009) studied Thecamoebians from the Šumava Mts.

A sedimentary well (profile thickness of 1.5 m, thickness of 3 cm, 36 selected layers) was taken from Stará Jímka Lake and provided by the Institute for the Environment. Communities of Thecamoebians were described from the collected samples. Most of the communities consists mainly of species with the agglutinated type of the test, because the sediment is composed mainly of particles of sand and sandy gravel. The individual samples differ not only in frequency and size, but also in species diversity, which includes only a few species, especially genus *Diffflugia*. For some selected samples, higher tests damage can be observed.

An american brown bear clade in the Late Pleistocene of the NW Iberia? A new model for brown bear expansion

Ana García-Vázquez¹, Alba Rey-Iglesia², Axel Barlow³, Michael Hofreiter³, Aurora Grandal d'Anglade¹

¹Instituto Universitario de Xeoloxía, University of A Coruña, A Coruña, Spain. ²Centre for Geogenetics, Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark. ³Institute for Biochemistry and Biology, University of Potsdam, Potsdam, Germany

Abstract

Of a total of 77 mitochondrial DNA sequences of brown bear from the Iberian Peninsula from literature, both fossil and modern, only 2 (2.6%) aren't from clade 1, the typical clade of Western Europe.

One of those individuals is a 27178 ± 433 years BP (31879 ± 349 calBP) male bear from Arlanpe cave (north central Iberian Peninsula) and belongs to clade 3c, and the other one is a female from Sumio de Casares cave (NW of the Iberian Peninsula), 25780 ± 220 years BP (30833 ± 381 calBP) from clade 4. For this work, the complete mitochondrial DNA of the Sumio de Casares bear has been sequenced. Both of those brown bears are from the final phase of MIS 3, which is characterized by a gradual cooling of the climate. Clade 4, is currently only found in North America, and the bear from Sumio de Casares is so far the only Western European individual from this group. Clade 3c is an extinct clade present on both sides of Beringia strait.

This work presents a hypothesis that explains how the Sumio de Casares bear has reached a place so far from its current geographic range, and serves as the basis for a model to explain the distribution of all modern and fossil brown bear clades. For this purpose, we combined data from the literature of modern and ancient DNA, radiocarbon dating and modern distributions of the different clades. The divergences between clades have been calculated using BEAST and comparing it with other published data.

This model proposes the existence of a cryptic core or cores located in central Asia from where the bears expanded again and again in all possible directions, but in a way conditioned to the orography and the different glacial and interglacial periods. The new expansions superimposed and erased the ancient ones, leaving the bears that expanded first relegated to the most peripheral areas of Eurasia and North America. So, subclade 3a is located from Eastern Europe to Alaska, making this clade one of the most recent and with less variability, whereas clade 1 or 4, are on the extremes of the distribution. The presence of a clade 4 bear in NW Spain, plus the presence of this clade in Contiguous United States and SW Hokkaido make this clade the one with the widest and most peripheral geographic distribution.

In addition, the $\delta^{18}\text{O}$ of the carbonates of the enamel of a molar and bone of Sumio de Casares bear has been analyzed and comparing it with other contemporary fauna of the zone, to know if this animal was a recent immigrant or if, on the contrary, it belonged to a clade settled extensively in the zone in that specific period

The Late Pleistocene reindeer (*Rangifer tarandus*, Linnaeus, 1758) of Britain and Western Europe: past migrations and seasonality

Emily Wiesendanger, Danielle Schreve, Ian Candy
Royal Holloway, Egham, United Kingdom

Abstract

During the last glaciation, reindeer (*Rangifer tarandus*, Linnaeus, 1758), a highly specialised cold adapted ungulate, was extremely common throughout Britain and Western Europe in marked contrast to the Arctic and Sub-Arctic distribution of the species today. Such high densities of herbivores would have had significant impacts on ecosystem processes and subsistence patterns for predators including early hominins. By reconstructing the palaeobiogeography (migrations and seasonality) of reindeer over the Late Pleistocene (125,000-11,700 years BP), the impacts of climatic, environmental and anthropogenic changes on reindeer ecology can be more tightly constrained. This is particularly important given the recent global declines in both the body masses and population sizes of reindeer.

As bi-annual migrators, reconstructions of reindeer palaeobiogeography are achieved by examining the seasonality of site occupations through the recognition of seasonal aggregations, primarily using the ageing and sexing of individual reindeer specimens. From the British Late Pleistocene, reconstructions of seasonality primarily imply that migratory reindeer followed a north-south trajectory between summer and winter grazing grounds. However, while these movements appear constrained to within Britain during MIS 5a and MIS 2, multiple signals of seasonality have been recognised from MIS 3 reindeer, particularly in the south of Britain. This has significant implications for reindeer palaeobiogeography under varying climatic and environmental conditions, especially given the fluctuating terrestrial connection between Britain and continental Europe during the Late Pleistocene and the potential, therefore, for east-west movement. In addition to the impacts of palaeoenvironmental and palaeoclimatic changes on fossil reindeer, the influence of herd-specific factors such as density dependence in this species are similarly important. This is evident from reconstructions of body mass from British specimens, which reveal further differences between the reindeer of MIS 5a, MIS 3 and MIS 2. Recent variations in reindeer body size demonstrate that the integration of both fossil and historical specimens is essential to constrain both past and ongoing impacts of climatic and anthropogenic changes on this ecologically vulnerable species.

How the Pleistocene morphogenesis of central Europe reflect genetic structure of small mammals: the case of the root vole (Rodentia)

Ewa Falkowska¹, Elżbieta Jancewicz²

¹University of Warsaw, Faculty of Geology, Warsaw, Poland. ²Department of Forest Zoology and Game Management, Faculty of Forestry, Warsaw University of Life Sciences – SGGW, Warsaw, Poland

Abstract

The aim of the research was to find out whether and how the landscape of eastern Poland, formed as a result of subsequent Pleistocene glaciations: Sanian 1 (MIS 16), Sanian 2 (MIS 12), Odranian (MIS 6) and Vistulian (MIS 2-5b), affects genetic differentiation of a species. The research was carried out on the root vole *Microtus oeconomus* (Arvicolinae, Rodentia), a model, boreal and hygrophilous species. Samples were collected from 439 vole individuals at 33 locations in different post-glacial landscape zones. Based on analysis of 12 microsatellite loci and the 908 bp of cytochrome b sequences (mtDNA), the genetic structure of *M. oeconomus* in the landscape zones of Polish Lowlands was determined. Longitudinal variability of the relief in the area of eastern Poland (resulting from different limits of Pleistocene glaciations) and the related specific configuration of hydrogenic habitats are reflected in the genetic differentiation of the root vole. All genetic parameters such as average allelic size range, average heterogeneity, the haplotype diversity and nucleotide diversity were very variable within the zones. Results were confirmed by PCA analysis which show population grouping based on F_{st} among populations and divided them into groups largely depending on the division of the landscape into zones. This division is especially very well visible in analyses of microsatellite DNA. Very similar results from STRUCTURE analysis were found (Bayesian clustering). The results show that the best living conditions for this species persist in large habitats with a high degree of connectivity - in swampy river valley systems of central eastern Poland. The relief of these areas was shaped mainly during the Odranian Glaciation (Wartanian Stadial). The lowest genetic variability indicates that the most difficult conditions for the tundra vole occur in the most mature, southern zone, the original relief of which was formed during the oldest glaciations (Sanian 1 and Sanian 2). It offers a completely different arrangement of habitats preferred by this species. The found relationships may also become, to some extent, an indicator useful in explaining the geological history of the region.

This study was financed by research grant No. N304 232035 from the Polish National Science Centre NCN to E. Jancewicz

P-1241

The effects of urbanization on four major rivers in the Gulf Coast region of the United States.

Rebecca Owens

Texas A&M University, College Station, Texas, USA. Tyler Junior College, Tyler, Texas, USA

Abstract

From 1997-2012, the population of Texas grew 15 times faster than the United States' national average, with much of this growth centered around the Dallas-Fort Worth Metroplex (DFWM) and in the Austin area, both of which are centered around major rivers. Studies of the effects of urbanization on rivers are numerous. Unfortunately, few have been conducted in areas with the climate (warm temperate, fully humid, hot summer) geology (predominantly limestone and shale) and relatively flat topography of the Gulf Coast region of the United States. Further, the effects of land cover change, such as that which occurs with urbanization, have not been studied at a large scale. Although humans have learned to adapt to long-term river adjustment, drastic anthropogenic changes can reduce time scales for geomorphic change to decades or centuries. Given the current population growth and projections for the region, we must understand the effects of urbanization on the major rivers in the Gulf Coast to prepare for fluvial adjustments induced by the rapid expansion of urban centers.

This study assesses the effects of urbanization on three major rivers in the Gulf Coast region of the United States: the Brazos River, Colorado River, and Trinity River in Texas. Objectives for this study are: (1) Determine the effects of urbanization on overall geomorphic channel stability of rivers in the Gulf Coast region, (2) Determine the effects of land use/land cover (LULC) on sediment size range of select rivers in the Gulf Coast region, and (3) Establish a channel stability assessment system for low-gradient rivers typical of those in the Gulf-Coast region. Qualitative assessment of channel stability is based upon the Modified Johnson et al. (1999) Method for Assessing Channel Stability, developed by Doyle and others in 2000. Local stream power and unit stream power were used as a quantitative indicator of stream stability. Effects of LULC were assessed by analysis of the HUC-12 sub-watershed using ArcGIS. Each sub-watershed was divided into constituent land-cover types, and sediment size range for each reach was compared to the proportions of each land-cover type at the specific as well as from upstream reaches.

Preliminary assessments show that although heavily urbanized stretches of the four rivers in this study are well protected and stabilized, a wide range of adjustments may occur downstream. Degraded channels immediately downstream of urbanized reaches can undergo rapid recovery if the river is protected from further alteration. In areas experiencing poorly-managed suburbanization, however, channel degradation continues even beyond the boundaries of heavily urbanized reaches. Protected public forests or land preserves on a watershed are thus particularly important downstream of heavily urbanized areas.

The Future Floodplains project: ecosystem services of floodplains under socio-ecological change

Renske Hoevers¹, Koen Beerten², Nils Broothaerts¹, Piet De Becker³, Marc Herremans⁴, Francis Turkelboom³, Pieter Vanormelingen⁴, Wim Verheyden³, Gert Verstraeten¹

¹KU Leuven, Leuven, Belgium. ²SCK-CEN, Mol, Belgium. ³Institute for Nature and Forest Research, Brussels, Belgium.

⁴Natuurpunt Studie, Mechelen, Belgium

Abstract

Rivers and alluvial floodplains represent many ecosystem services (ESS) such as biodiversity, carbon storage, groundwater storage, agriculture, water buffering and recreation. Many of these ESS are, however, conflicting for involved social users and policy makers. A thorough understanding of the functioning of floodplains and the sensitivity of the floodplain ecosystem services to (future) changes to internal and external driving forces is needed, to develop a sustainable management policy that suits the needs of as many stakeholders as possible. This requires a multidisciplinary approach in which scientists from different fields cooperate, and which forms the core of the currently running Future Floodplains project (2017-2021). This project is an interdisciplinary strategic basic research project funded by the Fund for Scientific Research – Flanders (Belgium) with the aim to focus on innovative research that can create prospects for societal applications.

To understand the functioning of floodplains, the Future Floodplains project does not only take into account the present changes river and floodplain in geomorphology, ecology and hydrology (geoecohydrology) but also the past changes at mid- to longer timescales. This long-term data is in turn used for scenario-based modelling of future changes in floodplain geoecohydrology and floodplain ecosystems services. This scientific knowledge will be relevant for all governmental and non-governmental institutes and organisations that are dealing with the development and implementation of sustainable management policies related to rivers and floodplains. This includes nature and environmental policies, nature conservation and management, floodwater management, cultural and natural heritage, and agricultural, hunting and recreation policies. Therefore, it is important that the gap between fundamental research on the one hand and the implementation of the project results on the other hand is bridged.

The Future Floodplains project provides this bridge through the use of participative approaches. Stakeholders are involved in the project from the preparatory phase all the way to the end of the project. Through a co-learning and co-design approach, stakeholders are provided with the necessary insights into floodplain dynamics, in order to allow evaluation of the sustainability of present-day integrated management and policies in river floodplains. In this way, it provides a framework to revise environmental decision support systems for the future that takes into account the dynamic nature of floodplain systems, for lowland rivers in general, and rivers in Flanders (Belgium) in particular.

Paleoenvironmental context of prehistoric human activity in the foreland of Polish loess uplands - case study: Sandomierz Upland and Iłża Foreland

Przemysław Mroczek¹, Marcin Szeliga², Radosław Dobrowolski¹, Irena A. Pidek¹, Jacek Chodorowski³, Andrzej Plak³, Piotr Zagórski¹

¹Department of Geomorphology and Palaeogeography, Maria Curie-Skłodowska University, Lublin, Poland. ²Institute of Archaeology, Maria Curie-Skłodowska University, Lublin, Poland. ³Department of Geology and Soil Science, Maria Curie-Skłodowska University, Lublin, Poland

Abstract

The contact zone of the South Polish Uplands with the Central Polish Lowlands is a fragment of the intersection of two major important Pan-European belts - loess and sandy. According to geomorphological criteria, these belts clearly differ in the dominant landscapes. This is mainly due to the different lithology of age-varying geomorphic forms dominating there. An example of a pair of such different geomorphological regions are: the Sandomierz Upland and the Iłża Foothills. The first of them, with an extremely erosive-denudative relief, covers a continuous loess, and the second - karstified Mesozoic rocks with a mosaic cover of glacial tills and aeolian sands. Geomorphological diversity is reflected in the development of different soil types and in the plant cover, and thus their radically different values and perspectives for potential settlement and economic activity of humans.

The different ecological and landscape conditions of both mentioned regions had a particularly significant impact on the nature and intensity of settlement processes occurring within them in the prehistoric times. This is particularly clear since the middle stratigraphic unit of Holocene (the Atlantic period), and especially the settlement of early agricultural communities existing in the 6th and 5th millennium BC. Until recently, the state of archaeological research pointed to the high contrast of settlement activity within the loess Sandomierz Upland and the sandy areas of the Iłża Foothills. It justified the unambiguous linking of the basic settlement preferences of these communities with the first of these regions, and at the same time the assessment of the latter as a zone associated only with occasional penetration, and not permanent settlement. It corresponded very well with the situation recognized in other areas of central and western Europe. A similar situation can be observed also in the case of the settlement of multicultural communities of the Bronze Age and the early Iron Age. In the light of the current state of research their most important settlement ecumene was the area of loess Sandomierz Upland. Only a few and very poor traces of human groups penetration in these periods were documented within the sandy areas of Iłża Foothills.

The results of our latest geoarcheological studies allow for a significant verification of current views on the actual settlement intensity of prehistoric agricultural communities in areas located beyond the edge of the continuous loess cover. Obtained data clearly indicate the existence of extensive and permanent settlement centers within them from the oldest phase of Neolithic to the early Iron Age. Their creation and functioning were undoubtedly connected with the breakdown by the multicultural agrarian communities of the significant ecological barriers and the adaptation to different (more severe) environmental conditions.

The study was supported by National Science Centre, Poland (grant no.: 2015/19/B/HS3/01720).

P-1244

Economic activity of the population in the territory of Southern Georgia in the Early Bronze Age

Inga Martkoplshvili

Georgian National Museum, Tbilisi, Georgia

Abstract

The Early Bronze Age is the longest period in the territory of Georgia. It started in the second half of the 4th millennium BC and lasted nearly 1200 years. The strongest warming took place at this time. In Georgia and Transcaucasia, the peak of this warming was 6000 years ago.

A new, Kura-Araxes, culture was originated and developed at this period. The number of settlements increased. Population mastered the highlands. In present day landscapes, where high subalpine and alpine meadows are common, there were broadleaved forests in the Kura-Araxes period. The results of a palynological study of the material of the Kodiani burial mound are a good example of it. This burial mound is located at the height of 2289 m a. s. l. and according to the archaeological data is dated to the 27-25 centuries BC. Palynological spectra show that given region was covered with forest at that time, where lime, beech and chestnut were mostly spread. Anthropologic indicators of pollen spectra show that human was mainly engaged in agriculture. Apiculture was also developed well.

The results of a palynological study of the Paravani burial mound (2000 m a. s. l.), the Chobareti settlement and the Tkemlara burial mound also point at the powerful development of agriculture in the highlands in the Early Bronze Age. While cattle-breeding prevails today in the region under discussion, in the Early Bronze Age wheat and other cereals were sown here, as well as flax. Because of warm climate conditions, viticulture and horticulture were also developed.

In the middle of the 3rd millennia the Kura-Araxes culture was replaced by the Bedeni culture. At that time, due to warm climate, zelkova and chestnut forests were spread on the high (1800-1600 m) plateaus of South Georgia. *Pterocarya* was observed in floodplain forests. Human cultivated even fig along with vine at this height. These plants do not grow in the mountains above 600-800 m at present.

Ethnopharmacology reached a higher level during the Bedeni period. While 48 species of medicinal plants were found in the burials and vessels of the Kura-Araxes period, this number increased significantly and reached 61 in the burial mounds of the Bedeni culture. A new tradition of burial appeared in the same culture, according to which the deceased person was accompanied with baskets and wooden boxes full of medicinal plants for the afterlife. Exactly such a four-sectioned "first aid kit" was found in the Bedeni burial mound № 10

P-1245

Environment and Human Activity of the Classical Period of Georgia According to Palynological Data

Maia Chichinadze

Georgian National Museum, Tbilisi, Georgia

Abstract

The sites of the Classical Period in Western Georgia - Vani, Nokalakevi, Pichvnari, and Tskheta - are palynologically investigated. Organic remains obtained from cultural layers (6th-5th century BC), burials (4th century BC), and a hoard (1st century BC), as well as modern samples were studied. The Khovle (3th century BC) and Mtskheta necropoleis (5th century BC), discovered in Eastern Georgia, were also investigated by means of the palynological method. Relying upon the palynological data, we could conclude that at various stages of the Classical Period paleoecological conditions were not homogenous in the central part of Georgia. According to the palynologica spectra, the climate in the 5th century became wet, causing swamping of the area. In the first half of the 4th century the climatic conditions seem to be the warmest since chestnut, zelkova and oak woods grew there. Wing-nut trees and royal ferns were spreading on the riverbanks and near lakes. Climatic xerophytic (decrease of the annual rainfalls) of the climatic conditions occurred in the second half of the 4th century. The 3rd century BC was especially distinguishable for worsening of the climatic conditions. It was marked with decrease of the mean annual temperature, while the volume of precipitation was increasing. Fall in temperature is clearly observed on the whole territory of Georgia. Worsening of climatic conditions supposedly began in the first half of the 1st century BC. Farming was well-developed in Vani, Pichvnari and Noqalakevi in the Early Classical Period, which was characterized with warm climatic conditions. The population was growing wheat, Italian millet, barley, millet, a lot of cultivated pulses, and flax. Horticulture and viticulture were well-developed. Olives, that need warm climatic conditions, were also grown. Apiculture was also advanced. According to the tradition, which is evidenced by the palynological data, in the Classical Period honey and wine was interred into burials for the deceased's needs in the next world. In the Late Classical Period because of the worsening of climatic conditions farming diminished, especially markers of arable farming were falling down. Cattle-breeding occupied advanced position. On the basis of palynological studies it was proved that forest ranges were drastically destroyed at the end of the 2nd century BC and the beginning of the 1st century BC.

³Heidelberg Academy of Sciences, Frankfurt/Main, Germany. ⁴Tübingen University, Tübingen, Germany

Abstract

Seasonal changes in resource availability are expected to have an impact on subsistence strategies of humans and thus on patterns of landuse and mobility. According to a basic scheme, patchy distribution of resources promotes a logistical movement pattern, while rather evenly distributed resources allow for residential camps and their movement. In order to test this hypothesis we compare occupation times at Neanderthal sites across Europe in a glacial (MIS 6) and an interglacial (MIS 5e) episode. Here we present first results of this study.

Length of stay is inferred from tool diversity in the assemblages expressed by a specialization index. The specialization index S_i correlates inversely with the diversity of an assemblage and the specific use of the camp. The shorter the duration of stay, the higher the specialization index, for instance at a specialized task camp. In residential camps, tool diversity is expected to be higher resulting in lower specialization indices and longer duration of stays.

In our present study, we assessed two types of food resources and their respective shifts in seasonal availabilities, in particular edible plants as well as large mammal herbivores, to monitor resource distribution. Although other types of food resources are available too, plants and large animals contribute a considerable proportion to the Neanderthal diet. Plant communities in MIS 5e and MIS 6 are assigned to comparable modern vegetation units and assessed for the seasonal availability of edible plant parts. The availability of herbivores in particular seasons is assessed by means of a model which links herbivore diet to migration potential on a quantitative basis.

Both types of resources experience fluctuations throughout the year, irrespective of a glacial and/or an interglacial background. Neanderthal mobility patterns reflect seasonally changing resource spectra in rather complex ways. On a regional and/or local scale, however, correlations can be observed. Despite consistently changing environments Neanderthals display considerable conservatism with respect to their material culture. This conservatism must not be considered as a disadvantage finally driving Neanderthals to their extinction. Instead remarkably flexible patterns of subsistence and mobility rest on the firm base of cultural continuity.

Long-term land-use, archaeological and environmental changes in Holyrood Park, Edinburgh

Carla Ferreira, Eileen Tisdall, Richard Tipping
University of Stirling, Stirling, United Kingdom

Abstract

Situated in central Edinburgh and covering an area of 259 ha, Holyrood Park is home to geologically important evidence of volcanic activity which took place 350 million years ago such as Arthur's Seat and Salisbury Crags. With the earliest evidence of human presence dating back to the 5th millennium BC, the continuous human occupation makes Holyrood Park ideally suited to reconstruct the local evolution of vegetation, land-use and human settlement from the late Mesolithic to the 19th century AD. The decision to undertake a study focusing on the evolution of the immediate surrounding landscape meant the sampling had to be conducted as close as possible to the study area, which posed particular challenges. The available sampling sites were not the "classical" palaeoenvironmental archives and factors such as sedimentation and post depositional processes were to be examined very closely.

Dunsapie Loch is located just to the East of Arthur's Seat and sits at the base of the Dunsapie Crag hillfort. The Loch directly faces some of the best preserved cultivation terraces in the wider region. Its privileged location makes the site particularly suited to obtain a high quality, high resolution pollen, Non Pollen Palynomorphs (NPP) and soil erosion record which can contribute to the understanding of the nature and chronology of the immediate archaeological features. For the Dunsapie sequence geochemical and data were compared with pollen and archaeological records to help inform the construction of the age-depth model and of a long-term sedimentation sequence, defining periods of natural and anthropic-led erosion. Multi-element analysis indicates that an erosion event occurring *circa* 4000 BC was preceded by a decline in *Ulmus* and other woodland taxa. The pollen record suggests a landscape dominated by grassland by *circa* 2700 BC with no significant woodland recovery throughout the remaining sequence. Grazing and cultivation, as suggested by the presence of NPP and cereal-type pollen, were first recorded during the 4th millennium BC and intermittently present until the close of the sequence.

The Dunsapie Loch pollen sequence is unique in the Scottish context and could be argued that the essentially local nature of the analysed proxies contributed to mute a wider regional signal. The findings from this study will assist future projects undertaking the interpretation of complex archaeological landscapes from the sediment and pollen records by highlighting the important contribution of local and, often overlooked, palaeoenvironmental archives. By understanding the convoluted relationship between the different archives, and through the use of a multiproxy approach, it was possible to obtain an essentially local, high resolution palaeoenvironmental record of the changes that took place within the Park area over the last 7000 years.

A Holocene Pollen Record from the Western Qilian Mountains and Its Implication for Regional Climate Change in Northwest China

Jun Zhang, Xiaozhong Huang, Zongli Wang
Lanzhou University, Lanzhou, China

Abstract

The sparsity of long-term reliable climatic records hampers our understanding of both vegetation ecological feedbacks and human-environment interactions in the semi-arid Hexi Corridor, northwest China. This study analyzed a pollen sequence from a small lake, the Tian'E Lake, in the western Qilian Mountains covering the past 10 ka (1 ka=1000 cal yr BP). The chronology is provided by reliable accelerator mass spectrometry (AMS) C-14 dates from nine terrestrial plant materials and one organic material in the sediment. The fossil pollen spectra suggested that the Tian'E Lake region vegetation were dominated by *Amaranthaceae* (=Chenopodiaceae), *Artemisia*, *Poaceae* and *Cyperaceae*. From 10 ka to 3.6 ka, the local vegetation was steppe dominated by *Artemisia*, *Poaceae* and *Amaranthaceae* with some sparse trees, indicating stronger Asian monsoon. After ~3.6 ka, a decrease of tree pollen suggests that forest vegetation disappeared from this region, and the local vegetation was desert steppe dominated by *Amaranthaceae*, *Artemisia* and *Poaceae* with the weakening of Asian monsoon. The ratio of *Artemisia* and *Chenopodiaceae* (A/C) could represent the regional humidity variations, and there was relatively dry period from 1.3 to 0.8 ka. The A/C ratio indicates that regional humidity decreasing significantly after ~3.6 ka. The regional humidity was overall increased during the Little Ice Age (LIA) and Century Warming Period (CWP), which might be caused by depressed the evaporation during the LIA and monsoon enhancement during the CWP. Comparison with tree-ring data indicates that some archaeological site and ancient cities of the Hexi Corridor were abandoned corresponding to continuous droughts.

Multi-proxy evidence for population dynamics in the Neolithic and Bronze Age of north-western Central Europe

Ingo Feeser¹, Jan Piet Brozio¹, Stefan Dreibrodt², Walter Dörfler¹, Martin Hinz³, Jutta Kneisel¹, Johannes Müller¹
¹Institute of Pre- and Protohistoric Archaeology, Kiel University, Kiel, Germany. ²Institute of Ecosystem Research, Kiel University, Kiel, Germany. ³Institute for Archaeological Studies, Bern University, Bern, Switzerland

Abstract

Population dynamics are regarded to be crucial for understanding social change and cultural organisation in prehistoric societies. Hereby summed probability distributions (SPD) of archaeological radiocarbon dates have been increasingly used as a palaeodemographic proxy during the last decades of archaeological research. This approach, however, is controversially discussed as several methodological uncertainties and biases are involved. In order to mitigate such proxy related uncertainties we use a multi-proxy approach. Hereby the comparative interpretation of several independent proxies allows the identification of demographic patterns with greater confidence. We use palaeoenvironmental data from northern Germany and southern-western Denmark, to reconstruct independent proxies of human impact during the Neolithic and Bronze Age. This involves, beside sum calibration of archaeological ¹⁴C dates, the quantification of human impact on the vegetation from pollen analysis using multivariate statistics as well as soil erosion history from stacked colluvial records. We postulate that the assumed relationship of human activity and population density in the SPD approach is also true for the other palaeoenvironmental proxies and use them accordingly as additional proxies for population dynamics.

Based on the comparison of the three proxies we define phases of growing (boom) and decreasing (bust) population in northern Germany. The boom phases date to ca. 4000–3500, 3000–2900, 2200–2100, 1450–1300 and 1000–750 cal. BC. The bust phases to ca. 3200–3000, 2400–2300, 1650–1500 and 1200–1100 cal. BC.

³MARUM—Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Abstract

Vegetation dynamics during previous warm interglacial periods shed light on human impacts on natural ecosystem trends during the Holocene. But only a few terrestrial records span such periods with a reliable chronology. Here we present a high-resolution marine pollen record from the northern South China Sea. We find that during five peak interglacial periods, MIS 13a, 11c, 9c, 5e and 1 (the Holocene), the vegetation successions in southern China were similar. At the beginning of each interglacial period, tropical rainforest conifers including *Dacrydium*, *Dacrycarpus* and *Podocarpus* and associated broadleaved taxa such as *Altingia*, expanded quickly at the expense of the subtropical/temperate montane conifer *Pinus*. Near the end of the previous warm periods, *Pinus* recovered and tropical taxa retreated. However, the Holocene process displays subtle but significant differences in which the species turnover was interrupted and the rainforest conifers never fully expanded. The Mg/Ca-based sea surface temperature record from the same site reveals that temperature was the major control on the rise and fall of the peak interglacial vegetation. However, exceptionally high charcoal fluxes during the Holocene suggests that human activities have completely, and possibly permanently, altered the natural vegetation trend five to six thousand years ago through forest clearance and burning.

Abstract

The South Atlantic Coast of the United States is known for its impressive shell middens, especially its shell ring sites, which are arcuate to circular deposits of shell, bone, ceramics, and other artifacts. Many of these rings are of massive proportions and in excess of over 100 meters in diameter with elevations of over three meters above the surrounding topography. In addition to possessing some of the earliest ceramics in North America, these sites are thought to represent, in part, a shift to sedentary village life along the coast. Besides shape, one of the commonalities that shell rings have is that the primary shellfish exploited by the inhabitants was the eastern oyster (*Crassostrea virginica*). Most interestingly, shell rings become largely abandoned by around cal. 3800 years ago. Recently, we began a project to explore oyster paleobiology on a large scale along both the Gulf and Atlantic coasts of eastern North America. The work presented here is a subset of this research. Here we explore patterns in oyster size from South Carolina and Georgia during the Late Archaic period. In total, we measured left valve height (LVH) and left valve length (LVL) of over 30,000 oysters from 14 sites. We observed statistically significant differences in the size of oysters collected across sites. Further, significant differences exist at an intra-site level, with oysters from the lowest, and hence, earliest deposits being larger than those exploited later in time at some sites. Regionally, there appears to be a non-random pattern in the mean oyster size exploited moving from sites situated from north to south. We interpret the observed variation at both the site and regional level to processes related to territoriality, fishing rights, and coastal environmental variability. We also place these oyster paleobiological data within the context of larger temporal trends of climate and environmental latitudinal gradients.

Using multiproxy analysis to identify the impacts of social transitions and crisis: Iona during the pre-Monastic to post-Viking era

Samantha Jones

University of Aberdeen, Aberdeen, United Kingdom

Abstract

The island of Iona in western Scotland has undergone numerous social transformations since prehistoric times. The island is well renowned for its early monastery constructed, in ~AD 563, where it quickly became an important centre for learning, agricultural innovation, and the spread of Christianity. Our knowledge for this period is improved by the availability of written records produced during the first 200 years of monastic life; however, between the 8th-12th centuries, Scotland experienced severe political and social upheavals, which ultimately saw the drying up of written records. This includes several Viking raids, which had a drastic impact on the monastic community; the waning of ecclesiastical power with the transfer of St. Columba's relics; and the restructuring of political borders - with Scandinavian settlement, the disappearance of Dal Riata and Pictland, and the gradual formation of Alba (Scotland).

Following on from a Historic Environment funded project to bring Charles Thomas' excavations (1956-1958) at Iona to publication, in 2017, a series of new excavations and environmental analysis took place at sites around Iona Abbey, directed by Ewan Campbell, university of Glasgow. By presenting the palaeoecological results of this investigation, this paper aims to provide additional information on the historical and archaeological resources, regarding the social transformations influencing Iona between the prehistoric and historic periods.

An integrated palaeoenvironmental record of land use and industrial pollution within Angkor Thom, Angkor.

Tegan Hall¹, Dan Penny¹, Brice Vincent², Martin Polkinghorne³

¹University of Sydney, Sydney, Australia. ²Ecole française d'Extreme-Orient (EFEO), Paris, France. ³Flinders University, Adelaide, Australia

Abstract

Here we present a multi-proxy record of environmental change from the administrative and ceremonial core of Angkor, within the urban enclosure of the 12th century citadel of Angkor Thom. Analysis of proxy data, including geochemistry, palynology, sedimentology and fire history, reveal a distinct period of elevated metal pollution between c. 1300 and 1600 C.E., demarcated particularly by elevated concentrations of lead and copper in the sediment archive. These results reveal periods of artisanal activity within the ceremonial core of Angkor Thom that can be linked to known sites of copper-based metallurgy adjacent to the Royal Palace in Angkor Thom. These results link palaeoenvironmental signals of changing land use with evidence for peaks in industrial metal pollution, and imply that activity in these ateliers continued uninterrupted throughout the supposed decline and demise of Angkor, in keeping with industrial metal working in other Khmer centres during this period.

Ancient cisterns as a palaeoenvironmental archive: A case study from the Negev Highlands (Israel)

Andrea Junge¹, Zachary C. Dunseth^{2,3}, Ruth Shahack-Gross³, Israel Finkelstein², Markus Fuchs¹

¹Justus-Liebig-University Giessen, Giessen, Germany. ²Tel Aviv University, Tel Aviv, Israel. ³University of Haifa, Haifa, Israel

Abstract

Drylands are characterised by a scarcity of sedimentary archives suitable for palaeoenvironmental reconstructions. This absence of established archives leads to the introduction of a novel sedimentary archive: ancient cisterns, with new possibilities and challenges. In this study, the ancient subterranean cistern system Borot Ramaliya (Negev Highlands, Israel) is evaluated for its potential to be utilized as a novel paleoenvironmental archive.

Ancient cisterns are frequently-occurring archaeological installations in the Negev Highlands. These installations collect and store water and can sustain settlements, agriculture and nomadic pastoralism under dry conditions. Despite the large number of cisterns in the arid Negev, these installations have not been systematically studied as sedimentary archives.

During precipitation events, surface runoff from adjoining slopes erodes and transports sediments, which are then deposited in the cisterns. Therefore, these archaeological installations serve as sediment traps, representing fluvial processes in their catchments. Additionally, the structures are usually constructed to prevent any water outlet, resulting in an undisturbed, often continuous sediment record of the infilling after their abandonment.

Crucial for the establishment of a palaeoenvironmental record are robust chronologies. Due to the removal of sediments during construction and maintenance of the installations, optical stimulated luminescence (OSL) dating proves to be the preferred dating method. The sediment record within the installations includes numerous environmental proxies (e.g., grain size, geochemical properties, botanical microremains, pollen, phytoliths), which can be used for palaeoenvironmental reconstruction, serving as an important archive in dryland areas.

¹University of the Basque Country, Vitoria-Gasteiz, Spain. ²Universidade de Santiago de Compostela, Santiago de Compostela, Spain. ³(3) Museum National d'Histoire Naturelle, Paris, France. ⁴University of Valencia, Valencia, Spain. ⁵University of Zaragoza, Zaragoza, Spain. ⁶IKERBASQUE, Basque Foundation for Science, Bilbao, Spain. ⁷Sapienza University of Rome, Rome, Italy. ⁸Pyrenean Institute of Ecology (IPE-CSIC), Zaragoza, Spain

Abstract

The past distribution of key tree and shrub taxa at European scale has increased noticeably during the last decades as consequence of the accumulated data production effort carried out by many palaeobotanical research groups. The number of chronologically well-constrained available pollen and anthracological data have allowed defining not only the location of both deciduous and evergreen species during the Last Glacial Maximum, but also characterizing the pattern of postglacial recolonization of central and northern European regions.

One of the widespread trees in the semiarid Mediterranean Iberia is the Aleppo pine (*Pinus halepensis* Mill.) whose distribution is confined to the thermo- and meso-Mediterranean biogeographic belts. However, the chronological timing and the drivers explaining the long-term presence of Mediterranean pinewoods across the Central Ebro Basin and borderlands are far from being fully understood. The available anthracological data support the early spread of *Pinus halepensis* during the Mesolithic (ca. 9700 cal BP) accompanied by Mediterranean trees and shrubs like evergreen *Quercus*, *Juniperus* sp., *Arbutus unedo*, *Pistacia lentiscus*, *Rhamnus/Phillyrea*, Cistaceae or *Rosmarinus officinalis*, probably, as a local response to global climate change in the early Holocene. During the arrival of the Neolithic, pollen and charcoal records demonstrate the progressive substitution of open thermophilous landscape by both evergreen and deciduous *Quercus* in response to the Mid Holocene rise in temperatures and humid conditions. This evidence, however, converges with the general idea that the presence and the concomitant spread of *Pinus halepensis* and associated thermophilous scrubland have usually been attributed to the onset of landscape anthropization in the literature. The frequency of xero-thermophilous open scrubland and the use of Aleppo pine for fuel progressively acquired more visibility during the Bronze and Iron Age periods, and especially in Roman and Medieval times, where the vegetation landscape in the Central Ebro was practically deforested as consequence of increasing demographic pressure and the establishment of proto-urban centers.

The reviewed palaeobotanical data reveal that the modern distribution of *Pinus halepensis* in the Central Ebro Basin is the consequence of a combination of factors, including long-term ecological responses to climate changes and the human-induced shaping of the landscape. Overall, the anthracological data support the spread of Aleppo pine woodlands during the Mesolithic and therefore the primary role in the vegetation landscape prior to the arrival of Neolithic socioeconomic transformations.

Abstract

Multi-proxy high-resolution palaeoecological studies on peatlands enable detailed reconstruction of forest development under variable human impact. In this study, we focus on the Kazanie fen, located in Greater Poland near Poznań. The aims of our studies were to (i) reconstruct the vegetation changes along with the progressing human impact related to the Polish state development, (ii) identify intrinsic and extrinsic factors in the peatland development, and (iii) extract the role of economic and historical turnovers for ecosystems' changes. We carried out pollen, plant macrofossil, charcoal, testate amoeba, and selected non-pollen palynomorph (NPP) analyses, supplemented by ¹⁴C AMS dates (each 10-20 cm) and historical sources. Results show a strong link between human impact and vegetation changes in the past. Palaeoecological research has enabled the detection of well-documented historical events. Among them was a rapid decline in the population of the Swedish Deluge in 1655-1660, which was followed by spontaneous reforestation. Oak-hornbeam forest that dominated in the vicinity of the site between ca. AD 900 and 1610 was replaced by forest dominated by *Pinus sylvestris*. The area of the coring spot before AD 1520 was functioning as an overgrowing lake. Then brown mosses spread, among which *Scorpidium cossoni* and *Pseudocalliergon trifarium* dominated, indicating the presence of calcareous rich fen. The transition from vegetation typical of a rich fen to a poor fen took place ca. AD 1984, when *S. cossoni* was replaced mainly by i.e. *Sphagnum fallax*, *S. teres*, and *S. fimbriatum*, indicating more acidic habitats. This transition was also recorded by testate amoebae among which *Microchlamys patella*, *Centropyxis aculeata*, *Pyxidicula* ssp. and *Diffflugia* ssp. were replaced by *Assulina muscorum*, *Nebela tincta* and the representatives of the *Euglypha* spp. Simultaneously to this transition *Alnus* and *Betula* became more frequent in the vicinity of the site. We believe that the results of our research, confronted with historical sources, will contribute to a better quantitative understanding of the impact of land use changes during the historical period on the functioning of terrestrial and peatland ecosystems. Research financially supported from the funds of National Programme for the Development of Humanities (Project: NPH012; PI: Piotr Guzowski).

Centennial fluctuations of climate wetness in southern Siberia and ancient human cultures of Eurasian Great steppe belt

Tatiana Blyakharchuk¹, Irina Kurina²

¹Institute for monitoring of climatic and ecological systems of Siberian branch of Russian academy of science (IMCES SB RAS), Tomsk, Akademicheski ave. 10/3, Tomsk, Russian Federation. ²Institute for monitoring of climatic and ecological systems of Siberian branch of Russian academy of science (IMCES SB RAS). Tomsk, Akademicheski ave. 10/3, Tomsk, Russian Federation

Abstract

Spore-pollen, testate amoeba and macrofossil analysis were performed for peat-lake sediment core from Bezrybnoye mire (52° 48' 36.29"N, 93° 30' 47.14"E, 1395 m.a.s.l.) located in Ergaki nature reserve (Western Sayan Mountains in the south of Central Siberia). Sediments of 600 cm thickness were accumulated during 3200 cal years. Dating is based on four radiocarbon dates. Resolution of palaeoecological series is 90-45 years per sample. The dynamic of the vegetation cover and humidity of climate together with wetness of mire surface were reconstructed based on palaeoecological data with appropriate transfer functions. By change in the assemblages of testate amoebae, 11 periods of lowering the mire water level and 9 periods of increased mire water levels were revealed.

Although the dynamics of the vegetation cover recorded in changes of the pollen zones reflected only long-term climatic trends, it turned out that the centennial and multi-decadal fluctuations in the abundance of the Scot's pine pollen (*Pinus sylvestris*) correlate positively with lowering of mire waters reconstructed by testate amoebas. Possibly pine reacted on the climate aridization either by increasing of its area at the expense of moisture-loving tree species – fir (*Abies sibirica*) and cedar (*Pinus sibirica*), or more mobile - by increasing its pollen productivity during dry time periods. In general during 3370 years we revealed 12 episodes of dry climate fixed both by testate amoeba complexes and by Scot's pine pollen - 77, 540, 897, 1152, 1526, 1753, 2023, 2313, 2503, 2879, 3114, 3302 cal yr BP. Comparison of these drought events with the historical data about desiccation of the steppes, cited in works of Russian ethnographer and historian Lev N. Gumilev, revealed a very good correlation between them. Our multi-proxy palaeoecological data confirm the hypothesis of strong influence of the centennial fluctuations in climate moistening on the history of ancient people in southern Siberia and in general in the Great Steppe Belt of Eurasia. We find confirmation of the identified periods of climate desiccation and humidification also in the data of dendrochronology. Both our palaeoecological data and published dendrochronological data evidence about better wetting of Great steppe belt during the heyday of the Mongolian empire and in Scythian times with two dry episodes at about 2500 and 2300 cal yr BP. We suppose that the revealed centennial fluctuations of climate humidity are related to the dynamics of solar activity.

⁴Department of Archaeology. University of York, York, United Kingdom

Abstract

The opportunities to follow the Holocene evolution through sedimentary archives are not numerous in south-eastern Mediterranean, and especially in the Aegean. In Crete, the largest Greek island, Kournas lake is the only natural lake and its sedimentary record offers the opportunity to study 10 millennia of environmental changes. On the 14 meters long core we extracted from the lake, multiproxy studies of sediments, pollen and non-pollen palynomorphs, and charcoals, were undertaken in order to document: 1) lake formation and evolution, 2) floods and slumps events, 3) land cover and biodiversity changes, 4) human agro-pastoral activities and 4) fire history.

The results highlight the Holocene environmental trajectory as well as key socio-cultural phases in the eastern Mediterranean basin. For example, early Neolithization, the development of Minoan civilization, Greek and Roman Antiquity and Venetian rule over Crete. The south-eastern Mediterranean is an area sensitive to climate change and/or rapid climate change events. In addition, the region is exposed to natural hazards such as volcanism and earthquakes, the most famous being Santorini eruption. This research allows us to assess and compare socio-cultural and natural process that shaped this typical Mediterranean landscape and the processes linking causes and effect in these changes.

At Kournas, considering changes in the vegetation cover, pollen biodiversity and fire regimes, our perception is that human disturbances are the main cause of changes. So are the different phases of olive cultivation that have succeeded one another since 6000 BP. From the Late Neolithic to the Present Day, the main stages comprise a sharp decrease at the end of Minoan civilization, a significant and sustained cultivation during Hellenistic and Roman periods, a decrease under the Venetian rule that favoured wine, and then, new growth from the Ottoman period onwards. Disturbances as an effect are more obvious on the hydrology of the watershed, including floods and changes in lake productivity. However, the major changes are often linked to multifactor causes. As an example, around 3600 BP, the Santorini eruption is not a disruption in the palaeoecological history in this area. But, at that time, seismic activities that caused several slumps in the lake, together with socio-political perturbations of the Late Minoan, and changes in agro-pastoral activities resulted in a significant environmental change.

Obviously, around the Cretan lake of Kournas, the main feature of the current landscape is a legacy of a 6 millennia-long olive cultivation, and the socio-cultural evolutions drove the rhythm of this major land-use. Nevertheless, only complex interrelations between natural and cultural changes led to ecosystems changes as may also succeed in the future.

Abstract

Although Northwest Patagonia was inhabited by hunter gatherer until historic times with evidence of “farming islands” in the north sector (mostly Diamante and Atuel River). Until recent time the human evolutionary trajectory had been focused in a coarse grained temporal resolution, using multi millennial units. This presentation explores the archaeological record in relation with climate variation during the last 1000 years. Using a paleoclimatic reconstruction of SAM (Southern Annular Mode) we compare human demography, diet, and technological organization. Different proxies indicate two different scenarios. First, between 1000 to 1300 years AD, dominated by SAM positive, hotter and driest summers were associated with stable human population, low use of high rank resources, like guanaco, and low frequency of non local rock and ceramics. Around 1400 years AD, start to dominate SAM negative, that implied cooler summer associated with an increase in precipitation. An abrupt increase on human population was observed in a period of ca. 200 years (ca. 1400 to 1600 AD). In addition, a notable increase in guanaco exploitation and significant change on stable isotopes trend on human bone (13C and 15N) indicate change in diet. An increase in a non-local rock like obsidian and non-local ceramic are recorded too. Clearly, these changes were operating before LIA and before the Hispanic domination (recorded ca. 1800/1880 AD in the area, ca. 1550 in a macro region). All these findings point out that the last millennium, in Northwest Patagonia was not a stable socio-ecological system. Contrarily, we detect abrupt changes associated with an increase in human demography and a significant increase in primary productivity as consequence of SAM negative modulation that generated summers with more precipitation and cooler than normal. This scenario of population growth in Patagonian hunter gatherers could cause their expansion to the North, retracting the limits of prehispanic farming, just a few centuries before the Spanish arrived.

A millennium of landownership, land use and environmental change in Iceland

Scott Riddell, Egill Erlendsson, Guðrún Gísladóttir
University of Iceland, Reykjavík, Iceland

Abstract

The present landscape of Iceland is marred by erosion scars and discontinuous vegetation cover having lost almost all natural woodland, and up to 50% of its soils, during the course of the last 1000 years. Palaeoecological studies show that woodland clearance followed by soil erosion, in both inhabited areas and upland range, has been underway since Iceland's initial settlement (Landnám) in the late 9th century. Ongoing discourse as to how such landscape degradation arose on such a scale, how it developed temporally and spatially, and what the nature of the underlying mechanisms responsible for these developments are, continues. Rarely do such studies explore social and/or economic variables influencing such environmental disturbance and nor do they situate them within theoretical models for environmental change (e.g. gradual or step-like etc.). Do particular instances of environmental change reflect changes in society or vice versa? This paper considers parity between palaeoecological data, bioarchaeological material, and historical sources. Three steps of environmental decline may be apparent in Iceland, all of which may be linked to socio-economic events: 1) Landnám and woodland clearance that triggers soil erosion during a period of relatively mild climate. 2) The replacement of a community comprised of independent farmsteads to one dominated by a manorial system and associated tenancies. This corresponds with a shift toward sheep farming at the expense of dairy cows, further woodland decline and an intensification of soil erosion between AD 1200 and AD 1400. 3) Environmental degradation is further amplified during the late 19th century in hand with an increase in sheep numbers in response to European markets for meat and wool, as well as agricultural improvement.

Abstract

The contribution aims to present first results of a multiscale and geoarchaeological approach to Human-Environment relationships into Maritsa-Iztok area (Bulgaria) and particularly nearby the tell of Sokol (Late Chalcolithic – Bronze Age). Our goal is analyze the role of agropastoral practices and climate events on the dynamics of mosaic landscapes for this time interval.

Up to that time the investigations were limited to on-site sequence study and palaeoenvironmental research was lacking. In order to overcome the taphonomic issue in some cultural layers, we attempt to use local sedimentary archives to identify periods of landscapes and socio-cultural changes around the closer inhabited areas. The presentation is based on preliminary results which combine geomorphological and palynological analyses (including Non Pollen Palynomorphs), from about six cores carried out into an alluvial context. Beyond the limits of interpretation linked to the quality of sedimentary archives studied, the analysis shows that the question of the effects of human activity on the landscape cannot be addressed without an accurate analysis of local and off-site contexts. Even, it remains difficult to identify cultivated or harvested plant species from pollen taxa recovered, the results obtained can be accurately compared with other palaeobotanical dataset from the tell. This long term analysis about vegetation cover dynamics provides food for thought to fill the archaeological shortcoming for this period, guiding the future investigations.

Finally, the results obtained around Sokol invite us to expand our study area, putting this methodological approach into practice to some of other multiperiod and discontinuous occupation sites in the densely settled lowland areas such as Upper Thracian. In fact, in order to fill a gap of our understanding of the Human-Environment-Climate relationships during these cultural periods, we need to renew and update the palaeoenvironmental dataset for regions where archaeological data are already significant and still ongoing.

Cultural and social trajectories of human occupation of the Chiloé Archipelago, Patagonia-Chile: change and interaction among marine-hunter-gatherer and agro-ceramic societies

Omar Reyes¹, Carolina Belmar², Manuel San Román¹, Augusto Tessone³, Flavia Morello¹, Ximena Urbina⁴

¹Centro de Estudios del Hombre Austral, Instituto de la Patagonia, Universidad de Magallanes, Punta Arenas, Chile.

²Departamento de Antropología, Universidad de Chile, Santiago, Chile. ³Instituto de Geocronología Geología Isotópica (CONICET-UBA), Buenos Aires, Argentina. ⁴Instituto de Historia, Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

Abstract

The northern Patagonian archipelago is an extended geographical area (600km) that breaks the continuity of the Pacific coast and it projects into an insular system with notable biogeographical discontinuities, such as channels, fiords, mountain chains and icefields that portrays the southern extreme of the western side of South America (Figure 1). This oceanic environment, modeled mainly by important tectonic activity, volcanic and glacial action, registers the first signs of human occupation dated at 5500 years BP by marine hunter-gatherer groups that have navigation technologies.

However, the southern zone of Chile and the Chiloé archipelago (41°-43°S), present an important change in the trajectories towards the last millennium, represented by the emergence of cultural traditions that have ceramic technology, horticulture and -probably- domestic animals. This new social and cultural scenario contrasts with what occurs in the adjacent regions south of the Corcovado gulf (43° S), where the subsistence systems continued based on marine hunting and gathering and fishing until historic epochs (S. XVI-XX), endorsed by the presence of groups historically known as Chonos, Kawésqar and Yámana, in the Patagonian archipelago. This setting is of crucial importance to understand the processes of change and social interaction between societies that produce food and marine hunter-gatherers.

The island of Chiloé and its surrounding continental and insular sectors can be conceived as a border territory, a place of contact and interaction between different social and cultural systems. From the archaeological, bioanthropological, isotopic and historical records, we evaluated these cultural trajectories and interactions between human groups with different lifestyles and technological traditions in the northern area of the western Patagonian channels.

In our recent studies, we have detected the occasional consumption of domesticated plants -bean, potato, and corn - present in the dental calculus of individuals of these marine hunter-gatherer societies around 1000 years BP. Microfossil studies will also be applied to ceramic and lithic use residues to evaluate the presence of these domesticated plants that function as a marker of this moment of contact between both groups. Ceramic and lithic studies are oriented to detect continuities and changes in the production of these types of technologies. The faunal assemblage is also integrated to evaluate possible variations in the procurement of this type of resource. Finally,

isotopic analysis of human remains from the late Holocene sequence will allow to precise the diet these groups had and the changes occurred through time, all of this evidence is dated as to understand the chronology of the continuities and changes among these marine hunter-gathering groups.

People, not climate, structured past fire regimes in south-central Utah

Vachel Carter¹, Andrea Brunelle¹, Mitchell Power¹, Isaac Hart¹, Justin DeRose², Matt Bekker³, Brian Coddling¹

¹University of Utah, Salt Lake City, USA. ²US Forest Service, Ogden, USA. ³Brigham Young University, Provo, USA

Abstract

Typically, climate is considered to be the dominant driver of fire regimes. However humans have been shown to influence fire regimes and override climate in the past. North American anthropogenic burning has been a controversial issue due to the widely perceived notion that low-density human populations had minimal impact on ecosystems. Recent research has illustrated that humans have had profound impacts on vegetation structure and fire regimes within fire-prone ecosystems for millennia. Understanding the successful coexistence between past human societies, especially from those societies living within lightning-fire-prone ecosystems, and fire can help provide insight into sustainable fire management; a topic of critical importance among many western North American land managers. Here, we investigate how humans may have influenced fire regimes over the past 1,300 years. We used a multi-proxy approach utilizing sediments collected from Fish Lake, Utah, a tree-ring-based record of drought, archaeological evidence, and Generalized Additive Models (GAMS) to model the relationship between fire, human occupation and climate. Fish Lake was seasonally used by the Fremont archaeological complex; a small farming and foraging group which inhabited an area roughly congruent with the modern borders of the state of Utah between 0-1400 CE, with a peak in site frequency occurring at ca. 1000 CE. Our results demonstrate that during the time of peak Fremont occupation, biomass burning was high, as were ethnobotanical herb pollen percentages. Despite the height of Fremont occupation occurring concurrent with the Medieval Climate Anomaly, our GAMS model found no significant correlation among charcoal influx and drought. Rather, our model demonstrates a significant correlation among charcoal influx and Fremont population densities. When Fremont populations densities declined beginning ~1400 CE, biomass burning and ethnobotanical herb pollen percentages simultaneously declined, while tree and shrub pollen percentages increased. It was not until Euro-American settlement ~1800 CE when biomass burning increased, despite the drastic change in vegetation composition associated with intensive grazing and ranching. Our results demonstrate how the Fremont potentially used sustainable fire practices for improving food-resource security.

Assessing climate change impacts on coastal and marine cultural heritage across the Middle East and North Africa: the MarEAMENA project

Kieran Westley¹, Lucy Blue², Colin Breen¹, Robert Bewley³

¹Ulster University, Coleraine, United Kingdom. ²University of Southampton, Southampton, United Kingdom.

³University of Oxford, Oxford, United Kingdom

Abstract

There is growing awareness of the impact of climate change on cultural heritage and an expectation that impacts will be exacerbated in the future. Effective management strategies are needed to meet this threat and minimize the loss of valuable scientific information and irreplaceable cultural resources. However, understanding threat and managing climate change impacts (both direct and indirect) can be hindered by a lack of baseline data, both on cultural heritage (e.g. site locations, condition, extent) and the impacts themselves (e.g. severity, spatio-temporal variability). This is the case across large parts of the coastal and maritime environment of the Middle East and North Africa (MENA). Its maritime cultural resource is currently little understood. There has only been limited and fragmented archaeological research, mostly undertaken by researchers from outside the region, while national governments have frequently overlooked its protection and management due to a lack of local knowledge and expertise. Although conflict is often regarded as the main adverse impact on the heritage of the MENA region, direct climate change impacts (e.g. coastal erosion) and indirect effects (e.g. urban expansion, offshore infrastructure) are also present and starting to take their toll. Consequently, the archaeology of the coastal and nearshore underwater zone is being destroyed or damaged at an alarming rate and there is a critical need to document it before it is lost. This has led to initiation of the Maritime Endangered Archaeology of the Middle East and North Africa (MarEAMENA) project, an offshoot of the ongoing terrestrially-focussed EAMENA documentation and risk assessment programme. MarEAMENA aims to comprehensively document the entire coastal and nearshore zone of the MENA region both on land and underwater, building on the extant dispersed coastal documentation, and ensuring the accurate identification, interpretation and risk assessment of maritime archaeological sites. To do so, it will adopt EAMENA's established documentation and monitoring strategy based on systematic analysis of historic (e.g. Corona) and recent (e.g. Google Earth, Landsat, Sentinel-2) satellite imagery, aerial photographic archives and archival sources. Where possible, this will be supplemented by ground-checking using conventional maritime archaeological methods (e.g. acoustic surveys, dive surveys). Additionally, since the relationship of maritime sites to the sea is changeable over time and space owing to sea level change and coastal sedimentary processes, MarEAMENA will also analyse Quaternary patterns of coastal change to better understand the nature and condition of maritime archaeological sites and be better placed to make an assessment of the particular threats which they face. This poster will introduce the MarEAMENA project, outline its aims, objectives and methodology, and report on interim results which demonstrate the impact of climate change on cultural heritage in the coastal and nearshore MENA region.

People and peatlands in the Peruvian Amazon

Katherine H. Roucoux¹, Christopher Schulz², Lydia Cole¹, Luis Andueza¹, Charlotte Wheeler³, Anna MacPhie¹, Althea Davies¹, Nina Laurie¹, Edward Mitchard³, Manuel Branas⁴, Cecelia Nunez⁴, Ian Lawson¹

¹University of St Andrews, St Andrews, United Kingdom. ²University of Cambridge, Cambridge, United Kingdom.

³University of Edinburgh, Edinburgh, United Kingdom. ⁴Instituto de Investigaciones de la Amazonia Peruana, Iquitos, Peru

Abstract

Interdisciplinary research by Quaternary palaeoecologists, ecologists, and social scientists has the potential to deepen our understanding of ecosystem function, stability and vulnerability in ways which are not possible for any one of these disciplines alone. This presentation will review the experiences and findings of the interdisciplinary work carried out recently by our research group to date, as we work on understanding the processes, dynamics and functioning of peatlands in Amazonia and attempt to ensure that our future research agenda on Amazon peatlands is useful, appropriate and culturally sensitive.

The peatlands of western Amazonia store a globally significant quantity of carbon and, in contrast to those of SE Asia, remain hydrologically intact. They harbour low, but unique, biodiversity and, like peatlands everywhere, preserve a palaeoecological archive of their own environmental history. Our palaeoecological work has shown that the peatlands are dynamic on centennial to millennial timescales and that the present day vegetation often only developed relatively recently. Our ecological research has demonstrated their importance as contributors to regional diversity and as stepping stones for dispersal between other biologically important habitats. We have shown that these peatlands are under threat from development of commercial agriculture and transport infrastructure, and from local resource exploitation. However, part of the picture has been missing from this research: the people who live in and around the peatlands.

The “Valuing intact tropical peatlands” project was a pilot study on the social, economic, and cultural values of peatlands in the Peruvian Amazon to complement existing scientific research on the carbon content, ecology, and formation of peatlands in the Pastaza-Marañón Foreland Basin, northern Peru. We worked closely with social scientists at the Instituto de Investigaciones de la Amazonia Peruana (IIAP) to conduct qualitative fieldwork in two Amazonian communities (one indigenous and one mestizo), which provided the first insights on people’s relationships with peatlands in the study area. The team conducted 51 interviews with local community members, two community-level participatory mapping workshops, and six site visits to peatlands guided by local people. The project successfully achieved its objective of cataloguing and mapping human activities in, and value of, peatlands in the region for the first time.

For the scientific research to contribute any positive impact to the region, the environment and its people, and in order to fully understand the functioning of these important ecosystems then future work must continue to incorporate people into the picture. Future projects will knit the social science and Quaternary palaeoecological and other scientific methods more closely together, for example, in establishing the extent and nature of peatland palm swamp degradation and engaging peatland communities in knowledge production.

Abstract

Society demands sound science communication schemes, as scientific concepts need to be informed to the general public in the most objective, evidence-based way possible. Communicating science should be indeed a corner-stone of Academia, as long as these publicly funded institutions have a compromise with society making findings available to tax payers.

However we, as researchers, often fail to communicate our findings probably due to several reasons: lacking the proper training as communicators; outreach is often not considered a milestone by science evaluators and, most often, because explaining complex concepts for non-academics is a difficult task. The case of palaeosciences is paramount of the latter, where even basic principles are sometimes difficult to communicate. While palaeosciences are essential to understand current Global Change, transmitting their findings and the scope of its evidences becomes challenging. Palaeosciences operate at multiple spatio-temporal scales, often connecting interpretative principles from current day processes and mechanisms with those of the past.

On a different realm of human cognition, frequently taken far from science, we find art. Art, especially painting and drawing, has the power of reconciling us with our reality, reawakening the essence of the easily forgotten value of our own lives by making ordinary occasions or items enticing. This is even more seductive when different media are used in the artistic process, pulling observers attention in a faster way, besides accomplishing a pedagogic function. Such is the case of body painting, that has rarely been used as a didactic tool but that it offers endless opportunities given the flexible, mobile and versatile nature of the media used.

Intending to communicate to the wider public why palaeosciences are critical to tackle current day problems, we present a dynamic video performance using body painting to explain landscape evolution, proxy production and deposition, patterns and processes at long-term scales and the interpretative principles featuring palaeoscientific knowledge.

Assessing the effects of the Pompeii urbanization on the Sarno river (Campania, Italy) between the Bronze Age and 79 AD

Cristiano Vignola¹, Jacopo Bonetto², Halinka Di Lorenzo³, Guido Furlan², Cristiano Nicosia², Elda Russo Ermolli³, Laura Sadori¹

¹Dept. of Environmental Biology, Sapienza University of Rome, Rome, Italy. ²Dept. of Cultural Heritage: Archaeology and History of Art, Cinema and Music, University of Padova, Padova, Italy. ³Dept. of Earth, Environmental and Resources Science, University of Naples "Federico II", Naples, Italy

Abstract

The Mediterranean basin is one of the key regions for the evaluation of changes of fluvial environments under anthropogenic impacts. During the Holocene, the river response to human forcing resulted into different processes in both sedimentation and vegetation dynamics (Hooke 2006, *Geomorphology* 79, 3–4: 311-335). Especially the Roman colonization affected the fluvial and coastal landscapes through the development of settlements and land use strategies (Pepe et al. 2016, *Journal of Paleolimnology* 56: 173–187).

This study is based on the new multi-disciplinary archive from the Sarno floodplain near the ancient city of Pompeii (Campania, Italy). A set of sediment cores were recovered in 2017 close to the *Terme del Sarno*, one of the main thermal baths at the southern edge of the settlement. This research project, led by the University of Padova in collaboration with Soprintendenza speciale per Pompei, focuses on the geoarchaeological investigation of the settlement evolution and the palaeoenvironmental reconstruction of the Sarno river plain (Furlan et al. submitted, *Journal of Cultural Heritage*). In particular, we present the ongoing results of palynological analyses from sediment levels dated from the Late Bronze/Early Iron Age to the AD 79 eruption of Somma-Vesuvius.

The palaeoenvironmental record is characterised by a succession of organic layers which formed the fluvial deposits of the Sarno river adjacent to the past coastline. The river environment was bordered by the Somma-Vesuvius slopes on the north, the Pompeii volcanic terrace on the east, the coastal dunes on the west and finally the river basin on the south (Vogel, Märker 2010, *Geomorphology* 115: 67-77). The preserved pollen grains refer to a vegetational landscape whose drivers of change through times were the human activities. The wet environment is evidenced by the presence of riparian trees (alder, ash) and aquatic plants that accompany deciduous and evergreen trees such as oaks, hazel and maple. An intensification of arboriculture and agriculture, in parallel with increasing use of fire, is recorded with the Roman urban growth in the last centuries BC. Such a process appears to have caused a consistent deforestation of the surrounding region, with a landscape characterized by fruit trees (walnut, hazel, olive) and herbs such as cereals, legumes and possibly vegetables from the spinach, cabbage and lettuce families. Caution is necessary in interpreting the presence of the latter because many wild and ruderal plants belong to the above-mentioned families. In any case the high number of herbs (among which also ribwort plantain and nettles) confirms strong human activities.

P-1268

A big gap between flora and insufficiently described pollen in China: new worry about old issue on Quaternary pollen identification

Limi Mao

Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China

Abstract

In the past several decades, some pollen atlases of living plants have been published as important references for Quaternary pollen analysis in China. According to newly updated online flora of China (www.foc.org), there are 29,246 species of seed plants from 3,144 genera and 271 families in China. So far, the numbers of described pollen published are only 2,155 species, covering 1340 genera and 192 families (Fig. 1A). Apparently, there's a big gap between such a rich flora and poorly documented or described pollen and spores in available publications up to date, particularly in the case of seed plants from subtropical and tropical areas in China. An example of one important family in north hemisphere Fagaceae shows that some genera, like *Quercus* subgenus *Cyclobalanopsis* and *Lithocarpus*, need more pollen morphological investigations (Fig. 1B).

An old issue on Quaternary pollen identification based on such insufficiently described pollen flora from living plants in China has long been a worry (Fig. 1A). Nevertheless it's too hard to describe pollen morphology for all the species of living plants, moreover, considering some families or genera without diversity in pollen morphology, such as Poaceae, Amaranthaceae, Cyperaceae, ideal pollen atlas at least covering all genera is applicably useful for Quaternary pollen identification, especially for those genera with low diversity of pollen morphology. However, in the case of those genera with high diversity of pollen morphology (e.g., *Euphorbia*, *Polygonum*), it's necessary to describe at least all pollen types within the same genus, therefore, to update pollen atlas either in printed books or online searchable pollen morphological database, is an urgent task in China, so much work should be done before reasonable and helpful pollen atlas are to be updated.

Fig. 1. A showing a big gap between numbers of living seed plants in China and insufficiently described pollen in species, genus and family levels; B showing an example of Fagaceae: numbers of species and genus VS numbers of described pollen, as well as 7 key pollen types in genus level below the diagram.

Notes: Number of seed plants in family, genus and species levels are based on Zhang and Gilbert MG (2015, Comparison of classifications of vascular plants of China. *Taxon*, 64, 17–26) and online FOC (www.foc.org); Numbers of pollen in family, genus and species levels are mainly based on Pollen atlas of China plants (Wang et al., 1995),

Tropical and Subtropical pollen of China (1985), and Pollen morphology of Fagaceae and its biogeography (Wang and Pu, 2004).

P-1269

Using Environmental Archaeological Data from Wetland Sites: From Resource Reconstruction to Nutritional Archaeology

Tony Brown

University of Southampton, Southampton, United Kingdom. Tromsø Museum, Tromsø, Norway

Abstract

As pointed out many years ago by Margaret Davies palaeoecologists are very good at creating large quantities of data but this data is generally under-utilised. Environmental archaeologists and specialists are highly proficient at producing long lists of taxa from excavations, particularly wetland sites where preservation conditions are particularly favourable. This data is then used, generally selectively, in the site narrative(s) and particularly in the case of fauna to provide a picture of the major components of human diet. This generally leaves the vast majority of the data languishing in the Report Appendices and unused, at least in the short term. The rise of environmental databases, from pollen to fish, has partly ameliorated this situation but is still limited by the approaches taken to analyse this data beyond diachronic mapping. This paper presents a conceptual methodology for using this data by coupling faunal and floral lists with nutrient databases with the aim of investigating the nutritional space associated with the archaeological sites. There are many problems with this approach (e.g. taphonomic, a uniformitarian assumptions etc.) but it can provide a heuristic methodology which seeks to examine the reality of our dietary and life-way reconstructions. The example used here is Jomon sites in Japan, a period which is particularly well suited due to the large number of wetland archaeological excavations over the last 20 years around the coasts which have recovered remarkably well preserved remains of fish, animals and plants. These remains have been used to create a nutritional landscape within which these peoples, lived and which produced the famous 'affluent hunter-gatherer' (Jomon) society. The data can also be used to look at food culture over the long-term which is of contemporary interest as one of the overall effects of this dietary and cultural history is that Japanese society has traditionally had one of the globally highest life expectancies as well as a distinctive food-culture.

P-1270

Archival data mining activities in northwestern Canada: serendipitous science and its use in advancing understanding of Quaternary environments

Rod Smith

Geological Survey of Canada, Calgary, Canada

Abstract

Many examples of known and likely yet to be discovered archival datasets held by industry, governments, and regulatory bodies contain invaluable treasure troves (sometimes quagmires) of observational and instrumental data. Recognizing and identifying the potential of these (particularly those collected for unrelated/unintended purposes) is often a first step to constructing databases that enable significant and at times serendipitous advances in understanding diverse aspects of Quaternary environments. This study provides examples of three such projects and discusses their application and issues surrounding data formats, accessibility, interoperability, and uptake by researchers and the public. Momentum created by these kinds of database projects manifests in establishing formal arrangements for future data collection, standardization, and digital integration.

The first dataset discussed is seismic shothole drillers' logs which were dismissed by industry as "junk data" and only fleetingly used by Mackay and Rampton in the early 1970s to investigate buried ice in Tuktoyaktuk Peninsula, Canada, and by the Geological Survey of Canada in 1974-1975 as an aid to hurried surficial geology mapping along a proposed 1400 km pipeline corridor. These logs of shallow (avg. 18.6 m deep) lithostratigraphy were collected by industry as a means of simply understanding what the seismic charge was seated in (pertaining to implications for potential static interferences). Originally discovered by the author as a forgotten archive of 76 000 4"x6" paper file cards with hand-written and typed logs, these led to a 4 year industry-wide archival recovery project, that manifested as the single largest source (n=360,000 records) of baseline, near-surface geoscience information across 0.5 million km² of northwestern Canada. Interpolative databases, and derivative GIS products and models led to more than 12 thematic geoscience reconstructions ranging from geohazard identification, granular aggregate resources, and regional till facies, to offshore marine bottom-fast and winter lake ice thickness and extents, to baselines for assessing vegetative recolonization and habitat alteration.

The second dataset relates to grab samples collected during drilling of seismic shotholes that were then used to provide lithogeochemical information. Approximately 9000 basal and intermediary sediment/bedrock samples were collected over a 4 year period of intense seismic exploration activity through the western Canadian arctic mainland and island archipelago. These samples permitted preliminary lithological, sedimentological, paleontological, and geochemical assessments to be made across a vast, often unexplored area, greatly expanding the understanding and mapping of regional geology.

The final dataset relates to diamond drill hole and petroleum well logs reported in exploration company assessment reports filed with government regulators in Canada's Northwest Territories. These provide unique records of drift and bedrock thicknesses, and are being used to construct drift isopach maps and model till and other glacial deposit facies as an aid to regional mineral exploration activities.

P-1271

The advantages and limitations of old data and collections on the study of a new interglacial

Aaron Rawlinson, Luke Dale, Mark White, David Bridgland
Durham University, Durham, United Kingdom

Abstract

Advances in the Quaternary sciences have had a major impact on the way archaeologists view the hominin occupation of Britain. While modern work is being undertaken, much of Britain's Palaeolithic record was recovered by antiquarians and amateur collectors before the invention of modern techniques. Data from these sites is compiled in the works of Roe (1968) and The English Rivers Project, valuable resources that are often used by Palaeolithic specialists. These have formed the foundations of current work on MIS 9. This work has highlighted the advantages and disadvantages of these large datasets as well as the old collections themselves. It is important to understand the limitations of past data and the need for some re-evaluation due to advances in methodology and in our understanding of Quaternary chronology. Sites previously obscured by a shorter chronology can now be assigned to previously unrecognised interglacials and provide insights not possible from previous work. Re-examination of assemblages from sites and find-spots dated to this period is giving MIS 9 a character of its own, as well as making contributions to the understanding of broader Palaeolithic patterns.

Roe's handaxe groups have recently been re-interpreted as being temporally significant, and the re-use of pre-existing collections is proving vital to fitting MIS 9 into the sequence. The re-evaluation of material referred to as Proto-Levallois/Simple prepared cores/tortoise cores offers the opportunity to examine the changes between the Lower and Middle Palaeolithic and the relationship between Levallois and other types of knapping.

Roe, D. 1968. *A gazetteer of British Lower and Middle Palaeolithic sites*. London, CBA research report 8.

The vegetation history of Greater London

Robert Batchelor¹, Ralph Fyfe², Florin Fletcher¹

¹University of Reading, Reading, United Kingdom. ²University of Plymouth, Plymouth, United Kingdom

Abstract

Over the course of at least the last 50 years, pollen analysis has been carried out on a vast number of sites across Greater London as a consequence of both research and developer-funded investigations. The investigation of each individual site has led to a reconstruction of various time periods since the beginning of the Holocene (~11,700 years ago). In short, Greater London contains a greater density and distribution of Holocene pollen records, than possibly any other major global city in the world. Over the summer of 2018, relevant palynological, stratigraphic and chronological data was systematically extracted and collated from a significant proportion of these palaeoenvironmental records, held at the University of Reading.

The taxonomy of the pollen data was harmonised across all sites, and new age-depth models constructed for all sequences. The majority of sequences included fewer than four radiocarbon dates, and thus linear or smoothing splines models were used to assign a calibrated age to individual samples. Counts were aggregated into continuous 250-year long time bins to facilitate correlation in both space and time. This resulted in count data for 112 taxa in 488 individual binned samples from 59 dated sequences. This is believed to be the densest concentration of pollen count data compiled to date. The majority of samples lie between 7000 - 2000 cal BP, detailing the period of time from the Mesolithic to the late Iron Age and the transition to settled agriculture across Greater London. Initial results show that the most significant transformation of vegetation took place between 3750 - 3250 cal BP, during the early to middle Bronze Age in this region, marked by a dramatic increase in taxa indicative of open ground conditions. This is broadly synchronous with the development of field systems, established from the archaeological record from the wider region. Mapping of key synanthropic taxa is beginning to reveal spatial patterning of land exploitation.

The future aims are: (1) to expand the Greater London database with palaeoenvironmental data from other sources and researchers, (2) use the dataset to explore the extent to which changing environmental conditions (such as topography, tidal influence, cultural activity) resulted in patterning of dryland and wetland taxa across Greater London.

Shilo, Magadan, Russian Federation. ⁵Quaternary Research Center, University of Washington, Seattle, USA. ⁶Newcastle University, Newcastle, United Kingdom. ⁷Department of Geography, University of Oregon, Eugene, USA

Abstract

Siberia and the Russian Far East (SRFE) together comprise a large land area that is considered highly susceptible to current global warming in terms of vegetation and biogeochemical responses. Understanding past responses to other instances of rapid warming, such as the transition from the Younger-Dryas (GS1) stadial to the Holocene, can help identify spatial and temporal patterns in ecosystem responses across this key region. Past changes have probably been manifested unevenly in space and time, given the huge geographic coverage, but this remains uncertain as there are few currently available records for regional reconstructions. This partly reflects the fact that SRFE has few science centres and there are major logistic constraints on field studies; but also the historically parallel development of Soviet and western science and, currently, language barriers and physical isolation mean that much Russian work does not reach the international community.

This year, a new group (DIMA) was formed to cooperate on studying past environmental change in SRFE. We set ourselves several tasks, one of which is data rescue and collation, with a first aim of examining evidence for the Younger Dryas oscillation across the region. Climatology argues for a varied response related to latitude, longitude and ocean proximity, and we will use transient palaeoclimate simulations to develop a working climatological framework. We are reviewing not only internationally published records but also national and institutional publications to assess the quality of information across the region. The main challenges are adequate dating and adequate sample resolution. The poster presents patterns of change developed to date and examines their fit to the palaeoclimatic framework.

* So far, scientists from 12 institutions across SRFE plus scientists from the UK form the DIMA group (Developing Innovative Multiproxy Approaches-for SFRE). The group is funded by several sources and welcomes new group members who are working in the region or who have an interest in working there. More details at <https://research.ncl.ac.uk/dima/> and <https://www.arctic.ac.uk/blog/>

The British Pollen Database (BPOL) - a metadata repository to enhance regional modelling of vegetation composition and data sourcing

Michael Grant

University of Southampton, Southampton, United Kingdom

Abstract

Pollen analysis provides a powerful and extensively utilised tool for understanding past vegetation composition, climate and human activity. This is due to pollen being preserved in a wide range of sedimentary environments and pollen being derived from, and therefore providing a record of, vegetation beyond the sampling location. Large datasets can now be compiled for identifying and exploring the complexities of pollen data temporally and spatially, facilitated by databases such as Neotoma. However such schemes are dependent upon voluntary contribution and may therefore only provide a snapshot of the total body of work undertaken within a given region. In order to bridge the gap between data freely available and potential datasets languishing with researchers, metadata repositories provide an important resource. The British Pollen Database (BPOL) has been developed to capture information on dated pollen sequences from sediment basins within England, Wales, Scotland and the Isle of Man, complimenting the metadata repository for pollen studies in Ireland (IPOL; <http://ipol.ie/index.html>). The database currently contains over 2600 dated sites dated up to 40ka, with full details of chronological data including over 9500 radiocarbon dates. This shows that <6% of dated British pollen sequences are currently available through the European Pollen Database

(EPD).

To illustrate the reanalysed timing of the arrival and expansion of *Fagus sylvatica* (Beech) in lowland Britain is reanalysed utilising 1200 sites, supplemented with archaeological charcoal data. These combined datasets conclusively demonstrate that Beech was present in the British Isles from at least 6ka, compatible with

palaeoclimatic model predictions but significantly earlier than models based upon pollen data held within the EPD. This finding highlights the need for greater access to raw data and the requirement to carefully consider biases inherent in the available data such as specific geologies, site types and spatial distribution.

From our correspondent in Wales: forty years of palynology recorded in the letters of Harold Augustus Hyde

Heather Pardoe¹, Kevin Edwards²

¹Department of Natural Sciences, Amgueddfa Cymru - National Museum Wales, Cardiff, United Kingdom.

²Department of Geography and Environment, University of Aberdeen, Aberdeen, United Kingdom

Abstract

H.A. Hyde was Keeper of Botany at the National Museum of Wales from 1922 until 1962. His life was shaped by his fascination for palynology and his research was published in more than 100 scientific papers. Hyde corresponded with many leading palynologists throughout his long career and archived copies of his correspondence survive in the National Museum Wales. These first-hand accounts indicate major influences on Hyde and hint at turning points in his life.

Throughout the early twentieth-century palynology was evolving as a discipline and the letters provide a record of the early decades in this process. Thus, letters to L.J.D. Richardson and P. Sears show how Hyde and D.A. Williams came to coin the term 'palynology' in 1944. In 1952 the subject of staining was clearly controversial and K. Fægri confided to Hyde that 'The Berne meeting went very well. I cannot boast that I have converted the heathens yet, but I have a feeling that the old deities have lost their grip on the congregation. It was decided that the method (i.e. staining) should have a fair trial'; while J. Iversen wrote later that year 'there can be no doubt that all details of structure in fresh pollen will be much easier to study when the grains have been stained'.

More personal letters reveal something of the contrasting personalities and complex relationships of celebrated palynologists. The candid letters of Faegri provide fascinating details of meetings where leading figures such as G. Erdtman, Iversen and H. Godwin were vying to influence the direction of the discipline.

The privations and practical problems associated with World War II and its aftermath are illustrated. In 1954, when Godwin writes to enquire about a bog site at Craig-y-Cilau, Hyde explains that he has long been deterred from putting a borer into the bog following reports that the bog had been 'peppered all over with hand grenades.'

Over his 40 year career, Hyde exchanged over 200 letters with his long-term friend Sir Harry Godwin. Their letters reveal their shared enthusiasm for palynology and professional achievements and disappointments. For example, in May 1948 Godwin wrote to Hyde 'You have my sympathy in the matter of the directorship, especially so since an exactly similar experience has just been my own in respect of the Cambridge Chair.' In April 1960 Hyde writes 'my heartiest congratulations and sincere good wishes on your election to the Chair of Botany'.

Such examples demonstrate the research potential of archive collections. Their ability to reveal opinions, attitudes and motivations are especially informative when tracing discipline development and the sociology of science.

Radiocarbon dating method – 70 years in service of the Quaternary sciences

Irka Hajdas¹, A. J. Timothy Jull^{2,3,4}, R. E. Taylor^{5,6}

¹Laboratory of Ion Beam Physics ETH, Zurich, Switzerland. ²University of Arizona, Geosciences, Tucson, Arizona, USA.

³Institute for Nuclear Research, Hungarian Academy of Sciences, Debrecen, Hungary. ⁴University of Arizona, AMS Laboratory, Tucson, Arizona, USA. ⁵University of California, Riverside, California, USA. ⁶Keck Carbon Cycle AMS Laboratory, University of California, Irvine, California, USA

Abstract

The first half of the 20th century witnessed dramatic development of nuclear techniques. The discovery of ¹⁴C was a consequence of this and the development following the early work on radioactivity and radioactive isotopes. The history of radiocarbon dating method and its application in Quaternary sciences is a fascinating story 'written' by numerous researchers during the last 70 years. In 1949 Willard Libby and his students published the first radiocarbon ages (curve of known) (Arnold and Libby 1949). Following this development, the first radiocarbon laboratories were created to establish chronologies of natural records and archives. The urge for obtaining absolute time mobilized geologists and their physicist colleagues to establish counting labs that would allow dating peat sections, mammoth bones and similar. In the USA the first labs: USGS Reston, Lamont, Chicago, Pennsylvania, and Arizona. News of the new method quickly reached Europe and the first laboratories were established in Cambridge (UK), Trondheim (Norway), Groningen (Netherlands), Uppsala (Sweden), Bern (Switzerland) and Gdansk (Poland) and others. A lab in New Zealand was also established about the same time. Despite the fact that grams of carbon were needed for a reasonable counting statistics (10 g in the first publication Arnold and Libby 1949) a number of radiocarbon dated samples grew rapidly and chronologies of important geological sites were created. By the end of the first decade lists of radiocarbon ages produced by 13 laboratories was published in the first issue of Radiocarbon Journal v. 1(1) (1959). In the decades that followed radiocarbon dating method was and is constantly developed and improved to become a modern and sophisticated tool that can be applied to the material as young as present day and as old as 50 ka. We will present an overview of this development and talk about the pioneers of the method.

⁴Tokyo Metropolitan University, Tokyo, Japan. ⁵Mongolian Academy of Sciences, Ulaanbaatar, Mongolia. ⁶National University of Mongolia, Ulaanbaatar, Mongolia. ⁷Kanazawa University, Kanazawa, Japan

Abstract

The mechanisms that lead to the appearance of the Initial and Early Upper Paleolithic (IUP-EUP) are of major importance in order to evaluate models of emergence/dispersal of Anatomically Modern Humans (*Homo sapiens*) in Eurasia. An aim of the present study is to understand detailed paleoenvironmental changes in Mongolia, situated at key crossroads for human migration between central, eastern, and northern Asia. Available archaeological evidences have suggested the emergence of IUP at around ca. 45-40 ka (e.g., Zwyns *et al.*, 2014; Rybin *et al.*, 2016; Izuho *et al.*, 2018). However, yet the paleoenvironmental changes of this period in Mongolia is largely unclear, preventing us to understand whether the possible environmental and landscape changes were significant as a major driving force for modern human's lifeway.

In this paper, we present new record of paleoenvironmental changes in southwestern Mongolia during MIS 3. In January 2017, we took two parallel cores (OROG01, 24 m; OROG02, 21 m) from Orog Lake, a shallow saline lake located in northwestern margin of Gobi Desert. The high-resolution major and minor element composition changes were obtained using μ XRF core scanner (Cox, Itrax) at Center for Advanced Marine Core Research, Kochi University. Based on the preliminary results of OSL and 14C age dating, basal age of sediment core OROG01 yielded ca. 38 ± 4 ka, nearly accordant with the basal age of ~ 45 ka reported in the previous study (Yu *et al.*, 2019). On the basis of our high-resolution elemental composition data, in conjunction with previous sedimentological and palynological data (Yu *et al.*, 2019), the paleoenvironments of southwestern Mongolia were more humid with higher lake levels during MIS 3 than Holocene. Our results also suggest periodic and higher amplitude paleoenvironmental changes in this region, which likely correspond to Dansgaard-Oeschger events. This new record would allow us to discuss potential relationship between paleoenvironmental changes and ecosystem changes in Mongolia during the IUP-EUP.

The specific technique of core platform preparation in the Initial Upper Palaeolithic assemblages of Kara-Bomian cultural tradition (Altai Mountains)

Alexander Yu. Fedorchenko, Natalia E. Belousova, Eugeny P. Rybin
Institute of Archaeology and Ethnography SB RAS, Novosibirsk, Russian Federation

Abstract

In this paper, we presented the results of a study of the main techniques of core platform preparation that are common in the Initial Upper Palaeolithic assemblages of Kara-Bomian cultural tradition. Kara-Bomian is the most ancient Upper Paleolithic tradition in the Altai region. The stone assemblages of this tradition have a similar set of cultural attributes, including specific technologies for producing elongated blades, the production of Upper Palaeolithic types of tools and personal ornaments, as well as evidence of the ochre use. The age of the Kara-Bomian IUP tradition complexes is in the chronological range of 47,000–37,000 cal yrs BP.

At present, questions about techniques of core platform preparation within the framework of the Kara-Bomian large blade production technology have been studied relatively poorly. Reliable evidence of the existence of a single set of these techniques in the complexes of this cultural tradition was absent. As part of our study, we studied the collections of core and blades from archaeological sites Kara-Bom (excavation area 4, 1992–1993, cultural horizon UP2), Ust-Karakol-1 (excavation area 1, 1986, habitation level 5.4–5.5) and Kara-Tenesh (lithological layer 3).

The traceological analysis and the study of cores and blades platform morphologies have shown that the technology of large blade production included a combination of several methods of fracture zone preparation. The first technique is represented by the reduction of the platform edge with a direct strike from the stone hammer or smoothing with unspecialized stone tools. The second method involves retouching of the platform edge transverse to the flaking surface, removing the overhang – reverse reduction. The third method of fracture zone preparation is very specific for the Initial Upper Paleolithic of Southern Siberia and Central Asia – the pecking. This technique suggested a point impact by a stone tool for crushing and removing small particles of stone raw material. The relatively even and rough surface created with these techniques provided better grip of the hard hammer stone with the core platform at the moment of impact, which was important for obtaining extremely long and wide blades. Careful preparation of the fracture zone significantly increased the degree of fracture control, allowed to standardize the process of production large blades and reduce the percentage of artisan errors.

The combination of pecking with the other methods of core platform preparation was noted in the context of the blade reduction of the Initial Upper Paleolithic assemblages of the of Southern Siberia and Central Asia. On the territory of the Altai Mountains, this specific technological method is reliably recorded in the context of the earliest archaeological complexes, mainly belonging to the Kara-Bomian cultural tradition.

We are grateful to the RFBR (grant 18-39-00167 and 18-39-20003) for supporting our research.

Kula Unesco Global Geopark: a valuable resource of data for river-valley and landscape evolution

Ahmet Serdar Aytac^{1,2}, Darrel Maddy³, Tuncer Demir^{4,2}, David Bridgland⁵

¹Harran University, Şanlıurfa, Turkey. ²Kula Unesco Global Geopark, Manisa, Turkey. ³Newcastle University, Newcastle, United Kingdom. ⁴Akdeniz University, Antalya, Turkey. ⁵Durham University, Durham, Turkey

Abstract

Kula Geopark. Located on the northern shoulder of the Alesehir graben in the Aegean Region of Turkey, is a tectonocally and volcanically region in which the most recent eruptions of basaltic lava, associated with volcanic cone formation, was in the latest Pleistocene and Holocene. Much older volcanism within the same volcanic province is also in evidence, with some of the older lavas capping mesa-style hills, such that they have preserved underlying poorly consolidated sediments that would otherwise have been lost to erosion. Beneath these hill-capping lava, above Neogene sediments representing endoreheic basin-fill, are early sediments of the River Gediz system, forming narrowly separated terraces (separation by a few metres) thought to have formed in response to the ~40 krs obliquity-driven climate cycles of the Early PLeistocene. The rarity of terrace preservation from this early part of the Quaternary makes this a very valuable aspect of the geopark, all thanks to the unique sitiation in which the unconsolidated fluvatile sediments have been protected by the resistant lavas. There is also evidence of periodic damming of the river system by lava eruptions, bringing about lacustrine phases that can be recognized from lake sediments and deltas that were built into the former lakes. The poster will concentrate on the evidence from the geopark for progressive deepening of the gediz valley, following 'inversion' of the Neogene endoreheic basin system.

Conserving our Quaternary geoheritage in the 21st century: the role of geoscientists and scientific associations in Britain

Eleanor Brown¹, David Bridgland², Neil Glasser³

¹Natural England, Worcester, United Kingdom. ²Durham University, Durham, United Kingdom. ³Aberystwyth University, Aberystwyth, United Kingdom

Abstract

Conservation of our Quaternary geoheritage is vital for both science and society. Scientists need access to well-managed sites for fieldwork (both for research and educating students), whilst society relies on information from Quaternary geoscience to understand how our Earth system works and changes over time. In Great Britain, there is considerable demand for land, housing and infrastructure development, mineral extraction and the provision of high-quality greenspace, all of which have the potential to enhance, threaten, destroy or prevent access to Quaternary sites. Furthermore, attempts to constrain or 'manage' geomorphological processes such as coastal and fluvial erosion can also impact Quaternary sites. Given these threats and potential opportunities to enhance sites in terms of access, study and interpretation, effective and evidence-based Quaternary geoconservation is needed now more than ever.

In Great Britain, nationally and internationally important Quaternary geoheritage is protected through legislation, with the delivery of conservation facilitated by Quaternary experts in government conservation agencies in England, Scotland and Wales. Locally important sites can also be identified and notified to local planning authorities whereby they are taken into account when planning decisions are made. However, ensuring that this protection delivers effective conservation on the ground relies on strong partnerships between conservation practitioners, Quaternary scientists and scientific associations. Quaternary and geological associations and individual Quaternary scientists have made a valuable contribution to successful conservation since the first geoconservation legislation was enacted in 1949.

Here we review the vital contributions that Quaternary geoscientists and scientific associations have made to national and local site selection and audits, the safeguarding of individual sites during development planning, and to the conservation and management of Quaternary sites. We discuss the wider role that scientific associations have had in Quaternary geoconservation, for example in engaging with government consultations, responding to local campaigns, providing evidence when sites undergo legal scrutiny and giving expert feedback to consultations on site management. Future opportunities for supporting conservation of our Quaternary geoheritage, including raising awareness of conservation approaches and principles, encouraging scientific involvement in conservation, providing funding for conservation and outreach, and enabling the sharing of evidence and best practice are also reviewed. Finally, the lessons learned from activities to date are explored and aspirations for the development of Quaternary conservation geoscience in future are set out.

P-1281

Recognising geodiversity and encouraging geoconservation – some lessons from Callander, Loch Lomond and the Trossachs National Park, Scotland.

Eileen Tisdall¹, Angus Miller²

¹University of Stirling, Stirling, United Kingdom. ²Scottish Geodiversity Forum, Edinburgh, United Kingdom

Abstract

Scotland for its size, has an internationally recognised geodiverse landscape. With a geological history of over 3 billion years, geological resources have contributed to the economic wealth of a nation and this geoheritage has also formed the basis for scientific thinking across natural history with Hutton, Lyell and Darwin all inspired by Scottish landscapes.

The importance of this geodiversity has been recognised in the formation of UNESCO Geoparks (North West Highlands Geopark and Shetland Geopark) and National Parks (Loch Lomond and the Trossachs National Park and Cairngorms National Park). Scotland's Geodiversity Charter (Scottish Geodiversity Forum, 2017) was first launched in 2012, coordinated by a group including non-governmental agencies (Scottish Geodiversity Forum, GeoConservation UK) and governmental bodies (Scottish Natural Heritage, British Geological Survey). The Charter encourages the promotion and management of Scotland's geodiversity and provides a framework for stakeholders and agencies to engage in sustainable geoconservation. The document has been kept live with regular updates and case studies and is now supported by 88 signatories, including national organisations, local authorities, community groups and businesses.

Here we present some of the barriers and challenges around the implementation of the Geodiversity Charter with a review of geoconservation issues around the town of Callander, a southern gateway to Loch Lomond and the Trossachs National Park. It has been a tourist destination since Victorian times but within the scientific community is known for its exceptional set of glacial geomorphological features including moraines, eskers, kame terraces and drumlins. These features face pressures, either from sand and gravel extraction or housing development. Over decades, important features have gradually been lost, often without adequate recording. The area presents an important case study about how the academic and geoconservation community can engage with the planning process, and the challenges of communicating with planning authorities and local communities. We consider what official designation of sites means for conservation and what a wider more holistic approach (for example green spaces, biodiversity, education) may bring to more effective local designation status.

The case study highlights that there is a real desire to protect sites that the scientific community view as valuable to science, but that challenges exist to balance demands on these sites. The Geodiversity Charter offers a framework that stakeholders can use to recognise the value of such features and work towards sustainable management and education. Case studies such as Callander provide lessons and solutions to overcome the challenges that arise and highlight the need for the participation of both national and local groups.

Scottish Geodiversity Forum (2017). Scotland's Geodiversity Charter 2018–2023. Edinburgh: Scottish Geodiversity Forum.

P-1282

Wansunt Pit SSSI: the importance of Visual Management Plans in Quaternary geoconservation in England

Lucy Flower¹, Peter Allen², David Bridgland³, Eleanor Brown⁴

¹Royal Holloway University of London, Egham, United Kingdom. ²Essex Field Club, Basildon, United Kingdom.

³Durham University, Durham, United Kingdom. ⁴Natural England, Worcester, United Kingdom

Abstract

Wansunt Pit Site of Special Scientific Interest (SSSI) (unit 1, Geological Conservation Review (GCR) number 846; TQ 515738) is a 1.44ha former gravel pit situated on the border of Greater London and Kent, UK. Notified for its Quaternary of the Thames features, the site provides exposures of Dartford Heath Gravel, overlain by the Wansunt Loam silt deposits for which Acheulian hand axes have been recovered. Historically, the site was better known for its much-debated stratigraphic relationships: whether the Dartford Heath Gravel was stratigraphically equivalent to the nearby Swanscombe sequence, and whether or not they related to the Boyn Hill Terrace. Now largely resolved, the importance of Wansunt Pit now lies with the in-situ Palaeolithic artefacts found within the Wansunt Loam, representing hominin occupation of the site and larger-scale connectivity to hominin activity at Swanscombe.

However, bridging the gap between scientific significance and public awareness (including that of the owners, occupiers and land managers) is key when considering how protected geological sites should be conserved and managed. At Wansunt Pit, a lack of contextualisation and understanding of its geoheritage correlated with overgrowth of vegetation, combined with a lack of communication of geoconservation strategies, meant that condition of the notified geological features, and hence the SSSI as a whole, had become unfavourable. Using Wansunt Pit as a case study, a partnership approach involving land managers, academics and geoconservation specialists was therefore implemented with the aim of returning the site to favourable condition using the creation of a Visual Management Plan (VMP) as a communication and collaborative tool. The VMP is a powerful way of imparting geoheritage information; fostering greater understanding of why conservation is needed, as well as illustrating geoconservation targets that are mutually agreed and achievable.

The Wansunt Pit VMP integrated text, maps and annotated photos in order to i). resolve previous issues with location of exposure localities and ii). pinpoint sections requiring management and iii). explain the importance of the geological and archaeological features. Two key areas were the focus of vegetation clearance: section 6 for the Wansunt Loam, plus a new section identified for the Dartford Heath Gravel, hereby named section 9. Agreed vegetation clearance and cutting techniques for both sections were illustrated in the VMP, along with the rationale for geoconservation. The VMP was well received by the SSSI land managers and the geoconservation work illustrated in the VMP is being planned. The Wansunt Pit VMP demonstrates the efficacy of visual plans for communicating and agreeing the geoconservation requirements of often complex geological SSSIs. As a collaborative effort, VMPs also have great potential for the sharing geoheritage knowledge, geoconservation techniques and best practice guidance, which is integral to transforming scientific discovery in to public knowledge.

P-1283

Capturing advances in Quaternary Science for geoconservation in the UK – an evolving approach spanning 70 years.

John Gordon¹, Vanessa Brazier², James Hansom³, Alan Werritty⁴

¹University of St Andrews, St Andrews, United Kingdom. ²Scottish Natural Heritage, Perth, United Kingdom.

³University of Glasgow, Glasgow, United Kingdom. ⁴University of Dundee, Dundee, United Kingdom

Abstract

In the UK the conservation of Quaternary deposits, landforms and landsystems is founded on the assessment and safeguard of key protected areas principally for their scientific values. The evaluation of site networks for Quaternary deposits and landforms (including glacial, fluvial, coastal, mass movement, karst and cave features) has evolved since the late 1940s in parallel with scientific advances, culminating in the Geological Conservation Review (GCR) site assessments undertaken between 1977 and the early 1990s. Significant scientific progress over the last 25 years has arisen, for example, from re-investigation of existing sites and discoveries of new sites, developments in geochronology and the formulation and application of new concepts and models. Both the GCR site lists and the supporting site documentation now require updating in the light of this progress. While updating the GCR is a valid and worthy approach, it binds conservation to a snap shot approach with the need for repeated scientific review. The inherited approaches from 1977 have some limitations, yet developments in science as well as wider geoconservation globally show other opportunities. Today there is greater emphasis on the wider, non-scientific values of geoconservation including, for example, on ecosystem services, links with biodiversity and cultural heritage, geotourism and the benefits for human health and wellbeing through improved understanding of dynamic landscapes, climate change and natural hazards. Involvement of wider public support beyond the geoscience community and fostering better integration of geoheritage within the developing nature conservation agenda, including protected area planning and management, natural capital and connecting people and nature will help protect our Quaternary geoconservation heritage.

P-1284

Palaeocological approaches to urban conservation: A case study of Sydney, Australia's water reserves

Rebecca Hamilton^{1,2}, Dan Penny³, Josephine Gillespie³

¹The Australian National University, Canberra, Australia. ²State Library of NSW, Sydney, Australia. ³The University of Sydney, Sydney, Australia

Abstract

Sites are often prioritised for conservation based on the premise that they represent remnants of bygone landscapes of natural and/or cultural significance. These approaches are, however, often constructed in the absence of any long-term socio-ecological data, making it challenging to draw parallels between the site being conserved, and the past landscape that it ostensibly mirrors. The marrying of palaeoecological and historical data can provide a wealth of information pertaining to the evolving natural and cultural values assigned to protected areas. This is an invaluable resource for reconstructing past physical environments, linking these changes to evolving social attitudes through time, and using these data to improve conservation management via redefining policy directions, constructing restoration objectives, or targeting new sites for protection.

The Lachlan Nature and the Botany Water Reserves are located within an urbanised zone of southern Sydney, Australia, and are managed as the last remnants of once-extensive swamplands that formed the basis of the city's water supply from 1827 to 1896 C.E. This research presents results of a married palaeoecological and historical reconstruction of these sites, to 1) assess the validity of the contemporary conservation goals applied to the sites; and 2) develop a spatio-temporal framework for future management of the Reserves. This includes assessment of the socio-ecological values that are actually reflected within the protected sites, and investigation of alternative sites that perhaps better mirror the 19th century swamplands.

Our results challenge core assumptions underlying the contemporary management approach applied to these sites, emphasising the key role that long-term socio-environmental perspectives can play in developing pragmatic conservation policy. We argue that a multidisciplinary historical and palaeoecological approach can provide an invaluable resource for evidence-based management of protected sites, and encourage a broader uptake within conservation practice.

P-1285

Quaternary palaeoecology and the historic environment: challenges and potentials

Zoe Hazell¹, Jane Corcoran², Hannah Fluck¹, Jonathan Last¹

¹Historic England, Portsmouth, United Kingdom. ²Historic England, Guildford, United Kingdom

Abstract

The potential contribution of the study of Quaternary palaeoenvironmental deposits to our understanding of the historic environment and archaeology, is considerable; from reconstructing past (changes in) climate and environment in order to understand landscapes previously inhabited, to identifying resources that were available and exploited – providing evidence of past cultures and societies.

Such palaeoecological and archaeological evidence is best preserved in waterlogged deposits, in terrestrial and coastal areas, and can be considered at both a landscape scale (e.g. the Somerset Levels), and at an individual site or feature scale – whether these are naturally formed (e.g. kettle holes, intertidal peat exposures) or constructed by people (e.g. ponds, moats). Work by Historic England aims to highlight the palaeoenvironmental and archaeological potential of such deposits more widely; for example, the report outlining the importance of small wetlands (Farrell and Hazell, 2016) and the on-going ‘*Exceptional waterlogged heritage*’ project (see Heathcote and Campbell, 2013). In addition, Historic England’s (2018) guidance outlines best practice if/when considering clearance of water features within historic environment settings – principles which can also be applied to a range of wet or waterlogged deposits preserved within other feature types, natural or human-made.

Yet often, when site works are undertaken – be it for development, or to achieve historic environment and/or nature conservation objectives (e.g. ‘restoration’ or habitat creation purposes) – the heritage value of these deposits is not considered adequately, and therefore their research potential is rarely fully realised. Possible reasons for this will be explored, starting with the difficulty in affording some of these sites statutory protection within current historic environment designations; perceptions of archaeological science within archaeology more widely, in particular why environmental archaeology is often overlooked or discounted within the discipline; and difficulties in establishing the significance and value to these deposits, especially where the remains are at depth, out of sight and (until discovered) hypothetical. Deposit modelling can provide early warning of organic deposits, but if they are not clearly linked to cultural remains, justification for detailed attention within an archaeological project, especially if development-led, is difficult. Given the lack of specific historic environment designations, protection can default to natural environment designations, which, understandably, have their own drivers and priorities; closer collaboration between agencies could help align methods and approaches.

This paper will outline, from a historic environment perspective, the heritage importance of the remains preserved within waterlogged deposits, whilst using case studies to explore commonalities with other disciplines. By promoting Historic England’s activities and interest in this collectively-recognised resource, it is hoped that the identification of complementary interests (e.g. via natural capital concepts) will help strengthen the understanding, value and subsequent protection of these Quaternary deposits to the benefit of current and future generations.

P-1287

Palaeolithic archaeological potential of Pleistocene deposits in England: a geological mapping approach

Keith Wilkinson¹, Monika Knul¹, Jenni Sherriff¹, Matthew Canti², Hannah Fluck², Jonathan Last²

¹University of Winchester, Winchester, United Kingdom. ²Historic England, Portsmouth, United Kingdom

Abstract

Both Article 5 of the *European Convention on the Protection of the Archaeological Heritage* (Council of Europe 1992) and associated national legislation/guidance [*National Planning Policy Framework* in England (Department for Communities and Local Government 2018)] requires that the potential impact on archaeological heritage must be considered when planners assess development plans. Archaeologists working for planning authorities and in the commercial Cultural Resource Management sector are familiar with the archaeology of and methods for investigating later prehistoric and historic period remains in turn meaning that robust approaches are in place for detecting and investigating Holocene archaeological sites. However, the Palaeolithic is another matter and these same archaeologists are much less confident in assessing where such sites are likely to occur and thereafter determining their importance. The *Palaeolithic archaeological potential of Pleistocene deposits in England: a geological mapping approach* project is a Historic England-funded initiative that will enhance resources available to English planning authorities in their consideration of the Palaeolithic. The Project takes the following as its source material: 1/50,000 British Geological Survey superficial geology maps; relevant national archaeological inventories, i.e. the Southern Rivers Palaeolithic Project, English Rivers Palaeolithic Survey, the Gazetteer of Upper Palaeolithic sites in England and Wales and National Record of the Historic Environment (NRHE); as well as the archive resulting from Aggregates Levy Sustainability Fund-sponsored Palaeolithic research and the published record. Archaeological (e.g. type and quantity of finds) and geological data (e.g. age, mode of formation, diagenesis) are cross-referenced to derive an index of Palaeolithic archaeological potential. The product will be an England-wide online GIS tool for curators comprising Pleistocene superficial geology polygons with appended Palaeolithic archaeological potentials and made freely/easily available to planning authorities via the British Geological Survey's LandFit portal. This poster presents results from the Project's first study area, namely the South-east of England, which show that areas of high Palaeolithic archaeological potential are associated with some river terraces and raised beaches, while areas of low potential coincide with higher river terraces and 'head'.

Council of Europe (1992) *European Convention on the Protection of the Archaeological Heritage* (Revised). <https://rm.coe.int/168007bd25>. (Accessed 8 January 2019).

P-1288

Studying Quaternary sedimentation, palaeontological occurrences and their site conservation through remote sensing and field observations in central Narmada basin, India.

Ravish Lal¹, Tosabanta Padhan¹, Bharti Jhangra¹, Shivam Sahu², Parth R Chauhan¹

¹Indian Institute of Science Education and Research, Mohali, Punjab, India. ²Banaras Hindu University, Varanasi, UP, India

Abstract

Since the 19th century, the Narmada River is well known for discovery of abundant vertebrate fossil localities, wide range of archaeological assemblages and first hominid fossil site in India near Hathnora. The fossil and archaeological remains occur in several sedimentary contexts: boulder conglomerate, sandy-pebbly gravel, cemented sandy gravel, and cross-bedded sand in the later Middle to Late Pleistocene deposits. Preliminary field investigations in the Central Narmada basin mark the presence of 26 individual localities within a stretch of 70 km² of the Narmada in Narsinghpur District. Paleontological analysis revealed that a variety of animals adapted to sub-humid climate of both aquatic and terrestrial landscapes thrived in this area during Pleistocene period. Various taphonomic processes in this region are responsible for the preservation and destruction of the fossil record in the different geological formations, soil type, climatic conditions, rich calcium carbonate presence, encrustation and patination.

It is interesting to note that most of the fossil localities are found at elevation range of 310-350 meter above mean sea level. During field surveys the fossil rich localities were found restricted within the river terraces, wide floodplains, river gravel bed and major occurrences were observed near the confluence of major and minor stream channels along Narmada River for example Devakachar and Umariya, Barmaan are high potential fossil locality for more than 100 years.

Most of the fossil occurs along with Middle Palaeolithic assemblages or in spatial proximity. The landscape all over the Narmada Basin was inhabited by prehistoric populations and a variety of fauna as evidenced the ample lithic and fossil assemblages across the region. There is a definitive pattern of occurrences of the Quaternary vertebrate fossils and archeological assemblages in the landscape which require detailed investigations and mapping to understand the spatial distribution pattern and nature of associated sedimentary environment.

In addition, this uniquely fossil-rich area requires proper protection and long-term preservation as it is heavily impacted by modern anthropogenic factors such as agriculture, sand mining and other activities.

Wistman's Wood: A tale of conservation value and forest dynamics

Claire Jones¹, Richard Bradshaw²

¹Edge Hill University, Ormskirk, United Kingdom. ²University of Liverpool, Liverpool, United Kingdom

Abstract

High conservation value has often been associated with the idea of long forest continuity in western European *Quercus* and *Fagus woodlands*, however this has rarely been tested (Bradshaw *et al.* 2015). The antiquity of bryophyte-rich woodlands in western United Kingdom has been discussed by a number of members of the palaeoecological community including Birks (1993), who presented evidence relating current plant community development as a result of late Holocene human activities. Small forest hollow pollen and charcoal analysis of Wistman's Wood, Cornwall, U.K., is used to demonstrate that the modern vegetation community within this ancient woodland, has in fact been influenced by recent human disturbances. Previous to human disturbance, the woodland had a rich tree flora until the eleventh century when it then experienced heavy grazing and browsing until the late nineteenth century, when *Quercus* woodland developed with its associated high conservation value. The diverse histories of western European woodlands is common and current conservation values being placed on the result of both natural and anthropogenic processes.

Cross-over between heritage- and geo-conservation of the Lower and Middle Palaeolithic: Middle Pleistocene fluvial sites in the south of Britain.

Luke Dale^{1,2}, Mark White¹, Aaron Rawlinson¹, David Bridgland¹

¹Durham University, Durham, United Kingdom. ²The British Museum, London, United Kingdom

Abstract

For archaeological heritage representing the earliest human presence in Britain, there has always been an absence of recognisable structures of the sort required for designation of heritage sites (such as scheduled ancient monuments). Given that there is an overlap with Earth-science interests, this shortcoming has been overcome by the designation of numerous important Lower Palaeolithic localities as geological sites of special scientific interest (SSSIs) and, in one case, a national nature reserve (NNR). The last mentioned is the celebrated Swanscombe locality (north Kent), where the discovery of numerous artefacts with at least three separate industries in superposition is perhaps surpassed in importance by the well-known hominin skull fossil. This 'jewel in the crown' is supported by a large group of SSSIs covering all parts of the Lower and Middle Pleistocene with a concentration of such sites in the Lower and Middle Thames. Issues arise, however, when geological sites lack scientific importance other than sediments which contain rich archaeological material, as the brief of the government agency responsible for Earth-science conservation (Natural England) does not include archaeology. Nonetheless a case can be made for rich artefact assemblages to be considered as trace fossils, and as such to be an integral part of geological science, sometimes of value for the relative dating of sedimentary sequences. This poster will explore case-study examples from ongoing research by the authors.

¹Center for Climate Physics, Institute for Basic Science (IBS), Busan, Korea, Republic of. ²Pusan National University, Busan, Korea, Republic of. ³International Pacific Research Center, University of Hawaii at Manoa, Honolulu, USA.

⁴Earth and Environmental Systems Institute, Pennsylvania State University, Pennsylvania, USA

Abstract

In our study, we present new model simulations with a recently developed three-dimensional coupled climate – ice-sheet model (LOVECLIM – Penn State University ice-sheet model) covering the period from 240 thousand years ago (ka) to 170ka (Marine Isotope Stage, MIS 7 to MIS 6). A series of initial sensitivity experiments reveals the presence of multiple climate – ice-sheet equilibria and run-away effects. To overcome unrealistic ice-sheet growth, we adjust several global parameters (such as climate sensitivity etc.) and enhance the basal sliding coefficient over Hudson bay; which suggest the importance of regional scale adjustments in simulating global responses to orbital variations. More realistic simulations also show the emergence of millennial scale variability. We further test the hypothesis that millennial-scale dynamics play a pivotal role in ice-sheet growth/decay on orbital timescales. Additionally, the effect of inherent instabilities in large ice sheets for rapid deglaciation are explored.

Climatic effect of Antarctic meltwater overwhelmed by concurrent northern hemispheric melt

Ruza Ivanovic¹, Lauren Gregoire¹, Andrew Wickert², Andrea Burke³

¹University of Leeds, Leeds, United Kingdom. ²University of Minnesota, Minneapolis, USA. ³University of St Andrews, St Andrews, United Kingdom

Abstract

Records indicate that 14,500 years ago, sea level rose by 12–22 m in under 340 years. However, the source of the sea level rise remains contentious, partly due to the competing climatic impact of different hemispheric contributions. Antarctic meltwater could indirectly strengthen the Atlantic Meridional Overturning Circulation (AMOC), causing northern warming, whereas Northern Hemisphere ice sheet meltwater has the opposite effect. This story has recently become more intriguing, due to increasing evidence for sea level contributions from both hemispheres. Using a coupled climate model with freshwater forcing, we demonstrate that the climatic influence of southern-sourced meltwater is overridden by northern sources even when the Antarctic flux is double the North American contribution. This is because the Southern Ocean is quickly resalinated by Antarctic Circumpolar water. These results imply that the pattern of surface climate changes caused by ice sheet melting cannot be used to fingerprint the hemispheric source of the meltwater.

¹University of Leeds, Leeds, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom. ³University of Bristol, Bristol, United Kingdom. ⁴University of Stirling, Stirling, United Kingdom

Abstract

Uncertainties in future sea level projections are dominated by our limited understanding of the dynamical processes that control instabilities of marine ice sheets. The last deglaciation of the British–Irish Ice Sheet offers a valuable example to examine these processes. The Minch Ice Stream, which drained a large proportion of ice from the northwest sector of the British–Irish Ice Sheet during the last deglaciation, is constrained with abundant empirical data which can be used to inform, validate, and analyse numerical ice sheet simulations. We use BISICLES, a higher-order ice sheet model, to examine the dynamical processes that controlled the retreat of the Minch Ice Stream. We perform simplified experiments of the retreat of this ice stream under an idealised climate forcing to isolate the effect of marine ice sheet processes, simulating retreat from the continental shelf under constant “warm” surface mass balance and sub-ice-shelf melt (figure 1). The model simulates a slowdown of retreat as the ice stream becomes laterally confined at the mouth of the Minch strait between mainland Scotland and the Isle of Lewis, resulting in a marine setting similar to many large tidewater glaciers in Greenland and Antarctica. At this stage of the simulation, the presence of an ice shelf becomes a more important control on grounded ice volume, providing buttressing to upstream ice. Subsequently, the presence of a reverse slope inside the Minch strait produces an acceleration in retreat, leading to a “collapsed” state, even when the climate returns to the initial “cold” conditions. Our simulations demonstrate the importance of the marine ice sheet instability and ice shelf buttressing during the deglaciation of parts of the British–Irish Ice Sheet. We conclude that geological data could be applied to further constrain these processes in ice sheet models used for projecting the future of contemporary ice sheets.

Figure 1: Simulated retreat of the Minch Ice Stream from the continental shelf edge through an idealised climate forcing.

Glacial-interglacial contourite dynamics on the Irish margin over the last 340,000 years: insights from IODP Site U1318, Northeast Atlantic

Stephen Gallagher¹, Xavier Monteys², Wheeler Andy³, Rory O'Donnell³, Russell Drysdale¹, Glen Stanislaus¹, Adele Westgard¹

¹The University of Melbourne, Parkville, Australia. ²Geological Survey of Ireland, Dublin, Ireland. ³University College Cork, Cork, Ireland

Abstract

IODP (Integrated Ocean Drilling Program) Expedition 307 cored an 95m thick sediment drift at Site U1318B, on the eastern fringe of the Porcupine Seabight (northeast Atlantic). Detailed sedimentological and microfossil analyses reveals a ~340,000 year record of Irish ice sheet advance and retreat and the resultant changes in contourite deposition. A basal late Miocene carbonate unit is overlain unconformably by a series of sediment drift deposits with alternation between active interglacial bottom-currents and lower energy glacial conditions near the ice sheet margin. New foraminiferal assemblage and oxygen isotope data suggest that this region experienced mixed polar water conditions (with abundant *Neogloboquadrina pachyderma* sinistral) for most of the last 400,000 years with occasional periods of subarctic conditions and inflows of warmer Mediterranean Outflow Water (*Globorotalia inflata*, *Neogloboquadrina incompta* and other warmer water species). The region was north of the polar front during Marine Isotope Stages 8, 6 and possible during MIS 4. IRD detritus (250mm) are most common when the region lay south of the polar front. Mean sortable silt data suggest generally high current velocities during warmer phases with the lowest current velocities when the region was north of the polar front.

Abstract

The relationship between the glacial Atlantic Meridional Overturning Circulation (AMOC) and the millennial-scale climate variability is still debated. Here, we overturn the common deep-centric perception of AMOC reconstruction by reporting changes in near-bottom flow speeds and water-mass chemistry from six French Atlantic margin sites (~1,000 to 2,450 m water depth). Grain-size proxies together with C/O and Nd isotopes reveal an intense glacial eastern boundary current (GEBC) in the North Atlantic ~50,000-20,000 years ago, interpreted as a southward shift of the North Atlantic Current system, *i.e.* the upper limb of AMOC, relative to present. GEBC variability suggests that a weaker/stronger thermohaline overturn corresponds to respective Dansgaard Oeschger cooling/warming. Our data also point to an intra-stadial / interstadial AMOC variability concomitant with far-field atmospheric changes but, more importantly, we note the persistence of a relatively vigorous upper limb of AMOC throughout the last glacial. The persistent poleward export of oceanic heat to the Northeast Atlantic impacted the surrounding ice-sheets, inevitably causing climate instabilities. Based on the above, we propose a conceptual model to explain the origin of climate changes in the glacial North Atlantic. In particular, we argue that the stadial and interstadial periods of Bond cycles are sequentially linked and, further, that Heinrich Stadials are events that break the inherent tendency of both the Bond and ~100 ka glacial cycles to drive Earth's climate towards colder and colder conditions. That is, Heinrich Stadials both prevent boundless climate cooling and are able to tilt Earth's climate from the glacial to interglacial state.

Drivers of change in the position of the Atlantic ITCZ

Pepijn Bakker¹, Matthias Prange^{2,3}, Frank Peeters¹

¹Vrije Universiteit Amsterdam, Amsterdam, Netherlands. ²MARUM - Center for Marine Environmental Sciences, Bremen, Germany. ³University of Bremen, Bremen, Germany

Abstract

Precipitation reconstructions from the low-latitude Atlantic indicate meridional shifts in the annual mean position of the Intertropical Convergence Zone (ITCZ). It is well-known that these shifts connect with large-scale patterns of climate change, including changes in continental ice sheets, ice-berg melting in the North Atlantic and changes in the strength of the Atlantic meridional overturning circulation. In general Atlantic ITCZ dynamics have shown high sensitivity to extra-tropical temperature changes in both the Northern and Southern Hemisphere. However, the complexity of reconstructed past precipitation changes doesn't allow us to disentangle cause and effect, or the effectiveness of different mechanisms driving ITCZ shifts. What role do (local) low-latitude insolation changes play in driving Atlantic ITCZ shifts? Are they driven by temperature change in the North Atlantic, changes in the Atlantic meridional overturning circulation, Southern Ocean temperatures? Perhaps Atlantic ITCZ shifts are a response to greenhouse-gas changes or the size of the continental ice sheets and could there be a role for changes in the amount of Agulhas leakage?

We combine new and existing results from various global climate models to describe the response of the Atlantic ITCZ to forcings such as orbitally-driven changes in insolation, freshwater input to the North Atlantic and the Southern Ocean, changes in greenhouse-gas levels, changes in continental ice sheets and test the potential impact of changes in the strength of Agulhas leakage. We discuss low-latitude Atlantic precipitation characteristics that are robust among models, uncertainties and implications for the interpretation of paleoclimate time-series.

The late Quaternary NW Pacific: regional ice-rafted debris sources and distribution, and fluctuations in regional climate and oceanography

Ambrose McCarron¹, Grant Bigg¹, Harriet Brooks¹, Melanie Leng², Jim Marshall³, Mike Rogerson⁴

¹University of Sheffield, Sheffield, United Kingdom. ²Stable Isotope Facility, BGS, Keyworth, United Kingdom.

³University of Liverpool, Liverpool, United Kingdom. ⁴University of Hull, Hull, United Kingdom

Abstract

The NW Pacific contains a largely unexplored late Quaternary iceberg-rafted-debris (IRD) record, but what data that exists points to multiple periods of enhanced iceberg flux from the NE Russian coast and indicates periods of significant change to the terrestrial ice masses of the Kamchatka-Koryak region (St. John and Krissek, 1999; Bigg, 2008; Barr and Clark, 2009). At times, in some places, the IRD concentrations are comparable in magnitude to the much more detailed records of North Atlantic Heinrich Events, however there is little evidence of temporal synchronicity of enhanced iceberg flux between the North Atlantic and the NW Pacific. Additionally, there is little understanding of the localised sources of icebergs in the NW Pacific due to lack of both terrestrial and marine core data.

Through IRD counts in two key NW Pacific cores (ODP 1207A on the Shatsky Rise: 37.79°N, 162.75°E; and DSDP 580 east of the Kurile Islands: 41.37°N, 153.58°E) in addition to previously published records, we address these uncertainties and find that the regional late Quaternary IRD signal does not indeed have a regionwide expression, and instead varies on a sub-regional-scale with no clear synchronicity in IRD peaks between cores. This suggests the existence of more iceberg sources than previously suspected, and a heightened possibility of a significant iceberg source on the Sea of Okhotsk coast.

The IRD record at ODP 1207A is particularly significant because IRD was not previously thought to be present as far south as 37°N in the NW Pacific. The core's age model, comprised of radiocarbon dates, benthic foraminiferal $\delta^{18}\text{O}$, tephrChronology and foraminiferal assemblages, place the periods of enhanced IRD flux in mid-late MIS 3. The planktic foraminiferal assemblages suggest, however, that the subarctic front of the NW Pacific moved southward of ODP 1207A more decisively during the penultimate glacial period (MIS 6), but this oceanographic shift was not accompanied by enhanced IRD. This implies that the southward extent of IRD is not governed by the position of the subarctic front but by changes to ice cover in NE Asia between glacial periods.

Seasonal discrepancies of the ‘Atlantic-Pacific thermal seesaw’ during Heinrich Stadial 1

Xun Gong¹, Lester Lemke-Jene¹, Gregor Knorr¹, Gerrit Lohmann¹, Jianjun Zou², Xuefa Shi²

¹AWI, Bremerhaven, Germany. ²FIO, MNR, Qingdao, China

Abstract

Paleoceanographic evidences have characterized the North Pacific sea surface temperatures (SSTs) by anti-phase changes against the North Atlantic during millennial-scale abrupt climate changes, thus constituting an ‘Atlantic-Pacific thermal seesaw’. During HS-1, a North Atlantic cold interval of the last deglaciation, the North Pacific upper ocean has been suggested for warmer or warming conditions by marine proxies. In contrast, some other paleoceanographic evidences have characterized the high-latitude North Pacific by insignificant change or even lower SSTs during HS-1, indicating an in-phase rather than seesaw change with the cooling over the northern North Atlantic. By decoding the complexity of the North Pacific climate change in HS-1, our modelling work in this study aim to further develop the understanding about the climatic linkage between the North Pacific and North Atlantic and thus the physics of ‘Atlantic-Pacific thermal seesaw’.

We utilized a complex Earth System Model, Max-Planck-Institute Earth System Model (MPI-ESM) and simulate the Last Glacial Maximum and HS-1 climates by applying the freshwater perturbation over the North Atlantic Ice rafted debris Belt. Our results characterized the North Pacific SST anomalies of HS-1 to LGM by a seasonal discrepancy of a summer cooling and winter warming compared to the LGM conditions, controlled by two processes of ‘ocean warming potentials’ and ‘atmospheric cooling effect’. Moreover, these seasonal behaviours resulted in inconsistent temperature change along with the depths in the North Pacific Ocean from the LGM to HS-1. According to our results, the existing heterogeneities of ‘Atlantic-Pacific thermal seesaw’ indicated by marine proxies correlate to their distinct depth and seasonal preferences among various marine proxies.

Abstract

Investigating key European records of the last climate cycle, we have demonstrated a strong correlation between millennial variations of loess accumulation rates in Europe, and the North Atlantic climate oscillations known as Dansgaard-Oeschger (DO) interstadial–stadial cycles that punctuated the last climate cycle. Stadials are cold and dusty glacial conditions; they are even colder when associated with the huge iceberg discharges from the Northern Hemisphere ice sheets known as Heinrich events. DO interstadials are warm phases, with reduced dust concentration in the atmosphere, following abrupt temperature increases in the North Atlantic (by more than 10°C in Greenland in less than 100 years). These interstadials correspond to paleosols found in European loess series, whose type depends on the interstadial duration. Longer interstadials correspond to more mature paleosols. New investigations of European loess records from MIS 6 reveal the occurrence of alternating loess intervals and paleosols, similar to those from the last climatic cycle. The paleosols are correlated with interstadials described in various Northern Hemisphere records. Therefore, referring to the warm events described in the record of the last climate cycle in European loess sequences, the MIS 6 interstadials can confidently be interpreted as DO-like events of the penultimate climate cycle. If this interpretation is correct, DO events and DO cycles are not restricted to the last climate cycle.

In parallel of our field work, our recently published model has shown to replicate the observed characteristics in $\delta^{18}\text{O}$ variations, such as the sawtooth shape of the DO cycles, with abrupt warming and slower cooling to glacial conditions, as well as the time intervals between successive DO events over the past 130,000 years, and also the opposite phasing of the observed climate signal in the Greenland ice cores and in Antarctica: when Greenland warmed, Antarctica cooled and conversely. This model has provided, moreover, a unified framework to explain the major characteristics of millennial climate variability, including both DO cycles and Heinrich events during the glacial intervals of the last climatic cycle.

Our results herein clearly indicate that these millennial oscillations appear to be solely due to mechanisms intrinsic to the climate system, and imply that their understanding requires further investigations that need to encompass at least the last two climate cycle.

First direct dates for northwest Laurentide ice-sheet deglaciation during the Younger Dryas from cosmogenic surface exposure ages of glacial erratics

Alberto Reyes¹, Anders Carlson², Jesse Reimink³, Marc Caffee⁴

¹University of Alberta, Edmonton, Canada. ²Oregon State University, Corvallis, USA. ³Carnegie Institute of Washington, Washington DC, USA. ⁴Purdue University, West Lafayette, USA

Abstract

The timing of northwest Laurentide ice-sheet deglaciation is important for understanding how ice-sheet retreat, and associated meltwater discharge, may have been involved in abrupt climate change and rapid sea-level rise at the end of the last glaciation. However, the deglacial chronology across the western Canadian Shield is poorly understood, with only a handful of minimum-limiting ¹⁴C dates constraining the timing and pattern of northwest Laurentide ice-sheet retreat across >1000 km of ice-sheet retreat to the marine limit west of Hudson Bay. We use cosmogenic ¹⁰Be surface exposure dating of glacial erratics at two sites, within a ~160,000 km² region with no reliable temporal constraints on ice-margin retreat, to directly date the timing of northwest Laurentide ice-sheet deglaciation. Five erratics sampled near the Acasta Gneiss "Discovery Site" have exposure ages between 12.8±0.6 and 12.2±0.6 thousand years ago (ka; ±1sigma), with an inverse weighted mean of 12.4±0.6 ka (including production rate uncertainty). Five erratics were also sampled 115 km to the east at Point Lake; four exposure ages are currently in-process, but one erratic from this site yielded an exposure age of 11.6±0.5 ka. When corrected for decreased atmospheric depth due to isostatic uplift since deglaciation, the data indicate that the Laurentide ice sheet retreated through this part of the western Canadian Shield ~13.3-12.1 ka, or >1 kyr earlier than inferred from the canonical compilation of minimum-limiting ¹⁴C dates for deglaciation and paleo-glaciological models. We tentatively infer preliminary ice-margin retreat rates of ~0.1 m kyr⁻¹ over this interval spanning much of the Younger Dryas which, compared to earlier estimates, implies a substantially lower volume of meltwater flux from the retreating northwest Laurentide ice sheet at this time. Additional exposure ages on glacial erratics across this data-poor region are needed for validation of existing deglacial ice-sheet models, which can in turn contribute to comprehensive testing of hypotheses related to northwest Laurentide ice-sheet retreat rate, abrupt deglacial sea-level rise, and potential forcing of associated climate change events.

P-1411

Key roles of sea ice–surface wind feedback in maintaining contrasting modes of glacial Atlantic meridional overturning circulation and climate

Sam Sherriff-Tadano, Ayako Abe-Ouchi

Atmosphere and Ocean Research Institute, the University of Tokyo, Kashiwa, Japan

Abstract

During the glacial periods, the climate and the Atlantic meridional overturning circulation (AMOC) varied between two contrasting modes. Previous studies focused on the role of sea ice in maintaining contrasting modes of the AMOC through its insulating effect of the oceanic heat flux and the buoyancy flux; however, the effect of feedback from the atmosphere remained unclear. Here, by conducting partially coupled experiments with a comprehensive atmosphere–ocean coupled general circulation model, we show that sea ice–surface wind interactions over the North Atlantic play a key role in maintaining the AMOC. Experiments show that sea ice reduces surface winds through suppressing oceanic heat flux, and the wind anomaly drastically reduces the AMOC through weakening the wind-driven ocean salt transport. Together with the sea ice–buoyancy flux and sea ice–surface wind feedback, changes in sea ice and oceanic heat flux maintain the contrasting modes of AMOC.

The Last Deglaciation Meltwater Paradox

Paul Valdes¹, Ruza Ivanovic², Lauren Gregoire², Andy Wickert³

¹University of Bristol, Bristol, United Kingdom. ²University of Leeds, Leeds, United Kingdom. ³University of Minnesota, Minnesota, USA

Abstract

In recent years, the ability of computer models to perform fully transient simulations of the Last Deglaciation (21 – 9 ka BP) has advanced greatly and is now the focus of a PMIP4 working group. Several modelling groups have run, or in the process of running, such simulations. The first GCM based simulation of this period was the TRACE 21k simulation (Liu et al., 2009) which has been hugely successful. The model was able to successfully reproduce some of the major climate change events during this period, particularly the Bolling-Allerod rapid warming event. The mechanism for this warming was the recovery (and overshoot) of the Atlantic meridional overturning circulation (AMOC) due to a sudden termination of freshwater discharge to the North Atlantic. However, the melt water discharge scenario was not based on glaciological reconstructions of the ice sheets and was at the upper end of sea level reconstructions. The PMIP4 deglaciation protocol recommends an alternative meltwater discharge scenario which is consistent with the glaciological reconstructions and is markedly different to TRACE21k.

We will show results contrasting the climate response to these two different meltwater discharge scenarios, using the HadCM3 climate model. The PMIP4 meltwater discharge produces a small weakening of the AMOC after Heinrich 1 and a large weakening at meltwater pulse 1A. This results in a climate response over Greenland which is inconsistent with the ice core record. However, if we use the TRACE21k meltwater scenario, then we successfully simulate the Bolling-Allerod warming, confirming the original result of Liu et al (2009) but using a different climate model.

This leads to the paradox. If we use the large meltwater forcing of TRACE21k (which is not consistent with glaciological reconstructions), then we successfully simulate the climate change over Greenland during the Deglaciation. However, if we use a more glaciologically realistic meltwater history, then the climate response does not accord with the data. Ideas to resolve this paradox will be discussed.

Liu, Z. et al. (2009) Science, 325, p310-214. [10.1126/science.1171041](https://doi.org/10.1126/science.1171041)

Cryogenic structures and desiccation cracks in the southwest of the West Siberian lowland

SERGEI LARIN¹, STANISLAV LAUKHIN², NATALIA LARINA³, VERONIKA ALEKSEEVA⁴, FEDOR MAKSIMOV⁵

¹Cryosphere Earth Institute SD RAS, Tyumen, Russian Federation. ²Russia State geological prospecting University, Moscow, Russian Federation. ³Tyumen State University, Tyumen, Russian Federation. ⁴Lomonosov Moscow State University, Moscow, Russian Federation. ⁵St. Petersburg State University, St. Petersburg, Russian Federation

Abstract

The wide spread of vein structures in the Siberian Pleistocene geological sections (not only in the northern parts of the region) was already known in the first half of XX century. Two alternative opinions regarding their origin were formed in the middle of XX. According to the first suggestion (Fedorovich, 1962) all these structures, up to 38° N in China, are ice veins pseudomorphs. According to second one – they are (at least, in Irtysh-Ishim interfluves) related exclusively to the desiccation fissures (Volkov et al., 1969). In particular, disseminated single (rarely - coupled) pseudomorphs on ice and/or ice-ground veins of Sartan Cryochron are presently proven to be widespread in southwest of the Western Siberia, to the South of 57°N, as well as in the Northern Kazakhstan (Aubekero, 1992; Larin et al., 2016). In recent years we have made an attempt to distinguish wedge structures of cryogenic and “arid” origins for certain geological sections in the southwest of the Western Siberia with a help of determination of the cryogenic contrast coefficient (CCC) suggested in (Konishev & Rogov, 1994). So it has been found out that the 11a vein near Uporovo settlement has CCC=1.03-1.99 at its basement, i.e. this vein was originally developed as cryogenic one. Meanwhile it evolved in its middle part without cogenesis (CCC=0.75-0.14) and only in its upper segment CCC increases up to 1.35, that is probably caused by the seasonal permafrost influence. Near Kamenka settlement CCC of the vein filling is decreased from the bottom to the top from 1.58 to 0.57 etc. The study of the surface morphology of quartz grains from sediments of ground vein near Uporovo with scanning electron microscope (with the increase from 300-400 to 1500-2000 times) shows the predominance of particles aeolian sedimentation environment (up to 92%) with cryogenic textures (up to 60-84%). The proportion of alluvial grains (up to 12-16%) and particles with traces of water transfer on average does not exceed 4-8%, sometimes - 20%. Low values of the Chemical Index of Alteration (CIA= 51-60) (H.W. Nesbitt, G.M. Young, 1982), Chemical Index of Weathering (CIW = 55-66) (Fedo et al., 1995), elevated values (greater than 1) the Index of Compositional Variation (ICV = 1.09-1.36) (Cox et al., 1995), a sign of weak change sediments groundwater lived in cold arid climate. Relative Sr/Ba = 0.23-0.47 (Retallac, 2001, 2003) also reconstructed cold but relatively humid landscape and climatic conditions. The values of the coefficients TiO₂/Al₂O₃ and Zr/TiO₂ (Bettina Schilman et al., 2001) show a fairly homogeneous substrate formed one maternal breed without the addition of any foreign material. This base of the data indicates that relict thread structures in under cover sediments were formed in a changing periglacial conditions.

Abstract

N.V.Kind (1974) has found in the Yenisei lower reaches the moraines of all four stages of Sartan glaciation. Then the authors of (Astakhov et al., 2016) have shown, that all the moraines, which were earlier attributed as Sartan glaciations structures, are pre-Sartan ones; with Sartan moraines being found to lie at the Kara sea bottom. In the light of these data, the assignment of the marks of eight glaciation stages in the Aksor Lake area (Zykyn et al., 2003) may seem to be strange. Actually, the Aksor Lake is located already in the mountains, between offsets of the Ulbin and Kalbin ranges, and the geological section studied in (Zykyn et al., 2003) reflects the eight stages of the latest mountain glaciation of the Altay-Sayan mountain area. Meanwhile, marks of the land ice-sheet glaciation ought to be expected in the central parts of the plain. However, no marks of the stages of this glaciation have been found in Sartan time layers in Ob river areas of Surgut region (Arkhipov et al., 1980; Laukhin et al., 2006 et al.). So, heavy loams, unlaminated and marked by palynological spectra of hygrophilous tundra vegetation (in the bottom of the sequence) but laminated and marked by the spectra of "arid" tundra plants, overlay paleosoils dated by ~27 Ka in the section of Kirias (Laukhin et al., 2006). Only southerly, in the lower reaches of Irtysh river between Semeika and Gornaya Subbota settlements, the author of (Arkhipov et al., 1980) has suggested the existence of Vertikoss Interstadial (~15 Ka.) marks. While the marks of Sartan Cryochron can be observed in the Kotachygy section, between Ishim and Irtysh rivers (Sychevskaya et al., 2015). In this section the paleosoil aged ~25 Ka is intensively crumpled by solifluction - the 1st, maximal, glaciation stage deposits - and overlaid by coastal lake sands inreached by abundant Malacofauna, which is characteristic for a climate similar to modern one. Sands are overlaid by loams with the texture transient from coarse-schliere type to the lattice one – it is the 2nd glaciation stage. All the sand-loam sequence is intruded by single epigenetic pseudomorphs along the ice-soil veins of 1.5-1.8m vertical scale – it is the 3rd stage of the glaciation. Intercalated 3.5m thick sequence of Holocene (?) loams lies above.

Role of ice sheet dynamics in the collapse of the early-Holocene Laurentide Ice Sheet

Ilkka Matero¹, [Lauren Gregoire](#)², Ruza Ivanovic²

¹Alfred Wegener Institute - AWI, Bremerhaven, Germany. ²University of Leeds, Leeds, United Kingdom

Abstract

The last stage of the deglaciation of the Laurentide Ice Sheet (LIS) (~9000 to 7000 years ago) provides an analogy and insight to the possible responses of contemporary ice sheets in a warming climate. What makes LIS particularly interesting is that meltwater from the collapse of an ice saddle over Hudson Bay was recently shown to be the most likely driver of the 8.2 ka event, an abrupt northern hemisphere cooling of several degrees. The evolution of the LIS during this period was likely influenced by its interaction with marginal lakes and the ocean, and its major ice stream, which exported ice towards Hudson Strait. Accurately simulating the early Holocene LIS evolution thus requires a latest generation ice sheet model such as BISICLES, which is capable of accurately and efficiently resolving ice stream dynamics and marine margin retreat (so-called grounding line migration) thanks to the combined use of higher order physics and adaptive refinement of the resolution.

We drive the BISICLES model using a positive degree day mass balance scheme with monthly precipitation and temperature from the HadCM3 climate model under climatic conditions from 10,000 to 8,000 years ago. We evaluate plausible rates of ice sheet retreat and associated sea level rise caused by the Hudson saddle collapse and the sensitivity of this to uncertain initial conditions, and model parameters. We find that dynamical processes are important for accurately simulating the pattern of ice retreat. Rates of meltwater discharge during the Hudson saddle collapse depend on basal sliding and surface mass balance parameters.

Time and impact of NE Pacific Late Pleistocene ice sheet related floods

Cristina Lopes^{1,2}, Alan Mix³

¹CCMAR, Faro, Portugal. ²IPMA, Lisboa, Portugal. ³CEOAS, Corvallis, USA

Abstract

Extreme freshwater inputs, such as megafloods, are known to have caused ocean circulation impacts. These floods normally are triggered by a collapse of glacial lakes due to warming (glacial/deglacial change). Such impacts, like the ones caused by floods originated from Lake Agassiz are related to climate changes as they affected the North Atlantic circulation. The timing and impact of such changes in the North Atlantic have been fairly studied. Similar floods happened in the North America and entered the North Pacific. However, even though these are less known, the impact of such amounts of freshwater into the Pacific must have caused regional effects in the NE Pacific environment. The first results from two cores off North California margin (600 km south of the Columbia River) show that during these floods, not only the salinity could have been decreased by as much as four salinity units, but also the known coastal upwelling system was suppressed as a consequence.

Here we present a reassessment of the magnitude and timing of North Pacific megafloods during the past 30,000 cal yr B. P., particularly after the Last Glacial Maximum. We studied the presence (relative percentage and assemblages) of freshwater diatoms in four cores located off Oregon and California. The source of these floods has been related to Glacial Lake Missoula (19,000 -17,000 cal yr B. P.). However, some of the freshwater diatom's peaks predate the existence of glacial Lake Missoula, implying some possible contribution from subglacial freshwater sources located in British Columbia.

Finally, we will present a comparison of the timing and magnitude between the floods known to affect the North Atlantic with the ones we identified in the North Pacific.

Abstract

Understanding the dynamics behind past abrupt climate changes, such as Dansgaard-Oeschger (DO) events, and thereby, more generally the mechanisms of the climate system, increasingly depends on the combination of disparate climate archives. However, comparing palaeo records requires compatible age models, which is often hampered due to the environmental-specific uncertainties (e.g. marine reservoir ages, etc.). Hence, an independent method to synchronize these records is needed to identify the leads and lags within the climate system.

Cryptotephrochronology offers such a key correlation, synchronization and dating tool as instantaneously deposited and geochemically unique tephra horizons can act as isochrons linking marine and ice core records (Davies, 2015).

Here, we investigate the potential existence of marine cryptotephra horizons common to those previously identified in the Greenland ice cores which specifically constrain rapid climate events (Bourne et al., 2015) aiming to synchronize a marine and ice core palaeo record. In particular, marine sediment core MD99-2284 from the southern Norwegian Sea has been explored for cryptotephra layers between ca. 32 – 40 ka b2k. Cryptotephra concentrations were counted using light microscopy and distinctly separate volcanic horizons were analysed using electron-probe microanalysis for determination of major element concentrations. Subsequently, the geochemical composition of each volcanic horizon was compared to that of the Greenland ice core horizons in order to establish tie-points that can link the different climate archives.

Our results argue for the existence of six horizons spanning a time interval of four DO events (DO 5-8). Five marine tephra horizons geochemically correspond, both graphically and statistically, to the previously observed tephra horizons within the NGRIP and NEEM ice cores. These findings allow for a refined age model elucidating the sequence of events. In particular, our results provide independent tephra-based evidence of a synchronous oceanic and atmospheric temperature rise during the stadial-interstadial transitions characterizing the last glacial period.

Variability of Asian summer monsoon during the MIS 7-9 inferred from a high-resolution speleothem $\delta^{18}\text{O}$ record

Xing Cheng^{1,2}, Yanjun Cai^{1,3}, Gang Xue^{1,2}, Le Ma¹, Hai Cheng^{3,4}, R. Lawrence Edwards⁴, Xianglei Li⁴

¹State Key Lab of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²University of Chinese Academy of Sciences, Beijing, China. ³Institute of Global Environmental Change, Xi'an Jiaotong University, Xi'an, China. ⁴Department of Earth Sciences, University of Minnesota, Minneapolis, USA

Abstract

The variability of Asian summer monsoon has been characterized by various geological archives, especially, the well-dated speleothem $\delta^{18}\text{O}$ records have unveiled the orbital to millennial scales Asian summer monsoon variations over the past 640,000 years. However, there is only one stalagmite from Sanbao cave with much lower resolution has been reported during the MIS 7-9, i.e. 190-337ka BP, hindering the in-depth study of Asian summer monsoon and the related mechanisms. Here, we present a high-resolution (average 77 years) speleothem $\delta^{18}\text{O}$ record from Didonghe Cave, Shaanxi Province, China, spanning the period from 190 to 337 ka BP. This record was based on two stalagmites DDH-B6 and DDH-B9 which were collected from a deep chamber inside the cave. The values of speleothem calcite $\delta^{18}\text{O}$ range from -12‰ to -3‰, slightly larger than that of the $\delta^{18}\text{O}$ record from Sanbao Cave. The replication of $\delta^{18}\text{O}$ profiles of these two stalagmites during the overlapped time period from 284-298ka indicates that the speleothem calcite was formed under the isotope equilibrium condition. We then interpret the calcite $\delta^{18}\text{O}$ as indicating the isotope composition of the drip water, i.e., the amount-weighted precipitation $\delta^{18}\text{O}$, considering the large changes of 9‰ in calcite $\delta^{18}\text{O}$ values.

On orbital scale, the precession period is prominent in both Didonghe and Sanbao records, and their general trends are consistent with the northern hemisphere summer insolation, further supporting the hypothesis that the Asian summer monsoons is driven by changes in Northern Hemisphere summer insolation. In addition to the general similarity aforementioned, our high-resolution record similarity aforementioned, our high-resolution record also discloses more characteristics than those observed in the $\delta^{18}\text{O}$ record from Sanbao Cave. For example, around the time period from 215-230ka, the peak summer insolation in the northern hemisphere during the past 600,000 years, a prominent weak monsoon event occurred, likely corresponded to a forceful ice-raft event in the north Atlantic. Also, the Termination IIIa exhibits a two-stage decreasing structure in our Didonghe $\delta^{18}\text{O}$ record, a pattern different from that shown in the speleothem $\delta^{18}\text{O}$ record from Sanbao, but similar to the changes in atmosphere methane recorded in Antarctic ice. We then discuss the potential factors and processes contributing to these dissimilarities in detail.

Insights into the Last Deglaciation using a Coupled Climate/Ice Sheet Model: the LGM, Bølling-Allerød, and Younger Dryas

Paul Gierz, Gregor Knorr, Gerrit Lohmann

Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Abstract

Climate changes accompanying ice age deglaciations represent the largest temperature and sea level changes seen during the last 800,000 years. These deglacial periods represent excellent test cases for models, which can then be used to attain a solid grasp on the mechanisms of cryosphere/climate interactions that may occur in the future. In the current study, we examine several key periods during the last deglaciation — the Last Glacial Maximum, the Bølling-Allerød, and the Younger Dryas — using a fully coupled, high resolution atmosphere/ocean/ice-sheet/ice-shelf model. We explore the phase space and test the sensitivity of the system with respect to key ice sheet parameters controlling the subglacial boundary conditions and ice-shelf/ocean interactions, as well as the classic orbital and greenhouse gas parameters influencing incoming solar radiation. For the first time in such a coupled framework, we are able to demonstrate the influence of ice sheet melting events on the climate system without the need for idealized freshwater perturbation experiments and disentangle cause/effect relationships between Laurentide ice sheet mass loss and Atlantic Meridional Overturning.

Sensitivity analysis of modelled Antarctic ice sheet dynamics during MIS 11 climate warming

Jorge Bernales¹, Martim Mas e Braga^{2,3}, Irina Rogozhina^{4,1}, Arjen P. Stroeven^{2,3}, Matthias Prange¹

¹MARUM – Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany. ²Geomorphology and Glaciology, Department of Physical Geography, Stockholm University, Stockholm, Sweden. ³Bolin Centre for Climate Research Stockholm University, Stockholm, Sweden. ⁴Department of Geography, Norwegian University of Science and Technology, Trondheim, Norway

Abstract

Marine Isotope Stage 11 (MIS 11; ~424-374 ka) is a long interglacial period that serves as a potential analogue to investigate the current interglacial, including projected variations in climate conditions. Although CO₂ levels and insolation were comparable to pre-industrial values, current estimates indicate that global mean temperatures might have been ~1 K warmer and sea level 6-13 m higher than today. Such sea level rise would require significant contributions from the Greenland and Antarctic ice sheets. While the evolution of the former during the MIS 11 has been relatively well documented, the history of the latter and its contribution to sea level remain highly unconstrained.

Using a version of the 3D thermomechanical Antarctic ice sheet-ice shelf model SICOPOLIS optimised for paleo-simulations and driven by MIS 11 atmospheric and oceanic conditions from the Community Climate System Model version 3, we perform an extensive sensitivity analysis of the dynamics of the Antarctic ice sheet during this super interglacial. Our analysis explores the complex interactions between uncertainties in the configuration of the ice sheet, external forcing, and other boundary conditions. Our simulations assess the individual impacts of a wide range of initial conditions and unconstrained processes, such as the choices of initial size-, coverage-, and internal thermal memory of the ice sheet, the interaction between the ice shelves and a warming ocean, perturbations to the climate forcing, the influence of post-glacial rebound, and uncertainties in the geothermal heat flux, bedrock topography, and basal friction. Based on this ensemble of simulations, we will provide a range for the potential Antarctic sea level contribution towards and at the peak of the MIS 11, while investigating the dynamics of the ice sheet under possible analogue conditions to those projected for the future.

P-1421

An astronomical mechanism for rapid climate change: a lunar role

Alison Kelsey¹, Peter Kershaw²

¹The University of Queensland, St. Lucia, Australia. ²Monash University, Melbourne, Australia

Abstract

The lack of a known mechanism and a poor understanding of abrupt climate change in the 1-3 ky range has triggered debates over potential causes. Various explanations have been offered to explain this quasi-periodicity, including changes in the thermohaline current, millennial-scale ENSO variability and intensity, lunar forcing, a combination of unknown factors with solar forcing, and stochastic processes internal to Earth's climate system. Dansgaard-Oeschger variations in atmospheric temperature were found in the oxygen-isotope record of Greenland ice-cores and occur at times of rapid warming between stadial and interstadial. Bond ice-rafted debris events occur in the North Atlantic and accompany Dansgaard-Oeschger events during the glacial, continuing into the Holocene. Both cycles are influential in the 1-3-ky range. The thermohaline current and ENSO were both criticised as candidates for this role. The deep-water formation/thermohaline scenario was seen as lacking a mechanism for rapid dispersal over the planet as the oceanic circulation system is sluggish. The tropical scenario was seen as lacking a locking mechanism and the ability for it to be locked in the first place. However, the global nature of the signal suggests external forcing.

Here I present statistically-significant results between independent total solar irradiance (TSI) reconstructions based on Antarctic ¹⁰Be data during the late Holocene and the modelled superposition the ~209-yr Suess de Vries cycle, a 133-yr cycle found in 5.5 ky of astronomical data during the Holocene, and extremes of sunspot maxima and minima. This 133-yr cycle is found in Earth-Sun and Earth-Moon distances and solar declination, based on the 19-yr cyclical interaction of the New Moon with perihelion, the closest point in Earth's orbit to the Sun. The Suess de Vries cycle is present throughout the extent of the ¹⁴C record and is an inferred solar cycle, even though the longest known solar cycle is the ~11-yr cycle of variability in solar luminosity. The ~209-yr periodicity is also found in lunar declination data. This cyclical interaction between these two factors results in a ~1470-yr cycle, which can be seen as a high-frequency expression of the Milankovitch precessional cycle. The ~21±2 ky Milankovitch precessional cycle is produced by the forward movement of the perihelion (apsidal precession) and the retrograde movement of the spring equinox through the tropical year (equinoctial precession). Equinoctial precession is produced by solar and lunar gravitational forces acting on the Earth's tidal bulge. From these results, it can be inferred that lunar gravitation modulates the cosmogenic nuclide in addition to the influence of solar variability and solar wind on cosmic rays. Together, the Sun and Moon, shape Earth's climatic record through tidally-forced climate signals of Earth's ocean and atmosphere.

Long-term east-west asymmetry in the influence of monsoon moisture over the Himalayas inferred from earlywood and latewood $\delta^{18}\text{O}$ records

Wenling An^{1,2}, Chenxi Xu^{1,2}, Xiaohong Liu³, Ning Tan¹, Masaki Sano^{4,5}, Mingqi Li⁶, Xuemei Shao^{6,7}, Takeshi Nakatsuka⁴, Zhengtang Guo^{1,2,7}

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China. ³School of Geography and Tourism, Shaanxi Normal University, Xi'an, China. ⁴Research Institute for Humanity and Nature, Motoyama, Kamigamo, Kitaku, , Kyoto, Japan. ⁵Faculty of Human Sciences, Waseda University, Tokyo, Japan. ⁶Institute of Geographic Sciences and Natural Resources, Chinese Academy of Sciences, Beijing, China. ⁷University of Chinese Academy of Sciences, Beijing, China

Abstract

In present study, we examined the relationships between earlywood and latewood $\delta^{18}\text{O}$ chronologies from two sites located in the east (YD) and west (JL) of Mt. Qomolangma (Everest) along the Himalaya. Climate response analysis reveals that earlywood and latewood $\delta^{18}\text{O}$ from both sites are influenced by precipitation in the early and late season of India summer monsoon (ISM), respectively. Generally, correlations between latewood $\delta^{18}\text{O}$ series remained positive and significant, however, remarkable discrepancy in earlywood $\delta^{18}\text{O}$ variations is detected in most of the investigation period. Combined with moisture transport models and published tree ring $\delta^{18}\text{O}$ series along the Himalayas, we found the east part of Himalaya is specifically influenced by ISM precipitation in May to October, while the influence of ISM on west part of Himalaya is from June to September. During the early season of ISM, the high ridges of Mt. Everest blocks most of the moisture from Bay of Bengal which results in the difference of earlywood $\delta^{18}\text{O}$ series. Furthermore, the running correlation analyses suggest that the influence of El Niño-Southern Oscillation (ENSO) on earlywood $\delta^{18}\text{O}$ is weak and not consistent. However, the response of latewood $\delta^{18}\text{O}$ to ENSO is relatively stable and significant over the time. This distinct response of Himalaya earlywood and latewood $\delta^{18}\text{O}$ to ENSO is consistent with the hypothesis that local Hadley cell circulation has affected the precipitation during the early season of ISM, and thus the earlywood $\delta^{18}\text{O}$; but the larger-scale ENSO, such as eastward or westward shifts in the Walker circulation, could be more responsible for teleconnections observed during the late season of ISM, and thus the latewood $\delta^{18}\text{O}$. Our finding suggests that the separation of earlywood and latewood may be important for the isotopic dendroclimatology study in this region.

Is Serbian loess represents a history of Košava wind?

Slobodan Marković¹, Zhentang Guo^{2,3,4}, Qingzhen Hao^{2,3}, Milivoj Gavrilov¹, Yang Song², Nemanja Tomić⁵

¹University of Novi Sad, Novi Sad, Serbia. ²Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ³University of Chinese Academy of Sciences, Beijing, China. ⁴Center for Excellence in Tibetan Earth Sciences, Chinese Academy of Sciences, Beijing, China. ⁵University of Novi Sads, Novi Sad, Serbia

Abstract

Loess covers huge parts of the continents, especially in the middle latitudes of the Northern Hemisphere. However, except in the case of the Chinese Loess Plateau, which is linked with the East Asian Monsoon, we do not know the potential relationship between loess formation and responsible air circulation type(s) in any other region. Current analyses of recent meteorological data, morphology of aeolian landforms and explicit numerical simulations that modelled prevailing winds from the second quadrant during the Last Glacial Maximum indicate the predomination of air circulation associated with the so-called Košava wind. Košava is a strong wind that blows from the southeast quadrant over Serbia, Bulgaria and Romania. The Siberian high and West-Mediterranean cyclones, together with the orography of the eastern Balkans, are the main drivers of the Košava wind. Generally, Košava blows during the whole year in several periods of a few days. In winter, this wind can cause temperatures to drop to even around -30° , however in the summer dry and dusty.

In this study, we present long-term variations of U-ratio, which represents proxy of wind strength and potential illustration of changes in domination of Košava wind during the last million years in the region. Surprisingly, we discovered that loess-paleosol sequences in Northern Serbia preserved unique information about the dynamics of several thousands and hundreds kilometers distant North European and Alpine glaciers, respectively. An increase in Northern European Ice volume influences significant migration on permanence of the Polar Front to the south. Higher contribution of coarse grains, the thinness of loess layers, sedimentation rates and increase of U-ratio is observed in Serbian loess-paleosol sequences associated with more pronounced decrease of Sea surface temperatures in the Western than in Eastern Mediterranean. These differences in the sea surface temperatures in the Western and Eastern Mediterranean illustrate more polar front fluctuations over the Alps and more frequent cyclone genesis in Genova gulf, which in association with anticyclones over the Russian plain initiates an increase in the Košava wind activity.

Magnetic signatures of natural and anthropogenic sources of urban dust aerosol

Haijiao Liu^{1,2}, Yan Yan³, Hong Chang^{1,4}, Hongyun Chen⁵, Lianji Liang⁶, Xingxing Liu^{1,4}, Xiaoke Qiang^{1,4}, Youbin Sun^{1,4,7}
¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²College of Earth Science, University of Chinese Academy of Sciences, Beijing, China. ³Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China. ⁴Center for Excellence in Quaternary Science and Global Change, Chinese Academy of Sciences, Xi'an, China. ⁵Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences, Shijiazhuang, China. ⁶College of Architecture and Civil Engineering, Beijing University of Technology, Beijing, China. ⁷Institute of Global Environmental Change, Xi'an Jiaotong University, Xi'an, China

Abstract

The characteristics of urban dust aerosols and the contributions of their natural and anthropogenic sources are of scientific interest as well as being of substantial sociopolitical and economic concern. Here we present a comprehensive study of dust flux, magnetic parameters, and magnetic particulates' morphology and elemental composition of atmospheric dustfall originating from natural dust sources in East Asia and local anthropogenic sources in Xi'an, China. The results reveal a significant inverse relationship between seasonal variations of dust flux and magnetic susceptibility (χ).

By comparing dust flux and χ records, the relative contributions of dust from local anthropogenic sources are estimated. The results show that local anthropogenic contribution decreases in spring and increases in other seasons. Local anthropogenic contribution variation exhibits a similar seasonal pattern to χ_{if} , but opposite trend to that of dust flux with the maximum in spring. This means that a great amount of distant natural dust input with less magnetic content makes a great contribution to atmospheric dustfall in spring, which results minimum χ_{if} and anthropogenic contributions during this period. Hence, the local contribution is reduced as a result of increasing natural dust flux.

Analyses using Scanning Electron Microscopy (SEM) combined with Energy Dispersive Spectroscopy (EDS) indicate that magnetic particulates from different sources have distinct morphological and elemental characteristics. Detrital magnetic particles originating from natural sources are characterized by relatively smooth surfaces with Fe and O as the major elements and a minor contribution from Ti. The anthropogenic particles have angular, spherical, aggregate, and porous shapes with distinctive contributions from marker elements, including S, Cr, Cu, Zn, Ni, Mn and Ca. Our results demonstrate that this multidisciplinary approach is effective in distinguishing dust derived from distant natural sources and local anthropogenic sources, and for quantitative assessment of contributions from the two end-members.

Using zircon U-Pb ages to assess the provenance of high-resolution ^{14}C dated loess deposits in Hungary

Yunus Baykal¹, Thomas Stevens¹, Gábor Újvári^{2,3}, Chiara Költringer¹

¹Uppsala University, Uppsala, Sweden. ²University of Vienna, Vienna, Austria. ³Hungarian Academy of Sciences, Budapest, Hungary

Abstract

Loess deposits serve as informative archives of past atmospheric dust dynamics. Despite its fundamental role in the climate system, our understanding of dust-climate interaction is limited by uncertainties over the source as well as transport pathways of the material. In order to decipher the source information of loess deposits, the use of single grain techniques with a focus on detrital zircon U-Pb dating has increased in the recent years. Through the application of this method, striking advances have been achieved in the understanding of the Chinese loess provenance. However, comparably few single grain provenance studies have attempted to unravel the specific dust sources of the Eastern European loess belt. The origin of the loess deposits in the Carpathian Basin has been subject of debate in numerous studies. Competing scenarios of dust transport have been presented evaluating the contribution of local sources, mountainous sources and long-range transported material under the varying atmospheric conditions of glacial and interglacials. Nevertheless, none of the proposed hypotheses regarding the dust source and the question of temporal source variability on Quaternary timescales has been demonstrated using single grain provenance techniques. The most precise age model for European dust deposits, based on 125 accelerator mass spectrometry ^{14}C ages from Dunaszekcső, Hungary revealed glacial dust deposition variability on centennial-millennial timescale that corresponds to fluctuations of the Greenland dust record. This high-resolution ^{14}C chronology from the Carpathian Basin allows us to investigate if observed changes in the dust deposition rate are associated with changes in dust source during the time slice of 36 to 24 ka b2k. Detrital zircon U-Pb age spectra of 13 samples selected according to the abrupt changes in the mass accumulation rate are used in combination with bulk geochemical data to detect variability in the material's provenance through time. Identifying the dust sources and transport pathways during the last glacial dust deposition variability may help to understand the atmospheric mechanisms underlying the North Atlantic climate fluctuations. Preliminary work and previous studies highlight the challenges of the applied method to unequivocally identify the provenance since potential source regions show overlapping zircon U-Pb ages.

P-1426

The loess deposits in Northeast China and the late Pleistocene monsoon evolution

Yiya Wang

National Research Center for Geoanalysis, Beijing, China

Abstract

Chinese loess deposits are extensively distributed in northern China, which are recognized, combined with polar ice and deep-sea sediments, as the three most important records for Quaternary paleoenvironmental studies. However, most studies of the Chinese loess have focused on the loess-paleosol sequences in the Chinese Loess Plateau. Loess deposits from other regions of China have long been less well investigated, and therefore the basic issue of loess deposits in other regions of China, especially in Northeast China, is not well known. In this study, we investigated the origin of the loess sequences in Songliao Basin, Northeast China, and the late Pleistocene evolution of monsoonal climate, through field observations and sedimentological, geochemical as well as fossil molluscan studies based on 27 sections. Our results show that loess deposits are extensively distributed over the Songliao Plain, without constraining by geomorphology. They are mainly composed of silts and major and minor elements that are similar to the loess sequences in the Chinese Loess Plateau. The fossil snails are all terrestrial, without freshwater and amphibian species. The dominant species are those from genera *Vallonia* and *Cathaica*. All these characteristics are similar to those from loess deposits in the Chinese Loess Plateau, indicating that loess in Northeast China is a wind-blown deposit and thus is a new record of monsoon evolution in the Pleistocene. Using ratios of major/minor elements ($\text{SiO}_2/\text{Al}_2\text{O}_3$, Rb/Sr) as summer monsoon index, the paleoclimate during the late Pleistocene shows a gradual cooling trend, which may be caused by weakness of the East Asian summer monsoon.

Erosional transition of shoreline blocks by lichen colonization in Cantabria associated to the end of the LIA

Raúl Perez-Lopez¹, José A. Ortega-Becerril², Javier Elorza³

¹IGME - Geological Survey of Spain, Madrid, Spain. ²Universidad Autónoma de Madrid, Madrid, Spain. ³Universidad del País Vasco, Bilbao, Spain

Abstract

Lichen colonization of surface rocks depends strongly of the environmental conditions and nutritional disposal, mainly nitrogen and carbon dioxide. The presence of lichens could accelerate the surface erosion by chemical weathering, although they could prevent mechanical erosion as well. Lichen covering prevent for this erosion except in the case of strong eolian weathering, where multiple impacts of grain-sized particles avoid the lichen growth. The presence of carbonate megablocks along the shoreline between Santander and Bilbao (Cantabria domains, north of Spain) exhibit different overlapping of erosional processes. These blocks show ventifacts (groove marks) along the external surface related to strong winds hitting with airborne quartz grains, and which size ranging between 0.1-0.3 mm. The present wind-blow trending in the coastal range is W-NW, which is coincident with the ventifacts arrangement and orientation. Overlapping to the ventifacts, we can observe a chemical weathering of the aeolian-polished sides of the blocks, and in different patches with centimetric extension and depth. We can observe that the wind-struck boulder-side has been colonized by calcicolous lichen specie, *Verrucaria maura* (tar lichen). This lichen is sea-spray resistant and its annual growth rate has been calibrated from cemeteries close to the shoreline, having similar environmental conditions that in the coast (precipitation and temperature). The lichen colonization of these beach boulders indicates a period of weak aeolian abrasion and prevalent chemical weathering. We assume that this fluctuating erosional process is directly related to a change in the climatic conditions during the LIA ending times affecting rainfall, humidity and therefore wind entrainment of sand grains affecting the shoreline. The oldest lichen measured in these blocks suggests that the end of the LIA could be in the year 1855 ± 6 yr. NAO variations and the annual precipitation curve in the area during the last 300 yr. support this data.

Distribution of branched glycerol dialkyl glycerol tetraethers (brGDGTs) in soils from Central Asia

Alexandra Engström Johansson¹, Alfredo Martínez-García¹, Alexandra Auderset^{1,2}, Laurent Marquer¹, Aditi Dave¹, Charlotte Prud'homme¹, Nosir Safaraliev³, Kathryn Fitzsimmons¹

¹Max Planck Institute for Chemistry, Mainz, Germany. ²Department of Earth Sciences, ETH Zürich, Zürich, Switzerland. ³Department of Geology, Tajik National University, Dushanbe, Tajikistan

Abstract

Loess-paleosol sequences are excellent recorders of terrestrial climate change over Quaternary timescales. Substantial deposits blanket the piedmonts of Central Asia, where the convergence of major continental climate subsystems (the westerlies, polar front and monsoon) makes it an ideal location to investigate causal relationships between dust dynamics and climate change. Past temperature changes are a key component for understanding climate dynamics in this region, yet terrestrial paleotemperatures have yet to be adequately explored with quantitative climate proxies.

New quantitative paleotemperature proxy information can now be obtained based on the distribution of glycerol dialkyl glycerol tetraether (GDGT) membrane lipids. Although the focus of this technique so far has been on marine and lacustrine environments, there exists strong potential to extend this approach to terrestrial sediments. In fact, several studies have quantified annual mean air temperatures (MAT) and soil pH for loess-paleosol sequences using the Methylation of Branched Tetraether (MBT) and the Cyclisation of Branched Tetraether (CBT) indices.

However, this approach lacks not only adequate regional calibration, but also systematic application to long loess-paleosol sequences in the Central Asian piedmonts. Reliable application of brGDGT climate proxies requires precise calibrations to temperatures using modern soil samples from the region of interest, for which climate parameters are known. No such calibration exists for Central Asia, either as a separate region or as included in existing global calibrations. Previous work also indicates that available brGDGT calibrations are uncertain in some arid environments, running the risk of air temperature overestimation. A reliable calibration dataset is therefore a critical first step for reliable climate reconstruction in the region.

Here we will present the first temperature calibration for brGDGTs from Central Asia, based on modern soil samples from mountain piedmonts in semi-arid Tajikistan and Kazakhstan. We discuss our results in relation to differences in elevation, vegetation cover and other potential influencing factors. We also provide the first paleotemperature framework for two late Quaternary loess profiles in Tajikistan (Karamaidan) and Kazakhstan (Remizovka).

The role of dust in glacial cycles dynamics

Matteo Willeit, Andrey Ganopolski

Potsdam Institute for Climate Impact Research, Potsdam, Germany

Abstract

Mineral dust aerosols affect global climate through its impact on Earth's radiative balance, clouds and biogeochemistry. Here we use the CLIMBER family of intermediate complexity Earth system models (the well established CLIMBER-2 and the newly developed CLIMBER-X) to assess the importance of dust for glacial cycles dynamics. More specifically, using transient and time-slice model simulations we explore the importance of the lowering of snow albedo by mineral dust deposition on ice sheet growth and melt and the effect of iron fertilization on ocean primary production and consequently on atmospheric CO₂ concentration during glacial times.

We show that the evolution of the Northern Hemisphere ice sheets over the last glacial cycle is very sensitive to the representation of the dust darkening effect on snow albedo in the model. Ignoring the effect of dust on snow albedo leads to an excessive ice build-up during glacial times and consequently to a failure in simulating deglaciation. We also show that assuming slightly different optical properties of dust leads to very different ice sheet and climate evolutions in the model.

The increased rate of dust deposition over the ocean during glacial times compared to present day acts as a fertilizer for primary production in iron limited regions like the tropical East Pacific and the Southern Ocean, strengthening the biological pump and leading to an atmospheric CO₂ decrease of ~10-30 ppm in the models. The actual decrease in CO₂ strongly depends on the assumed change in the magnitude of dust deposition between glacial and interglacial times, which is very uncertain.

LGM experiments using MIROC Earth System Models: some preliminary analyses on dust aerosol

Rumi Ohgaito¹, Ayako Abe-Ouchi^{2,1}, Akitomo Yamamoto¹, Tomohiro Hajima¹

¹JAMSTEC, Yokohama, Japan. ²AORI, U. Tokyo, Kashiwa, Japan

Abstract

The deposition flux of mineral dust aerosol has synchronously changed with temperature reconstruction through glacial-interglacial cycles (Winckler et al. 2008). However, it has been difficult to obtain enough dust flux at glacial time by models (Takemura et al. 2009, Hopcroft et al. 2015). Therefore, in modelling studies, realization of dust amount in glacial era is one of key issues to understand the mechanism of interaction of dust and climate (Mahowald et al. 2006). We discuss how to realize dust distribution at the Last Glacial Maximum (LGM) in two versions of MIROC earth system models and discuss how the dust interact LGM climate.

We performed LGM experiments using MIROC-ESM (Watanabe et al. 2011). One experiment had done with the standard Paleoclimate Modelling Intercomparison Project phase 3 (PMIP3) type setting (Sueyoshi et al. 2013). In other experiment, glaciogenic dust flux estimated by Mahowald et al. (2006) is constantly imposed (Ohgaito et al. 2018) on the standard PMIP3 LGM experiment. Ohgaito et al. (2018) concluded that the appropriate amount of dust flux over the Southern Ocean affects surface temperature surrounding of the Antarctica through aerosol-cloud interaction. We are now testing a LGM experiment with erodibility map proposed by Albani et al. (2016) which is recommended by Paleoclimate Modelling Intercomparison Project phase 4 (PMIP4) protocol instead of glaciogenic dust, as an advanced method to emit higher dust flux at LGM.

On the other hand, in order to contribute PMIP4, we are now conducting a LGM experiment using a newly developed model MIROC-ES2L. In the procedure of setting up the experiment, we adopted the erodibility map. The effect of the erodibility map resulted about doubling of dust deposition in global average compared to another LGM experiment without the erodibility map.

In the presentation, we will discuss the robustness and model dependence of the effect of dust on the LGM climate using the above listed LGM experiments.

A Holocene geochemical peat record for paleo-dust tracing in NE China

Steve Pratte¹, Kunshan Bao¹, François De Vleeschouwer^{2,3}, Chuxian Li², Clemens von Scheffer⁴, Wenfang Zhang¹
¹State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China. ²ECOLAB, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France. ³Instituto Franco-Argentino para el Estudio del Clima y sus Impactos, Universidad de Buenos Aires, Buenos Aires, Argentina. ⁴Institute for Ecosystem Research, Kiel University, Kiel, Germany

Abstract

Atmospheric mineral dust-climate interactions and their underlying factors can be studied through geological archives. Although the deserts of East Asia are one of the main sources of atmospheric mineral dust [1], there is still a lack of terrestrial records in the region. The potential of peatlands as climate and geochemical archives (dust deposition and source tracing) is now well established [2, 3, 4]. Rare earth elements (REE) are recognized as valuable dust provenance tracers [3, 4].

Here we present a Holocene geochemical dust record from the Hani peatland, northeastern China. Elemental (lithogenic and rare earth elements (REE)) and isotopic (Nd and Sr) geochemistry was combined with grain-size analyses to help in the reconstruction of past climatic events and the identification of dust sources as part of an ongoing study on the influence of the East Asian Monsoon on the dust cycle in NE China.

The REE patterns, ϵNd (-7.8 to -9.2), $^{87}\text{Sr}/^{86}\text{Sr}$ (0.71017-0.71599) and grain size suggest that, for most of the Holocene, the source of the dust deposited on Hani peatland was relatively constant and represented a mixture of particles originating from desert dust (Gobi, Taklamakan). A number of episodes display distinct Eu anomalies ($\text{Eu}/\text{Eu}^* > 1.2$) when compared to the rest of the record ($\text{Eu}/\text{Eu}^* : 0.98-1.05$) especially around 11ka and 1.8ka BP. Particles deposited during these events also display distinct ϵNd (-2.4) and $^{87}\text{Sr}/^{86}\text{Sr}$ (0.70513) signatures as well as greater grain-size which could be pointing to a more local source. This is further confirmed by the REE patterns which are similar to local soils and volcanic rocks in the region. We postulate that these events are linked to a strengthening of the East Asian Summer Monsoon resulting in increased rainfall facilitating the supply of locally derived mineral particles.

The role of Saharan dust in modulating monsoon response in MPI-ESM mid-Holocene simulations

Roberta D'Agostino¹, Stephanie Fiedler¹, Sabine Egerer², Ulrike Niemeier¹, Sebastian Rast¹, Hanh Nguyen³, Johann Jungclaus¹

¹Max Planck Institute for Meteorology, Hamburg, Germany. ²GERICS Climate Service Center, Hamburg, Germany.

³Australian Bureau of Meteorology, Melbourne, Australia

Abstract

In mid-Holocene (ca. 6,000 years ago) different orbital conditions caused more summer insolation in the Northern Hemisphere than at present-day. This had led to a dramatic increase in the vegetation cover in North Africa and a strengthening of the West African Monsoon (WAM). Since the Sahara was mainly covered by grassland and savanna, the atmospheric burden of Saharan dust was substantially lower than today. It is typically difficult to fully reproduce the WAM behaviours in mid-Holocene from proxy reconstructions with climate models, if they do not account for accurate changes in vegetation and dust aerosol. While many models have implemented interactive vegetation in Earth System Models, dust aerosol is often prescribed with a climatology and not interactively calculated in paleo-simulations, e.g., due to the computationally expensive aerosol schemes. Here, we present results from mid-Holocene simulations performed with the Max Planck Institute Earth System Model (MPI-ESM). The prescribed distribution of dust aerosol and its optical properties are derived from an aerosol-climate simulation with ECHAM6-HAM (Egerer et al., 2016), that has the same atmospheric model as MPI-ESM. Our results show that accounting for Saharan dust reduction substantially warms mid-Holocene summers both locally in the Sahara and even globally, with a global mean warming of about +1.2 K relative to the control simulation, based on pre-industrial dust. The regional hydrological cycle changes substantially. Evaporation increases in the region between 10°N - 20°N of the ascending branch of the Hadley circulation, leading to a dramatic change in the P-E balance there. The net effect of this response is an about 14% weaker and narrower WAM compared to the simulation with the pre-industrial dust aerosol. These changes are an improvement of the model performance in comparison to the proxy reconstructions in deep tropics (5°N - 10°N) and in the Sahel region (15°N - 20°N). Our results point to the importance of desert-dust aerosol for simulating global and regional climates.

Abstract

The mechanism, timing and dynamic of paleoclimatic changes in southern Patagonia in the Holocene, still remain unclear. The main climatic driver in the study zone are the Southern Westerlies Winds (SWW), whose changes have the potential to modify dust emissions in southern South America. During the Holocene in Patagonia, the SWW in environmental paleorecords have shown changes in position and strength. In order to understand paleoclimate dynamics in southern Patagonia and correlations between dust deposition and SWW, we sampled an ombrotrophic peat bog in the locality of Rio Rubens, close to the present-day SWW core maximum position, on the east flank of the Andes Mountains. Elemental analyses from ombrotrophic peat bogs have allowed successful reconstruction of past atmospheric dust changes, providing new data for interpreting and determining variations in the atmospheric circulation through the Holocene.

Previous palynological studies carried out in this bog indicate a basal age of 13 ka, with a purely ombrotrophic section of 5 ka. In order to determine the dust fluxes, a 1,5 m long core was recovered and subsequently subsampled each 1 cm, for elemental inorganic geochemistry (major and rare earth elements) as well as for radiocarbon and Pb210 dating. Preliminary results show an increase in the magnitude of dust flux interpreted as a southward shift in the SWW position, bringing the core of the SWW closer to the Rio Rubens peat bog through the late Holocene.

Aeolian relationships across the Al-Azraq Basin, Jordan and Quaternary implications for regional dust fluxes using grain size, geochemistry, and IRSL

Caroline Davies¹, Kaleena Salazar¹, Khaldoun Ahmad²

¹University of Missouri Kansas City, Kansas City, USA. ²St. Cloud Technical and Community College, St Cloud, USA

Abstract

second largest draining the east side of the Rift Valley highlands and southern Syria. The very near surface sediment of the Al-Azraq Qa are early Holocene in age demonstrated by previous research, covered by thin layer of modern alluvial and aeolian surface sediments. Within the basin are three distinctly different deflated and eroded older aeolian deposits. On the western margin of the basin, flanking the Al-Azraq Oasis, are low, grey vegetation-anchored nabkahs. A nabkah (NK1) is composed of 80 percent aeolian silt-sized sediment of dominated by quartz and feldspar mixed with evaporite minerals of calcite and organic inputs from the oasis. Along the northeast margin of the qa is a linear stretch of white carbonate-cemented dunes composed of euhedral quartz, feldspar, calcite, gypsum, and clay minerals, possibly chlorite. The linear dunes are in close proximity to spring deposits and are dominated by calcite. Forming the eastern margin is a large red massive dune field sampled to 4.5 meters below the dune surface. Analyses reveal a wider range of minerals including subhedral quartz, feldspar, mica, heavy minerals, and green clays. Secondary gypsum indicates longer sedimentary history with episodes of evaporation. This research examines sedimentary and temporal relationships between these distinct aeolian deposits within the Al-Azraq basin and compares them to regional dust flux records.

Abstract

Dust recovered from Antarctic ice cores represents a valuable archive of the atmospheric paleo-circulations in the Southern Hemisphere (SH) during glacial and interglacial periods. Dust preserves the chemical and isotopic composition of the region where it was deflated and on the basis of different geochemical tools, many studies have shown compelling evidence that South America seems to be the major dust source for Antarctica. However, there is no consensus on the relative contribution of potential secondary sources like Australia, New Zealand, South Africa and Antarctica itself. In particular, South Africa has recently called the attention of researchers due to its growing potential to enhance the airborne particle production and thus, plays an important role in the global radiative balance, hydrological cycles and climate system. In southern South Africa, Namibia is considered as a small, but persistent dust source but its relevance and extent to Antarctica are still not well constrained. Most of the studies to exclude South Africa as a dust supplier to East Antarctica are based on global meteorological and climatic models and a lack of systematic and detailed studies based on the specific potential source areas it became apparent. Keeping that in mind, we carried out a comprehensive and comparative geochemical characterization of several potential dust source regions in southern South Africa, followed by simulated experiments to reproduce the dust genesis from the sediment precursor. In Namibia, sediments from large dry river beds (Omaruru and Huab rivers) were collected and then, aerosols were generated into an atmospheric simulation chamber (CESAM) to mechanically reproduce the saltation and sandblasting processes responsible for the release of mineral dust in natural conditions. The initial bulk sediments, together with the obtained mineral dusts collected on Teflon filters were digested and analyzed for their trace element abundances (HR-ICP-MS) and Sr, Nd and Pb isotopic compositions (Nu Plasma MC-ICP-MS). The obtained results were compared with data recovered on atmospheric particles, filtered from subsurface snow samples from East Antarctica (Dronning Maud Land). In general, this study will fill the important gap concerning the identification of secondary dust sources in the SH and the wind circulation and the contribution of South Africa as a potential dust supplier for the East Antarctica.

¹University of Missouri-Kansas City, Kansas City, USA. ²Minnesota Community College, Minneapolis, USA

Abstract

This research project characterizes the texture, morphology, composition, mineralogy and geochemical of dune sediments from the Al-Jafr Basin, Jordan. Using various analytical methods reveal the paleoenvironmental processes dominating landscape formation at this location. Microscope examination revealed the presence of vegetation and fossils. Grain size results throughout the sand dune samples identified the sediment as predominately silt size particles, predominately fine silt. This indicates moderate and steady wind energy to transport these particles.

The Al-Jafr dune samples are rich in numerous organic materials, along with evidence of fossil brachiopod and ostracod remains. The brachiopods maybe secondarily deposited, form older eroded landscapes. The ostracods potentially indicate past aquatic conditions.

Geochemical characteristics of Holocene aeolian deposits and their paleoclimatic implications: a case study in East of Qinghai Lake, China

Zhiyong Ding

Beijing Normal University, Beijing, China

Abstract

Abstract: The paleoclimate evolution in the northeast of Qinghai-Tibet Plateau (QTP) has always been concerned by scholars, due to the particularity of geographical location, especially the Qinghai Lake Basin (QLB). However, because of the ambiguity of proxies and the lack of enough precise chronological data, the evolution of paleoclimate since Holocene in this region has been controversial. Hudong Dunefield is located in the east of Qinghai Lake, which is the largest sand accumulation area in QLB. Aeolian sand-paleosol sequences of Hudong Dunefield are precious terrestrial archives that contain information on paleoclimate change and aeolian activity. In this study, deposits of the Holocene aeolian sand-paleosol sequences CGE and QHH in Hudong Dunefield are systematically analyzed to determine their elemental geochemical characteristics and paleoclimatic implications. Combination with the grain size, total organic carbon (TOC) and redness, emphasis is placed on the paleoclimate change since Holocene in this region and its response to the East Asian Summer Monsoon (EASM). The relatively consistent immobile elements content and ratio indicated that the aeolian sediments have similar sources during the Holocene, which mainly from the insitu weathering products of the rocks. The higher $\text{Na}_2\text{O}/\text{Al}_2\text{O}_3$ and lower chemical index of alteration (CIA) showed most of them in the stage from unweathered to weakly weathered degree, except some samples reach the moderate weathered during mid-Holocene, implying that several transition from warm-wet to relatively cold-dry during the Holocene epoch in the QLB. The multi-proxy indicated that the regional climate was broadly coincident with the northeast of QTP and most regions of northern China, implying that the paleoclimate of QLB was closely correlated with the evolution of EASM during the Holocene. Additionally, after the 9.2 ka BP cold event, the chemical weathering increased gradually; in 8.7-4.0 ka BP, the higher CIA and TOC, lower redness and mean grain size are possibly associated with the mid-Holocene climate optimum period, indicated an intensified chemical weathering, denser vegetation cover and weakened aeolian activity in QLB in response to warmer and more humid climate. After 4.0 ka BP, the obviously weakened chemical weathering indicates that the study area is dominated by a relatively cold and dry climate, and there have been several alternating warm-wet and cold-dry intervals in 3.2-0.6 ka BP. Collectively, our new multi-proxy data add supporting evidence for the mid-Holocene climate optimum period, in addition, we also conclusion that the EASM dominated the chemical weathering in the HSL region

Holocene dune activity – implications for multidecadal drought in the Colorado Plateau, USA

Harriet Cornachione¹, Tammy Rittenour¹, Michelle Nelson²

¹Utah State University, Logan, UT, USA. ²USU Luminescence Laboratory, Logan, UT, USA

Abstract

The Colorado Plateau and the Colorado River headwaters, a critical water supply for the southwestern United States, are linked through similar regional climate factors, especially for drought. Recent multi-annual drought has stressed this region, already limited in water resources. Longer term decadal to centennial droughts are recorded in tree-ring records and have been implicated in the past abandonment of pre-historic communities. The potential for multi-decadal drought driven by climate change is a serious concern in this region. Dune activity records here contribute to our understanding of natural climate variability, aiding in development of adaptive strategies for predicted climate change characterized by higher temperatures and decreased precipitation.

Sand dunes are complex geomorphic landforms responsive to threshold climate conditions of aridity, wind power, vegetative cover and sediment supply. Using optically stimulated luminescence (OSL) dating and radiocarbon (¹⁴C) ages from charcoal we investigate eolian activity in two dune fields in southern Utah. Geomorphic maps were constructed for each dune field based on vegetation density and dune morphology. The stratigraphy, geomorphology, sedimentology (grain-size), and age control obtained from OSL and ¹⁴C dating are used to differentiate sediment packages and develop a chronostratigraphic record of dune activity. We interpret coeval dune activity in these dune fields as representing persistent (\geq decadal scale) regional droughts leading to changes in threshold conditions for dune mobility. In addition to the record of past dune mobility we present analyses of modern wind regimes from climate stations across the region, reflective of late Holocene conditions. We present geochemical and grain size analyses to determine the sediment source for two dune fields and discuss geomorphic processes contributing to dune field development.

Abstract

Arctic sea ice is a critical component of the climate system, changing and affecting the gas exchange, salinity, heat and moisture between ocean and the atmosphere. Current developments in the use of IP₂₅ (Ice proxy with 25 carbon atoms only synthesized by Arctic sea ice diatoms) have proven it to be a suitable proxy for palaeo-sea ice reconstructions over shorter to longer timescales. For the NE-Baffin Bay, a climate-sensitive region characterized by strong seasonal sea ice variability and strong melt-water discharge from the Greenland ice Sheet, however, such proxy records are not available so far. In order to fill this gap, we have investigated several sediment cores along the north-south transect that provide high-resolution Holocene sea-ice records. IP₂₅, open-water phytoplankton biomarker and PIP₂₅-based sea ice reconstructions carried out at Core GeoB19927-3, the northernmost site of our transect (Melville Bugt, 73°35.26' N, 58°05.66' W; water depth: 932 m; recovery: 1147 cm), indicate seasonal to ice-edge conditions during most of the Holocene period. Between 11.1 to 10 cal ka BP, our proxies display very low biological growth near the core site characterized by extensive sea ice cover and enhanced terrigenous debris deposition points to the ablation of ice sheets and a cooling event, followed by a period of a persistent, albeit strongly variable, appearance of the West Greenland Current (WGC) between 10.0 and 8.6 cal ka BP. This early-Holocene warming can be characterized by reduced sea ice cover as a result of enhanced deglacial melting induced by high insolation coupled with enhanced WGC penetration up to the northern Baffin Bay. From about 8.6 to 7.8 cal ka BP, we notice elevated values of IP₂₅ signaling towards enhanced seasonal sea ice cover, and opening of Nares Strait led to the increased influx of Polar Water into Baffin Bay and consequently a cooling event. Between 7.8 and 3.8 cal ka, most likely, a relatively warm and strong WGC was continuously present as reflected by gradual decrease in sea ice diatoms. This indication of a mid-Holocene warming trend is widely reported in studies from East/West Greenland, Canadian Arctic islands and Baffin Bay areas. From about 3.8 cal ka BP, our combined proxies suggest, a long-term Late-Holocene ("Neoglacial") cooling, interrupted by short warming events (RWP - Roman Warm Period, MCA - Medieval Climate Anomaly). The variable advance and/or retreat in sea ice cover is supported by records from Disko Bay and North Atlantic marine as well as terrestrial records. The observed change in sea ice seems to be connected to regional and global changes in oceanic circulation in the North Atlantic driven by solar forcing.

Abstract

The rapid loss in the extent and thickness of Arctic sea-ice cover is one of the most significant signs of Arctic climate warming. Sea-ice decline affects e.g. global carbon balance, marine and terrestrial ecosystem dynamics and global climatic and oceanic/atmospheric circulation. To fully predict the consequences of future sea-ice decline, there is a need to understand past natural sea-ice variability beyond the satellite observation era.

Marine protists such as diatoms have a rich and abundant (sub)fossil record, and surface sediment calibration sets based on species assemblage compositions are often used to infer past sea ice conditions. In order to reliably use these calibration sets, and interpret reconstruction results, understanding the living environment and ecology of the taxa is essential. However, the biology and ecology of the key species used in diatom reconstructions is not well known, and the role of some sea-ice associated species as ice indicators appears complicated. Therefore, more knowledge of the annual sea ice dynamics and diatom species succession are needed.

As the sedimentary record represents essentially an integration in time and space, an important aspect is to refine the complex environmental triggers that structure community composition over seasonal cycles. To address this issue, we analysed diatom fluxes from two differing Greenland fjord systems: Young Sound, a high-Arctic fjord in NE Greenland and Godthåbsfjord, a sub-Arctic fjord in SW Greenland. These two fjords have distinct oceanographic settings and ice regimes. Young Sound is covered by sea ice for nine to ten months each year, whereas Godthåbsfjorden experiences inter-annually varying extent of sea ice only in the innermost parts of the fjord for less than six months per year. We will present results of seasonal diatom succession based on sediment trap analyses from both fjords. Sediment samples were collected over a year at 1 week to 1 month intervals and are investigated to determine seasonal time windows for diatom production in the water column and ice, with special focus on sea-ice associated species. The diatom assemblages from both fjords are compared to assess the presence of ice-associated species in comparison to the sea-ice conditions. This will provide important information for evaluating the potential and limitations of diatom-based sea-ice reconstructions.

¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Research Unit Potsdam, Polar Terrestrial Environmental Systems, Potsdam, Germany. ²Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany. ³GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany. ⁴University of Potsdam, Institute of Geosciences, Potsdam, Germany. ⁵University of Potsdam, Institute of Biochemistry and Biology, Potsdam, Germany

Abstract

Past climate oscillations have led to the presence or absence of sea ice in the North Pacific Ocean, which in turn has driven changes in community compositions. Marine diatoms (Bacillariophyceae) are unicellular, siliceous organisms that can respond sensitively to environmental change such as sea surface temperatures. Moreover, they are the dominant group of sympagic microalgae in the Arctic with a few species producing the sea ice proxy IP₂₅ – a highly branched isoprenoid with 25 carbon atoms. So far, marine diatom records have been mainly analysed by microscopic observations, while only a handful of studies attempted a paleogenetic diagnostic. Here, we present an 18,000 year record based on ancient sedimentary DNA metabarcoding of diatoms for the Northwest Pacific Ocean and tackle the question if this approach is suitable as a new proxy for sea ice reconstructions. Our study site is located near the coast of Kronotsky Peninsula (Kamchatka). We collected 54 marine sediment samples from the 9.05 m long core SO201-2-12KL, which was taken at 2173 m water depth (N 53.992660, E 162.375830) and covers the time period since the deglaciation after the Last Glacial Maximum. In this core IP₂₅ was previously detected in time slices representing Heinrich event 1 (15.1 ka BP) and Younger Dryas (12.2 ka BP). Since chloroplast DNA is present in several copy numbers in diatoms the probability of its long-term preservation in marine sediments is very likely. Therefore, we applied a short metabarcode of the chloroplast *rbcl* gene (76 bp), which was amplified for each sample three times independently. Subsequent PCR products were prepared for high-throughput sequencing. In a pre-study with a subset of only 12 sediment core samples all four classes of diatoms were detected, expectably centric diatom genera like *Porosira*, *Chaetoceros* and *Thalassiosira* dominated the dataset. Genera containing ice-associated diatoms, such as *Melosira*, *Rhizosolenia*, *Navicula* or *Haslea* were recovered, but sparsely. Based on our preliminary results, we await high quality data for the larger data set. By now, our study demonstrated that DNA metabarcoding of marine diatoms has the potential to support and complement the analysis of long-term developments of community composition and diversity changes, e.g. in areas of low diatom preservation due to silica dissolution.

Abstract

Records beyond observational time scales are essential for documenting and understanding the natural variations in Arctic sea ice extent. However, the tools to document the evolution of sea ice conditions on historical to geological time scales are few and have limitations. It makes that sea ice, although a crucial component of the Arctic and global climate system, remains incompletely understood. Using *sed*aDNA in paleoceanographic and paleoclimatic studies is still in its infancy. Here, we have explored using sedimentary ancient DNA, or *sed*aDNA, as a novel tool for past sea ice reconstructions. We used metabarcoding and single-species quantitative DNA detection methods to document the sea ice conditions in a Greenland Sea marine sediment core. Metabarcoding has allowed identifying biodiversity changes back to ~100,000 years ago that we relate to changing sea ice conditions. Detailed bioinformatics further revealed several sea-ice-associated taxa, of which several were previously unknown from the “traditional” (micro)fossil record. The results from our genetic approaches corroborate sea ice reconstructions by traditional tools (dinoflagellate cyst assemblages and sea ice biomarker IP₂₅). In summary, we show that *sed*aDNA has great potential for documenting past sea ice conditions beyond instrumental time scales and provides a new tool to better understand past sea ice evolution.

Environmental sensitivity of diatom biomarker lipids linked to phytoplankton blooms dynamics in high latitude settings.

Lukas Smik, Simon Belt
Plymouth University, Plymouth, United Kingdom

Abstract

The different ecological habitats of various classes, genera or species of microorganisms in polar marine settings offers the potential to identify unique or source-specific lipids that may serve as suitable biomarker proxies for discrete oceanographic settings.

Highly branched isoprenoid (HBI) alkenes represent one such a class of lipids. These structurally unusual secondary metabolites are biosynthesised by a relatively small number of diatom genera, but are, nonetheless, common constituents of global marine environment. And while their cellular roles remain unknown, the source-specific nature of HBIs makes them potentially useful biomarkers for paleo environmental studies.

Over the past decade, the source or environmental specificity of certain C_{25} HBIs has seen their application as organic geochemical proxies for seasonal sea ice reconstructions, particularly in the Arctic. Thus, while sedimentary analysis of a mono-unsaturated C_{25} HBI, termed IP_{25} , has been shown to provide a direct proxy measure of the past occurrence of seasonal Arctic sea ice, more detailed descriptions of sea ice conditions have been obtained by combining IP_{25} data with those of other HBIs, particularly those derived from open-water marine phytoplankton.

In the current study, we continue to build on the previous HBI work in the Arctic and explore the potential of two closely related tri-unsaturated HBIs, biosynthesised by pelagic phytoplankton community, to provide further refinement to HBI based sea ice reconstructions in the Arctic. The sedimentary data, mapping occurrence and distribution of two isomers were obtained through analysis of ca 200 surface sediments from the European Arctic and sub-Arctic regions, specifically in the Barents Sea and the neighbouring Norwegian Seas. Outcomes of sedimentary data were compared with overlaying oceanographic settings extracted from regional satellite records. Both biomarkers were readily detectable across study region, with distribution between the two isomer clearly varying between the different regions of the study area.

Early findings indicate, that within the study region at least, the distributions of two tri-unsaturated HBIs, may potentially provide otherwise unavailable proxy-based measurement of temporal shifts in phytoplankton blooms dynamics in high latitude settings. Such an insights could also be invaluable in the further contextualisation of e.g. sea surface temperature (SST) proxies, for which seasonality data are generally absent or assumed.

To provide further context to the sedimentary findings, we also conducted temporal investigation into the occurrence and distribution of the two isomers from temperate location, and compare findings with known environmental variables including those associated with productivity indicators.

Out-of-Phase relationship between the East Asia summer and winter monsoon variations during the early Holocene

Xingxing Liu¹, Youbin Sun¹, Jef Vandenberghe², Xu Zhang³, Hu Yang³, Zhisheng An¹

¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²Institute of Earth Sciences, Vrije Universiteit, Amsterdam, Netherlands. ³Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Abstract

Great differences were observed in previous studies of the relationship between the East Asia summer monsoon (EASM) and winter monsoon (EAWM) due to the scarcity of winter monsoon geological archives. Here we present high-resolution elemental results together with twelve ¹⁴C dates of a 13.5-m terrace sediment on the western Chinese Loess Plateau to infer the monsoon variability since the last deglaciation. Our results indicate that the ratios of Rb/Sr and Zr/Rb are sensitive indicators of chemical weathering and winter wind intensity, respectively, exhibiting significant fluctuations since the last 16 kyr BP. During the last deglaciation, two cold intervals of the Heinrich event 1 and Younger Dryas were characterized by intensified winter monsoon and weakened weathering intensity. In the early Holocene, weakening of the winter monsoon was gradually weakened around 10.7 kyr BP, leading to the abrupt increasing of the chemical weathering around 9.7 kyr BP. The winter monsoon intensity was relatively strong during the early Holocene and decreased gradually afterwards, whereas the summer monsoon intensity reached a maximum during 8-4.5 kyr BP. Such a discrepancy is likely attributable to different impacts of solar insolation and the remnant Laurentide Ice Sheet on the wind and moisture changes.

P-1445

Provenances and Paleoclimatic Response of Holocene Sediments in the Inner Shelf of the East China Sea

Qi Li

China University of Geosciences, Beijing, China

Abstract

Holocene sediments from the inner shelf of the East China Sea (ECS), with its high deposition and continuously sedimentary record which is sensitive to environmental change, is an important recorder of regional responses to global paleoclimatic and paleoenvironmental changes. Based on the precise AMS¹⁴C dating data, We analyze grain size, clay minerals and trace elements of S05-3 sediment cores, investigating the sediment provenances of the southern inner shelf of ECS, deducing the evolution of East Asia Monsoon in the past 4.7ka. Comparing the clay minerals in the southern inner shelf of ECS with one from different potential source areas, the results indicate that sediments in the study area came from the Yangtze River, the Yellow River and rivers from Taiwan, while every potential source area making contribution in the different periods. In the period of 4.7-4.2ka, sediments from the Yangtze River and Taiwan's river is the main source of sediments. From 4.2ka to 3.2ka, sediments of study area mainly consist of the sediments of the Yangtze River and the Yellow River. Since 3.2ka, sediments from all of potential source areas had some response on the study area.

The evolution of East Asia Monsoon in the past 4.7ka can be deduced based on the grain size sensitive components, the ration of Rb/Sr and montmorillonite/kaolinite. Referring to the $\delta^{18}\text{O}$ of GSP2 and stalagmite of Dongge Cave and the evidence of cooling of different materials in other regions, 9 high values could be recognized corresponding to the cooling events caused by the East Asia Monsoon. The core S05-3 records 4 strengthen periods of the East Asia Monsoon: weak and stable during 4.7-4.2ka BP; increased and began to fluctuate during 4.2-3.2ka; a little weak with highly fluctuation during 3.2-2.0ka BP; the East Asia Monsoon increased slightly with fluctuations weakened.

History of Lake Ulaan in southern Mongolia since 16 ka: the ostracod, gastropod and charophyte record

Steffen Mischke¹, Min Kyung Lee², Yong Il Lee³

¹Faculty of Earth Sciences, University of Iceland, Reykjavík, Iceland. ²Korea Polar Research Institute, Incheon, Korea, Republic of. ³School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea, Republic of

Abstract

Lake Ulaan was a terminal lake in the Gobi Desert until the 1990s when the lake desiccated. The Ongin River is the main tributary of the modern playa originating in the southeastern Khangai Mountains ca. 250 km to the northwest. A sediment core of 5.88 m length was obtained and the chronology of the sediments established using OSL and radiocarbon dating.

Calcareous and other fossils from the sediment core were studied to reveal the lake history since the late glacial and in the Holocene. Most abundant microfossils in the sediments are valves of ostracods (micro-crustaceans). The ostracod assemblage is dominated by *Limnocythere inopinata* in the late glacial and early-mid Holocene section of the core. Valves of *Ilyocypris cf. gibba* and gyrogonites and oospores of charophytes occur almost exclusively in the postglacial section. Gastropod shells of *Gyraulus* and *Radix* were mostly recorded in the early Holocene sediments of Lake Ulaan.

Sediments are almost devoid of fossils during the periods from ca. 15-12.5 and 6-3 ka, likely indicating least favorable conditions in the lake environment. In contrast, the highest concentrations of fossils and the highest diversity between ca. 11-8.5 ka probably result from wettest conditions in the catchment of Lake Ulaan. The presence of valves of *Cypridopsis vidua*, *Heterocypris salina*, *Sarscypridopsis aculeata* and *Pseudocandona* sp. in addition to those of *L. inopinata* and *I. cf. gibba* indicate that Lake Ulaan was a shallow lake with fresh to slightly brackish waters during the most stable, favorable period in the early Holocene.

Spatial contrasts of Holocene climate evolution across East Asia

Yurui Zhang¹, Hans Renssen², [heikki heikki.seppa@helsinki.fi](mailto:heikki.heikki.seppa@helsinki.fi)³

¹Université de Brest, Brest, France. ²University College of Southeast Norway, Bø, Norway. ³University of Helsinki, Helsinki, Finland

Abstract

The East Asian climate, with its monsoon system, is a very dynamic component of the global climate system. To extend our understandings on climate evolution and its spatial patterns, we investigated the spatial patterns of this East Asian climate during the Holocene by analysing the results of multiple palaeoclimate models (with full-climate forcing).

Our analysis on these simulations suggests that the Holocene climate patterns and trends are not the same everywhere in East Asia. The most distinct feature is the contrast in the Holocene wetness evolution between the northern and southern East Asia. The wetness in northern East Asia increased during the Holocene with a drier early Holocene, while the Holocene wetness had a decreasing trend in the southern East Asia (with a boundary of $\sim 40^{\circ}\text{N}$). This N-S contrast in wetness trends is supported by proxy data, including quantitative precipitations records and composite moisture reconstructions. This N-S contrast in Holocene climate/wetness changes can be attributed to different mechanisms. Reduced early Holocene wetness and related increasing Holocene trend of wetness over the northern East Asia is associated with the strength of the westerly airflow. By contrast, in southern East Asia enhanced wetness at 11.5 ka and the decreasing Holocene wetness trend is caused by the monsoon circulation.

What is new in this present study is that we diagnosed a spatial contrast in the Holocene wetness evolution over East Asia in multi-model simulations performed with full-climate-forcings. We also explored the potential drivers behind the detected latitudinal wetness contrast. Additionally, enhanced wetness during the early Holocene in the southern East Asian domain is similar as the predicted high rainfall for the future. Thus, the early Holocene can be an analogue to the future climate over the Asian domain.

Climate variability in the northern Arabian Sea during the Holocene

Niclas Rieger^{1,2}, Thibaut Caley¹, Enno Schefuss³, Philippe Martinez¹, Bruno Malaizé¹, Sébastien Zaragosi¹, Gerrit Lohmann⁴, Franck Bassinot⁵, Nadine Ellouz-Zimmermann⁶

¹EPOC, Pessac, France. ²University of Bremen, Bremen, Germany. ³MARUM, Bremen, Germany. ⁴AWI, Bremen, Germany. ⁵LSCE, Paris, France. ⁶IFPEN, Paris, France

Abstract

The Arabian Sea is affected by an extremely dynamical climate system characterized by a pronounced seasonal monsoonal atmospheric circulation associated to changes in ocean circulation. Seasonal reversals and intensity changes of wind systems drive the development/suppression of strong coastal upwellings. High surface productivity, linked to upwelling reinforcement, together with supply of oxygen-poor intermediate waters result in establishment of an intense oxygen minimum zone in the water column and sediments. The seasonal reversal in wind direction is also associated with variable moisture sources. Currently, there are limited studies from the northern Arabian Sea that reconstruct high resolution hydroclimatic and terrestrial environmental changes during the Holocene and their potential link with marine conditions.

In this study we use a multi-proxy approach (from marine and terrestrial indicators) of a partially laminated marine sediment core (MD04-2875C; recovered during CHAMAK campaign, 2004) in the upper part of the Makran accretionary prism (northern Arabian Sea) to investigate the climatic variability and its local manifestation on the marine and terrestrial environmental system during the Holocene.

Based on combined hydrogen and carbon isotopic composition of leaf wax n-alkanes (δD and $\delta^{13}C$), we identify three time periods (0.5-4.5 kyr BP, 4.5-9 kyr BP, 9-12 kyr BP) with distinctive δD signatures exhibiting successively depleted values towards the end of the Holocene. $\delta^{13}C$ values, which can be seen as an indicator for a vegetation composition change between C3 and C4 plants, show only marginal changes between 4.5-12 kyr BP and remain constant thereafter. Based on this we propose changes in local precipitation and moisture sources as the principal drivers of δD signature. Since the start of sediment lamination coincides with the observed δD shift around 4.5 kyr BP, we propose that a major atmospheric reorganization is synchronous to the creation of an oxygen minimum zone. In this context, we also discuss possible implications of climate variability on the development of regional human societies.

Plant Diversity and Climate during the Quaternary: palynological evidences of species extinction and migration from India

Anjum Farooqui

Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

A substantial palaeoclimate data exhibiting vegetation succession during the Quaternary period in varied biogeography such as Trans Himalayan, Himalayan, Desert, Semiarid, Western ghat, Deccan plateau, Gangetic plain, North east and the Coastal zone is available from the vast territory of India. Spanning a time period of about 2.6 million years ago of the Earth's history, the palynological records in sedimentary archives have revealed the responses of vegetation to the climatic spasms during the period. Palynological records from India show that the cyclic episodes of interglacial and glacial periods have impacted upon vegetation which has led to endemism, local extinction, migration and introduction of new plant species. For this, multiple sedimentary archives have been investigated for identifying the diversity and evolution of vegetation through time. Most of the endemic flora which is found nowhere in the World is present in the Western ghats of India and is one of the hotspots of biodiversity. The relicts of the oldest vegetation in the Indian-subcontinent is now present only in the south-western ghats. The palynological records reveal that the monsoonal pattern in this region has remained similar since the Miocene time period and therefore, the endemic biodiversity is recorded till date in this part of India. However, the extinction of many species cannot be ruled out as is evidenced in palynological records of the past in the region. A continuous record of pollen-based vegetation from this region is available since ~140 ka to present. Similar rainforest palynological records are available ~ 1.95Ma from the Karewa Basin, Kashmir, in the north. It is concluded that although the vegetation in most part of the Indian-subcontinent remained in equilibrium with the fluctuations in Quaternary climate, the landscape/geomorphological evolution in varied biogeographic zones have left impact on vegetation particularly in the Himalayas and the coastal zone. Overall palynological results reveal that the rainforest vegetation although rejuvenated during Middle Holocene warm period in most part of the Indian-subcontinent but during Late Holocene it has squeezed into pockets in the south-western ghats, coastal areas and north-eastern region of India. The two plant species, *Ongoekia gore* and *Basella keralensis* recorded in sedimentary archives deposited before 74Ka (YTT event- Volcanic eruption in Sumatra) are now not present in the Indian sub-continent. While the former has migrated to more moister south-east Asia, the latter became extinct from the globe. Thus, *B. keralensis* can be used as palyno-marker of pre YTT time period until its palaeorecord is further available from any part of the world.

P-1451

Indian summer monsoon variability of the last 2000 years documented from lake pollen records, Yunnan Plateau, Southwestern China

Xuemei Chen

Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences, Lanzhou, China

Abstract

A high-resolution pollen-based precipitation reconstruction from a sediment core from Xingyun Lake, central Yunnan Plateau, southwest China, reveals the Indian summer monsoon (ISM) evolution over the last 2000 years. Pollen assemblages document four stages of regional vegetation history: (i) During 350 BC-700 AD, the Xingyun Lake catchment was covered by mixed forest of pine and oaks, with a variety of ferns and herbs in the understory. (ii) From 700 to 1400 AD, broadleaved forest dominated by evergreen oaks expanded to the maximum and the pine forest areas shrunk. (iii) From 1400-1900 AD, *Abies* and *Picea* forest occurred on the surrounding high mountains, and at the same time, the regional vegetation became more open, with pine forest increased but broadleaved forest declined. (iv) Since 1900 AD, the regional vegetation was dominated by a secondary forest of *Pinus* and *Alnus*. The vegetation history of Xingyun Lake indicate a drying climate and a gradually strengthened human activity during the last 2000 years. Despite the intensifying human influences, the Xingyun Lake records still reflect a general pattern of the climate change. The variations of the pollen-based quantitative precipitation suggest that the ISM weakened gradually during the last two millennia, with the strong ISM influence occurring during the Medieval Warm Period (MWP) with a weak ISM during the Little Ice Age (LIA). Besides, several important climatic periods were also captured, such as the weak monsoon period in 1000-1100 AD during the MWP and the strong monsoon period in 1600-1800 AD during the LIA, as well as the most remarkable dry period of the recent 200 years. Our reconstruction of the ISM is compatible with the records both from Yunnan Plateau and the ISM domain. In addition, our record bears significant solar activity cycles, suggesting that the solar forcing may affect the variability of the ISM and likely the ENSO as well.

Environmental conditions framing the evidence of the first *Homo sapiens* in Indochina (Tam Pà Ling cave, NE Laos)

Stefania Milano¹, Fabrice Demeter^{2,3}, Jean-Jacques Hublin¹, Philippe Durringer⁴, Elise Patole-Edoumba⁵, Jean Luc Ponche⁶, Laura Shackelford⁷, Somoh Duangthongchit⁸, Thongsasayavonkhamdy⁸, Phonephanh Sichanthongtip⁸, Daovee Sihanam⁸, Viengkeo Souksavatdy⁸, Kira Westaway⁹, Anne-Marie Bacon¹⁰

¹Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany. ²Center for GeoGenetics, Copenhagen, Denmark. ³Musée de l'Homme, Paris, France. ⁴Ecole et Observatoire des Sciences de la Terre, Strasbourg, France. ⁵Muséum d'histoire naturelle, La Rochelle, France. ⁶Laboratoire Image Ville et Environnement, Strasbourg, France. ⁷University of Illinois at Urbana-Champaign, Urbana, USA. ⁸Ministry of Information, Culture and Tourism, Vientiane, Lao, People's Democratic Republic. ⁹Macquarie University, Sydney, Australia. ¹⁰Université Paris Descartes, Paris, France

Abstract

Tam Pà Ling cave (northeast Laos) holds evidence of the first arrival of *Homo sapiens* in Indochina. Recently, several modern human remains have been excavated and dated about 70 ± 8 kya. These findings support the hypothesis of migrations across Southeast Asia during MIS 4 and they represent an important record to understand the colonization of this area of the world by our species. Generally, environmental conditions are important factors framing human movements. However, the limited information available for this region challenges the interpretation of Tam Pà Ling archaeological findings. This study uses the stable isotope composition of biocarbonates to investigate the environmental conditions prevailing from MIS 4 to MIS 1 in northeast Laos. The analyses are conducted on terrestrial gastropod shells excavated throughout the sequence. Shell carbon stable isotope composition ($\delta^{13}\text{C}$) is used to infer the proportion of C_3 (arboreal vegetation) and C_4 (grasses and shrubs) plants. The availability of these specific vegetation types relates to the occurrence of open vs closed habitats. Furthermore, shell oxygen stable isotope composition ($\delta^{18}\text{O}$) is adopted as precipitation proxy. The results indicate that during MIS 4 and MIS 3 (from 70 ± 8 to 34 ± 2 kya) the landscape was mainly dominated by arboreal vegetation, as it is in modern times. These forested environments were sustained by enhanced precipitation derived by intense summer monsoons. However, during MIS 2, the shell stable isotopes record a significant environmental change with the disappearance of closed forests in favor of more open habitats and the tendency toward drier conditions, potentially related to the weakening of the monsoon system. Ultimately, during Holocene, the area returned to be characterized by wet and forested conditions. These results provide insights into the type of environment encountered by the first *H. sapiens* populations in Indochina and how it changed through time.

P-1453

Holocene Geomorphology And Evolution of the Lower Palar River Basin, Tamil Nadu

Resmi MR¹, Hema Achyuthan²

¹Banasthali Vidyapith, Jaipur, India. ²Anna University, Chennai, India

Abstract

The Palar River is an eastward flowing river in Southern Peninsular India and receives dominantly the NE monsoonal rains. Neotectonic activity, that occurred owing to the prolonged stress along the Mulki Pulikat Axis (MPA), during the Quaternary times, uplifted the western side of the Palar River, which resulted in rejuvenating the preexisting faults and lineaments in the upper and middle reaches of the Palar River. The Palar River migrated ~25km south. The present day Palar River and its paleochannels located in the southern peninsular India were investigated with a multidisciplinary approach. The main aim of the study was to reconstruct the palaeoenvironment history of the Palar River basin and to delineate the role of Holocene fluctuations that played a major role in the geomorphological evolution of the region since the Holocene period. The results obtained based on sedimentary facies analysis supported by elemental concentrations and optically stimulated luminescence (OSL) dates, reveal distinct seven climatic phases since the last ~10 ka. Phase 1 signifies a very high precipitation as supported by the low CWI with high Rb/Sr ratio. Subsequent to Phase 1, a decreasing trend in the Northeast monsoon rainfall (NEMR) is observed (phase 2). Phase 3 (~4.83 ka - 3.59 ka) reflects a decrease in NEMR further supported by low Mn/Al, Mg/Al and CIA values. Phase 4 (~ 3.59 ka) is marked by high sand flux, K/Al, Ti/Al, Rb/Sr and Ba/Sr coupled with lower values of CaO/MgO, Mn/Al, Fe/Al indicate wetter conditions in the catchment area resulting in the intense weathering of the bedrocks caused owing to the increase in NEMR precipitation. Phase 5 (3.26 ka- 2.42 ka) reveals a decline in NEMR precipitation coupled with rapid upstream avulsion due to neotectonic activity that occurred in an intense dry phase. Phase 6 (~1.88 ka - 1.44 ka) is marked an augment NEMR causing high K/Al, Mg/Al, Ti/Al ratios, CIA and CWI values. Finally, phase 7 (~1.44 ka to present) is marked by lowered elemental solubility and mobility reflecting short periods of weaker or deteriorated NEMR. The documented record of Palar River and paleochannels suggest Holocene NEMR variability in the study region and is synchronous with the various proxy records of NEMR dominated regions however revealing an inverse coupling with SWMR during the Holocene period.

P-1454

Late Pleistocene Monsoon History of the lower Bengal Fan (IODP Expedition 354)

Michael E. Weber¹, Brendan T. Reilly², Petra S. Dekens³, Hendrik Lantzsch⁴, Supriyo K. Das⁵, Yasmina M. Martos⁶, Peter A. Selkin⁷

¹University of Bonn, Bonn, Germany. ²Oregon State University, Corvallis, USA. ³San Francisco State University, San Francisco, USA. ⁴University of Bremen, Bremen, Germany. ⁵residency University Kolkata, Kolkata, India. ⁶NASA Goddard Space Flight Center, Greenbelt, USA. ⁷University of Washington, Tacoma, USA

Abstract

IODP Expedition 354 drilled seven sites along an east west oriented core transect of 320 km length at 8°N in the lower Bengal Fan (France-Lanord et al., 2016). The sites were recovered to reconstruct the Himalayan uplift, the monsoonal development, and the turbiditic depositional mechanisms. We studied the Pleistocene sections of these sites using physical, optical, geochemical, stable isotopic, and grain-size properties, to establish the chronology and provide constraints on the depositional history of the last 1.25 Ma in relation to monsoon, climate, and sea-level development. Low-resolution bio-, magneto- and tephrostratigraphy were used as ground-truth chronological control to identify five sedimentary units that mostly changed synchronously across the fan: two regionally extensive hemipelagic Units (2 and 5) as well as three intercalated turbiditic Units (1, 3 and 5).

The top hemipelagic Unit 5 was studied in detail at Site U1452C (Weber et al., 2018, Global and Planetary Change). This ~5 m thick sequence shows dominantly precession cycle forcing of wet-bulk density as well as color reflectance b^* and L^* . Using these fluctuations, we are able to provide an insolation-tuned chronology for the last 200 ka (MIS1–7). This chronology agrees well with an independent age model derived from relative paleointensity and shows that moisture-driven monsoonal changes happened synchronously to $\delta^{18}\text{O}$ changes reported for Chinese cave records. Accordingly, grain-sizes were coarser and marine productivity was higher during insolation minima, indicative for an enhanced NE monsoon during glacials and stadials. Our proxies indicate teleconnections to both high northern and high southern latitudes.

Using orbital cyclicity detected in sediment physical properties of all seven sites, we also tuned high-resolution color reflectance data (L^*) to the LR04 benthic isotope stack to obtain new constraints on the timing of depositional changes since the Middle Pleistocene (Weber and Reilly, 2018, Quaternary Science Reviews). Accordingly, above turbiditic Unit 1, the lower hemipelagic Unit 2 commenced around 1.25 Ma, and terminated around 0.68 Ma - the start and end of the Middle Pleistocene Transition (MPT), respectively. The dominantly turbiditic Unit 3 ends around the time of the Mid-Brunhes Transition (~MIS 12). The following turbiditic Unit 4 likely changed asynchronously across the eastern fan during MIS 8-7, where it transitions into the topmost hemipelagic Unit 5. All in all, we find evidence that deposition across the lower Bengal Fan changed with the evolution of Pleistocene monsoon, climate, and sea level and hence responded to external controls on sediment accumulation and fan architecture rather than to fan-internal, autocyclic mechanisms alone.

Palynological evidences of major climatic events of the past two millennia from Southeast coast of India

Jyoti Srivastava, Anjum Farooqui
Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

A high-resolution palynological reconstruction of vegetation succession in two sedimentary profiles from the Godavari delta, India was analysed to decode the events of extreme climatic variability during the last 2 millennium. These historical records of natural climate variability are crucial in quantifying the future climate change with enhanced anthropogenic inputs. Climatic periods inferred from the pollen record include (1) a basal warm/humid period (BC 250–AD 450) with dominance of mangroves and tropical moist deciduous taxa, (2) a gradual weakening of monsoon leading to arid conditions with a decline in true mangroves and arboreal taxa comparable to Dark Ages Cold Period (AD 450-910), (3) a Medieval Warm Period (AD 910–1385) with a strengthened summer monsoon as evidenced by rejuvenation of true mangroves and tree taxa, (4) a relatively cool and dry condition with abundance of dry deciduous and non-arboreal taxa possibly corresponding to Little Ice Age (AD 1385–1850) with a weakened monsoon, and finally (5) the current warm period, since AD 1850. A semiquantitative aridity index based on variations in humidity has also been used to detect for the first time in India the millennial-scale climatic cyclicality in the pollen record. The Little Ice Age is recorded with high aridity values between AD 1385 and 1850, with a peak at AD 1700 (Maunder Minimum) whereas the Roman and Medieval Warm Periods are noticed through low aridity values at BC 250-AD 450 and AD 910-1385, respectively.

Abstract

A number of records provides evidence of Asian monsoon variability over the last 125, 000 years. However, the regional response of the tropical hydroclimate to increasing greenhouse gas concentrations and global temperatures and the controlling factors modulating this response remain among the most challenging questions. This study focuses on the dynamics of the Indian Summer Monsoon (ISM) subsystem, which brings most of the annual rainfall in areas such as Central India, in the so-called Core Monsoon Zone (CMZ) where the ISM has its most representative expression.

This work seeks to characterize changes in vegetation and monsoon rainfall in Northeast India, within the CMZ, in response to the large global climate changes that operated during the last and penultimate deglaciations and during the current and last interglacial periods. We will present results derived from pollen analysis of marine sediments from the IODP site U1446. This site, which covers the last 1.4 Myr, was collected during the IODP expedition 353 "Indian Monsoon Rainfall" on the eastern Indian margin off the Mahanadi river exit, recruiting pollen from the vegetation of this river basin. Pollen data will be compared to sea surface temperatures derived from alkenones analysed in the same sample set than pollen. We will also present results on MIS 11c (~ 400 kyr ago), one of the best orbital analogues of the current interglacial, to examine further the ISM response during periods of weak insolation forcing (MIS 1 and 11c), contrasting with the strong insolation forcing of last interglacial period (MIS 5e).

Our preliminary results show that during glacial-interglacial transitions the Mahanadi landscape dramatically changed from a grassland and marshland dominated vegetation with very sparse trees to a temperate moist deciduous forest inland with a well-developed mangrove in coastal areas, showing the strengthening of the monsoon rainfall. Over the course of the interglacial periods, mangrove strongly reduced and grassland expanded as boreal summer insolation decreased.

Abstract

The Indian Summer Monsoon (ISM) bringing up to 80-90% of the annual rainfall in areas such as Central India, in the so-called Core Monsoon Zone (CMZ), is highly variable and sensitive to global climate change. Its impact affects the daily lives of billions of people (IPCC 2014) and has had large devastating impacts on populations and economies in the past. However, predictability of the ISM variability by numerical simulations are still uncertain, especially because processes underlying the natural variations of the ISM at the different timescales remain unclear and are still debated.

With the aim to better constrain the ISM variability in response to abrupt climate changes or changing boundary conditions, such as CO₂ increase, ice sheet melting and insolation change, we investigated samples from the IODP Site U1446 collected during the Expedition 353 "Indian Monsoon Rainfall".

Our study is based on an original approach that consists of pollen analysis of marine sediments. Pollen assemblages at IODP Site U1446 represent an integrated image of the regional vegetation, and therefore climate, in the Mahanadi hydrological basin, which is ideally located in the eastern part of the CMZ. This approach enables a direct comparison of terrestrial and marine tracers without chronological ambiguities.

We present herein the preliminary results of our palynological investigations. Pollen data is compared with others records from site U1446, such as SST estimates derived from alkenones. The outstanding nature of the record provides insight on the key mechanisms driving the ISM variability at orbital and millennial scales. More specifically, we document the ISM response to insolation changes in a glacial context (MIS 4 to MIS 2) and to the abrupt climate changes of the last glacial period. At centennial to millennial time scales, we attempt to discriminate the respective influence of the northern high latitude forcing, controlling the pace and magnitude of weak monsoon intervals, from the subtropical forcing, impacting Indian Ocean surface temperatures and, thus regional evaporation feeding summer rainfall in India.

A ~6000 year high resolution continuous paleoproductivity and paleoenvironmental record reconstructed from the paleolake sediments of Pinder valley, Garhwal Himalaya

Varsha Rawat¹, Suman Lata Rawat¹, P.S. Negi¹, B.S. Kotlia²

¹Wadia Institute of Himalayan Geology, Dehradun, India. ²Kumaun University, Nainital, India

Abstract

The Holocene epoch which spans ~11,700 years before present is considered significant for understanding the natural variability of climate before the industrialization in the absence of anthropogenic activities. Indian Summer Monsoon (ISM) which is of great socio-economic importance to millions of people of Indian sub-continent has varied during the Holocene. Several short and long term weakening and strengthening phases of ISM have been recorded during this time interval which have been linked to the evolution and collapse of various civilizations. Thus, comprehensive study of spatio-temporal variability of ISM during Holocene will help in understanding the past climate events and their impact on human settlements. In this regard, total organic carbon (TOC), stable carbon isotopes ($\delta^{13}\text{C}$), grain size, major and trace element concentrations were analyzed to reconstruct the paleoproductivity and paleoclimatic variability at centennial scale during the last ~6,000 cal yr BP from paleolake sediments of Bedni, Pinder valley, Garhwal Himalaya, India. In this study, evidences of several centennial scale cold-dry and warm-wet events were recorded that corresponded with global climatic events e.g., cold-dry periods between ~2830 and 2630 cal yr BP and ~500 and 320 cal years BP (AD ~1450 to 1630) correspond with the Bond event 2 and Little Ice Age respectively. The warm and wet periods between ~2630 and 1750 cal yr BP and ~1010 and 760 cal yr BP (AD ~940 to 1200) correspond to the Roman warm period and Medieval Warm Period respectively.

P-1460

Mid- to late Holocene changes in the Indian Summer Monsoon: a multi proxy record from Bhagirathi valley, Northwest Garhwal Himalaya

Suman Lata Rawat, N.R. Phadtare
Wadia Institute of Himalayan Geology, Dehradun, India

Abstract

The agricultural based socio-economic development of over a billion people depends on the moisture availability from the Indian summer monsoon (ISM). To understand the future precipitation variability, an understanding on the past climate and its forcing mechanisms are essential. Significant spatial-temporal variability in precipitation at regional scale has been observed in the Himalayan basins. Several studies have demonstrated that Holocene climate in Himalayan regions is more complex and heterogeneous than other parts of the Northern hemisphere. Therefore, for precise and regional understanding of the Holocene climate history of Himalaya, high density as well as high resolution and multi-disciplinary palaeoclimate data are indispensable. A new multi proxy dataset (pollen, loss on ignition and magnetic susceptibility) constrained by AMS ^{14}C radiocarbon dates from the peat deposit located at an alpine meadow of Dayara, Bhagirathi valley, Northwest Garhwal Himalaya is presented. The dataset provides a high resolution continuous palaeovegetation and palaeomonsoonal variability for the past ~ 6100 cal yr BP. The peat accumulation in Dayara region has begun at ~ 6100 cal yr BP, which is marked by the sharp lithologic contact with the underlying debris flow sequence and an abrupt decline in detrital influx. Between ~ 6100 and 5930 cal yr BP, pollen assemblages were dominated by the diverse herbaceous and tree taxa. The tree taxa characterised by the coniferous and broad-leaved trees, indicates a mixed forest landscape in the region in the prevalence of reasonably warm and wet climate. The progressive decrease in percentages of evergreen tree pollen and LOI% from ~ 5930 to 5320 cal yr BP indicates a relatively reduced ISM precipitation than the preceding pollen assemblage. From ~ 5320 to 3690 cal yr BP and ~ 1860 to 950 cal yr BP, percentages of evergreen broad-leaved tree pollen decreased, while coniferous tree pollen and magnetic susceptibility increased substantially, indicating a deterioration of summer monsoon in the Bhagirathi valley. An increase in broad-leaved, herbaceous taxa and fern over conifers, and decrease in magnetic susceptibility during ~ 3690 to 1860 cal yr BP and ~ 950 to 500 cal yr BP suggest warm and wet climatic conditions during these periods. The high resolution multi proxy palaeoclimate record from the ISM dominated Dayara peat profile, Bhagirathi valley reflects rapid response of ecosystem to even small scale changes in ISM precipitation. The large scale (millennial) palaeovegetation and palaeoclimatic changes reconstructed from Dayara peat profile are in accordance with the palaeoclimatic records of other ISM dominated regions, whereas small scale (decadal to centennial) palaeovegetation and palaeoclimatic variability is due to the variation in altitude, basin topography and distance from the sea.

P-1461

Late Holocene hydroclimate changes in central Taiwan inferred from pollen and Itrax XRF elements records from an alpine pond

Liang-Chi Wang

Department of Earth and Environmental Sciences, National Chung Cheng University, Chiayi County, Taiwan

Abstract

We studied pollen, grain size, and the Itrax XRF element analysis from a lacustrine core, in central alpine Taiwan, Tunlumei Pond (TLM), to investigate vegetation dynamics and environmental changes during the past 2,400 cal yr BP. The trend in variation between percentages of temperate coniferous forest taxa and wetland taxa suggested that climate changed from cold/dry to warm/humid climate from 1,800 cal yr BP, reflecting the fluctuation of East Asian summer monsoon intensity. The rapid increase in mean grain size, and the ratios of Sr/Ti and Rb/Ti indicate a strong variation in local hydroclimatic condition at 1,510 cal yr BP and the Little Ice Age (LIA). The extremely precipitation may be caused by the intense paleo-typhoon activity, correlating to ENSO fluctuation, which increases strong or/and frequent typhoons passing through Taiwan and the southern China.

Interpreting event layers in lacustrine records using XRF core scanning

Ludvig Löwemark¹, Tsai-Wen Lin¹, Jyh-Jaan Steven Huang², Alice Chien-Yi Liao¹

¹Department of Geosciences, National Taiwan University, Taipei, Taiwan. ²Institute of Geology, University of Innsbruck, Innsbruck, Austria

Abstract

Lacustrine sedimentary records often contain discrete layers of distinctly different color and composition, compared to the general lithology. The origin of these layers are often the subject of animated discussions. Are they representing periods of distinct events or shifts in the climate system? Are they caused by stochastic variations in lake-internal processes? Or, are they caused by lake-external processes acting in the catchment?

Interpreting these layers often requires using a mosaic of different proxies to solve the puzzle, as single proxy records can give very misleading results. Here elemental ratios (or log ratios) obtained through XRF core scanning can provide a powerful tool to help disentangle the relative influence of the different processes. Based on examples from a number of lakes in Taiwan, it is demonstrated how activities and processes such as landslides, infrastructure construction, typhoon events, and lake level fluctuations can be distinguished from climatic trends and shifts.

An improved understanding of the different processes that are recorded in the sediment is particularly important when dealing with late Holocene material, because agriculture, forestry and other human activities may locally overshadow natural climate variability.

Abstract

We present a review of the application of XRF data in Tasmania to date with details of a selection of sites spanning the west-east environmental gradient across Tasmania from a wetter, rainforest dominated west to a drier, sclerophyll dominated vegetation in the east. XRF data is interpreted in light of complementary pollen, charcoal and other sediment analyses and depositional settings.

P-1464

Evaluation of quality assurance and quality control (QA/QC) of XRF-core scanning data by a novel depth-dependent local similarity approach

Jyh-Jaan Steven Huang¹, Arata Kioka¹, Karin A. Koinig^{2,3}, Christoph Daxer¹, Jasper Moernaut¹, Michael Strasser¹
¹Institute of Geology, University of Innsbruck, Innsbruck, Austria. ²Institute of Ecology, University of Innsbruck, Innsbruck, Austria. ³Institute for Alpine Environment, Eurac Research, Bozen, Italy

Abstract

XRF-core scanners allow fast, non-destructive, and ultra-high resolution analyses of relative element abundances directly on the sedimentary archives and therefore have revolutionized paleo-environmental research over the last decade. Since the XRF-core scanning (XRF-CS) data are originally outputted as elemental peak area (counts), a timely- and economically-efficient QA/QC evaluation is essential towards robust data processing and interpretations. To date, several approaches have been proposed to evaluate the repeatability and/or reproducibility of XRF-CS results. However, most of these methods focus on reporting the entire trends of replicate measurements in the original scanning resolutions, while elements are usually not evenly distributed along the scanning samples or show isolated perturbations at certain depths. Those QA/QC evaluations, therefore, may be over- or underestimated and thus led to misuse and misinterpretation of XRF-CS data, especially for the elements with either low concentration or low detectability. Here we propose a depth-dependent local similarity approach to evaluate the repeatability of XRF-CS data locally. By using this mathematical method, the correlation coefficients of replicate scanning measurements at a given scanning point can be calculated and visualized in order to appraise the performance of each individual element throughout the sample. Moreover, our method can also determine the optimal calculated resolution with reasonable correlation coefficient by changing the depth window. To verify our new method, we further used two alpine lacustrine XRF-CS datasets obtained from the Eastern Alps, including Lake Fischersee (high-organic vs. glacially detrital sediments) and Lake Millstättersee (laminated sediments comprising event deposits). Our method can therefore better address the long-standard challenges among the XRF-CS community, including which quantitative and/or relative-trend information of which elements within which core intervals at which scanning resolution can be reproduced, allowing reliable analyses and scientific interpretations of XRF-CS data.

P-1465

An application of ITRAX XRF scanning of lake and marsh sediment cores for palaeotempestology.

Emma V. A. Readitt, Joanne Egan, Claire Jones, Cherith Moses
Edge Hill University, Ormskirk, Lancashire, United Kingdom

Abstract

Hurricanes are one of the world's most destructive natural disasters and it is believed that these large scale events are increasing with global warming. As instrumental records only date back to the 1850's, it is essential to examine longer time periods to analyse the effects and aid future predictions. Palaeotempestology is the study of hurricane events during the Holocene by a multitude of geological proxies. This study uses a multi-proxy approach to analyse Holocene hurricane frequency and intensity and to assess environmental change as a result of these large scale events at Gulf Shores, Alabama, USA. It highlights the potential of ITRAX XRF core scanning as a tool for palaeotempestology.

In May 2018, two 6 m lake cores and one 3 m marsh core were extracted from Middle Lake and Little Lake Marsh, Alabama, USA. The cores were split open and inspected for visible sand layers. Identifying visible sand layers is the most commonly used method for initially identifying hurricanes. Sand layers represent hurricane presence as during a hurricane event, storm surges and strong winds transport sand and beach debris inland and deposit into lake and marsh environments.

Once visually inspected, the cores were then processed through an ITRAX scanner at the University of Manchester, U.K. The cores were scanned at 1 mm intervals, with a 30 s dwell time, using a Molybdenum x-ray tube. High-resolution photographic images and radiographic images were acquired at 200 μm resolution throughout the cores.

Preliminary results of the XRF count data and the ratios; Si/Ti, K/Ti, Ca/Ti, Fe/Ca will be presented, highlighting the potential of ITRAX XRF core scanning as a tool for palaeotempestology.

P-1466

Improvement of the data shifting problem when interpreting XRF core scanner data from sedimentary cores

Chien Yi Liao, Ludvig Löwemark
National Taiwan University, Taipei city, Taiwan

Abstract

XRF core scanner has an important place in paleoenvironmental research to help reconstruct paleoclimatic records. It can efficiently provide nondestructive, continuous data for both lake and marine sedimentary cores, as well as for many other kinds of samples. In order to get a reliable downcore XRF data, consistent parameter settings should be used during scanning of different sections of the same core to minimize differences between sections and generate a continuous result. However, despite using identical settings, shifts between different sections are sometimes observed in the elemental data. Previous studies have demonstrated the influence of the water content during core scanning. However, a number of other factors may cause the shifting of data. For example, the data tuning process of the Q-spec software, or different oxidation level between different sections leading to migration of elements towards or away from the sample surface can both cause systematic shifts between core sections. Our aim is to use different methods to understand the underlying processes that are responsible for the observed discontinuities, and outline the most efficient ways to minimize the shifting in order to produce authentic and verifiable results when interpreting XRF core scanner data from sedimentary cores.

The interpretation of micro-XRF geochemical data from a tropical nearshore basin in Kingston Harbour, Jamaica

Kadane Coates¹, Michael Burn², Debbie-Ann Gordon-Smith¹, S. Yoshi Maezumi², Suzanne Palmer³

¹Department of Chemistry, The University of the West Indies, Mona, Kingston, Jamaica. ²Department of Geography and Geology, The University of the West Indies, Mona, Kingston, Jamaica. ³Department of Life Sciences, The University of the West Indies, Mona, Kingston, Jamaica

Abstract

Hunts Bay is a shallow, eutrophic embayment located in Kingston Harbour, the 7th largest natural harbour in the world. The bay is one of the most polluted in Jamaica and receives freshwater and sediment input from multiple sources including rivers, storm drains and gullies that traverse the city of Kingston and nearby alluvial plains. Environmental management efforts at Hunts Bay have been stymied by a paucity of knowledge about its natural pre-industrial state, as well as insufficient understanding of the key drivers of environmental change in these settings. To this end, we investigate both natural and anthropogenic drivers of environmental change in the Bay using ITRAX μ -XRF geochemical data from sediment cores recovered from Hunts Bay. However, the interpretation of elemental data from marginal marine environments is challenging given that these systems are highly dynamic and respond rapidly to consistently changing coastal processes leading to significant signal variability over relatively short spatiotemporal scales.

Our data reveal that positive excursions in the molybdenum incoherent:coherent scattering (incoh/coh) ratio are consistently associated with organic-rich lithostratigraphic units and support the use of the incoh/coh ratio as a suitable proxy for organic matter. Similarly, the interpretation of the Ti and Fe signals are straightforward because these elements are strongly positively correlated across the basin and consistently reflect changes in both lithostratigraphic and radiographic profiles. Therefore, the signal variability of these elements is likely associated with changes in terrigenous material with a combined fluvial and aerial provenance. In contrast, the signals for Ca and Sr are more variable spatiotemporally because of the diverse sources of Ca and Sr (principally authigenic versus detrital) and this underlies one of the challenges of using these elements in the palaeoenvironmental reconstructions of tropical karstic settings. In Hunts Bay, the possible sources of Ca and Sr were differentiated based on the nature of their correlation with detrital elements (K, Ti and Fe). A negative correlation was interpreted as suggesting authigenic precipitation of calcium carbonate (or a marine source) while a positive correlation implied a detrital source. The interpretation of the Mn/Fe ratio is also less straightforward because the signal in some lithostratigraphic units might possibly reflect early and post-depositional diagenetic chemistry of Mn rather than a palaeoenvironmental signal. Additional multiproxy analyses (particle-size and palaeoecological analyses) of the sediment cores are ongoing in order to better constrain our interpretation of the geochemical data.

μXRF analysis of Lateglacial Swedish clay varves

Rachel Devine¹, Adrian Palmer¹, Alison MacLeod², Stefan Wastegård³, Ian Matthews¹

¹Royal Holloway, University of London, Egham, United Kingdom. ²University of Reading, Reading, United Kingdom.

³Stockholm University, Stockholm, Sweden

Abstract

One of the most widely recognised varve chronologies is the Swedish Timescale (STS). It is based on cross-correlation of numerous clastic varve series and provides an annually resolved record of Fennoscandian Ice Sheet retreat. However, the total number of varves in the STS is contested and several researchers have identified that there are “missing varves”, in particular 700-900 years are missing during the Younger Dryas - Pre-Boreal period (12.9-11.35 ka BP). One explanation for missing varves is a lack of precision in macroscale varve counts which are the traditional means of developing site varve chronologies. This emphasises the need to analyse STS varve records at the microscale however, microscale sediment analyses have not been routinely applied to these varved sediments. Whilst thin section analysis is commonly applied to varve records to generate precise varve chronologies, production is extremely labour-intensive and costly. This project explores the potential application of the much cheaper and non-destructive μXRF analysis as a glaciolacustrine varve counting tool using sediments from the STS.

We present the results of μXRF analysis of clastic varves from three Lateglacial/early Holocene records in Östergötland, Sweden. Principal Component Analysis of normalised μXRF data was used to determine which element ratios demonstrated the greatest variation and therefore were useful in detecting grain size changes between the coarse-grained (summer) and fine-grained (winter) lamination within a single varve. Element ratios were site-specific, reflecting local sediment sources within the Baltic Ice Lake basin. When compared to particle size analysis, X-radiographs, core surface images and thin sections, changes in μXRF element ratios (at 200 μm resolution) appear to mirror grain size changes within a single varve. However, varves counted under thin section were not consistently identified by μXRF element ratios due to the presence of thin laminations (<1 mm). For greater than 1cm-scale varves, there are 2-3% fewer varves counted from μXRF analysis than from thin sections. However, for <1 mm scale varves, the difference between thin section and μXRF counts can be as high as 40%.

The results demonstrate that μXRF analysis is effective at identifying grain size changes within cm-scale varves. However, varve count data demonstrate that thin section analysis is the most effective method for varve identification and counting. If continuous thin section analysis is not feasible within the time and cost constraints of the researcher, μXRF analysis, in combination with X-radiographs and core images, can be used to produce a minimum varve count. If feasible, targeted thin sections across a range of varve thicknesses should be produced to estimate the associated varve count error if μXRF analysis is the primary varve count method.

P-1469

Using high-resolution geochemical data from XRF core scanning to interpret major climatic events at the Uddelermeer site (The Netherlands)

Patricia Gadd¹, Henk Heijnis¹, Leonie Peti², Stefan Engels³

¹Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia. ²University of Auckland, Auckland, New Zealand. ³Birkbeck, University of London, London, United Kingdom

Abstract

High-resolution X-ray fluorescence (XRF) scanning data is used as a palaeoclimate proxy on a long sediment record retrieved from Lake Uddelermeer. Lake Uddelermeer is the only lake in The Netherlands to contain a continuous record of environmental and climate change from the late Pleistocene to present. Due to its unique character, the lake has been studied by various research groups since the 1950s. Here we focus on a newly retrieved sediment core which has been radiocarbon dated and for which a variety of palaeoecological and palaeoclimatological data is available. We scanned the 15.6 m sediment sequence at 200 μm interval and geochemical proxies were utilised to infer changes in the lake system during major climatic events, and compared our results to existing palaeoecological and palaeoclimatological data from the same sediment sequence. Commonly used proxies such as Si/Ti can imply changes in biogenic silica and Rb/Sr can suggest chemical weathering. These proxies were looked at in detail in conjunction with the dates to confirm the timing and impact of the following major events: the Bølling-Allerød, Younger Dryas, Pre-boreal oscillations, the 9.3 ka, 8.2 ka, 2.8 ka and the Little Ice Age.

Additionally, the use of high-resolution XRF scanning can be very useful for finding crypto tephra, and in this presentation, we will explore the potential occurrence of the Vedde Ash (Iceland) and the Laacher See Ash (Germany) in the sediment sequence, as well as other unidentified crypto tephra during the Last Glacial termination.

P-1470

μ -XRF-inferred evolution of the Orakei maar paleo-lake (Auckland, New Zealand)

Leonie Peti, Paul C. Augustinus

School of Environment, The University of Auckland, Auckland, New Zealand

Abstract

Late Quaternary lake sediment cores are important archives of past environmental and climatic change. Maars, lakes formed in volcanic craters, are phenomenal depositional basins thanks to the small size of the catchment. Thus, sediment at the lake bottom can be understood as a direct record of processes in the atmosphere and water column. An important aspect of paleoclimate reconstructions are changes in the geochemical composition of the sediment deposited in the lake.

Non-destructive μ -XRF core scanning is an increasingly common and powerful technique for the study of Quaternary sediment sequences. Changes in the elemental composition of the sediment allows interpretation of the depositional processes and origin of the sediment.

The Orakei maar in the Auckland Volcanic Field (AVF) presents an outstanding, long and high-resolution record from northern New Zealand. The Orakei sediment sequence is a crucial window into the climatic past of the SW Pacific. Down-core elemental variations recorded by the μ -XRF Itrax core scanner allow the reconstruction of the maar's evolution from the crater-forming phreatomagmatic eruption to a rim-breaching sea-water incursion in the early Holocene:

The local basement Waitemata sandstone is overlain by unconsolidated basaltic ejecta derived from the Orakei eruption resulting in a crater soon after filled by a lake. A small interval indicating a shallow lake with oxic conditions is overlain by finely laminated sediment with anoxic bottom water followed by an episode of common mass movement deposits from the crater rim identified by the geochemical signature of the basaltic eruptive material from the rim. Further alternating episodes of deep lake sediment and fast deposition from the crater rim are overlain by a multitude of locally-sourced (AVF volcanoes) basaltic tephra layers causing large-scale disturbance in the area which is reflected in the sediment deposited at the bottom of the Orakei maar lake. Low Fe/Mn indicating oxic bottom water is recorded during massive fine sediment and overlying greyish sediment with wavy laminations. A return to calmer depositional conditions is manifested in laminated sediment overlain by coarser fluvial sediment deposited by the Pourewa creek breaching the crater rim. The upper interval of the Orakei sediment sequence consists of sediment deposited in a shallow lake overlain by peat under anoxic conditions. On top of the peat follows marine mud deposited since the post-glacial sea-level rise which breached the Orakei maar crater wall and turned the lake into a tidal basin.

Palaeoenvironmental insights from end-member modelling of high-resolution XRF core-scanning data

Marina A. Morlock¹, Hendrik Vogel¹, Flavio S. Anselmetti¹, James M. Russell², Martin Melles³, Satria Bijaksana⁴
¹Institute of Geological Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ²Department of Earth, Environmental, and Planetary Sciences, Brown University, Providence, USA. ³Institute of Mineralogy and Geology, University of Cologne, Cologne, Germany. ⁴Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung, Bandung, Indonesia

Abstract

Lacustrine and marine sediments often record a complex history of environmental change. However, disentangling the different depositional processes leading to the signals of interest in a sediment record can be challenging. Recently, X-ray fluorescence (XRF) core scanning has become a standard technique in sediment-core processing, facilitating the generation of geochemical data sets down to a spatial resolution of 200 μm . The resulting large data sets call for the application of statistical tools to identify and analyse different sedimentary processes interacting through time.

We present a study of sediments from Lake Towuti (2.75°S, 121.5°E), one of the oldest and deepest lakes in Indonesia. We combine high-resolution (0.5 cm) XRF core scanning of Lake Towuti sediments, covering the last \sim 1 million years, with an end-member modelling analysis to get an objective and quantitative description of the lithologies in our sediment sequence. End-member modelling is a statistical tool to unmix data into characteristic structures of -in this case- similar elemental composition. Analogous to grain-size analysis, where end-member modelling is more frequently applied, the underlying concept is that different sedimentary processes are reflected in characteristic elemental compositions, e.g. terrestrial influx is characterised by variations in Al and Ti concentrations.

For Lake Towuti sediments, end-member modelling of the XRF data set separates processes related to climate, diatom productivity, redox processes, post-sedimentary mineral formation, and tectonics. Sediment stratigraphy across the 100-m record based on the end-member modelling results generally matches the initial visual core description, but shows more detailed variations, particularly in the central part of the record. We show that the combination of high-resolution XRF core scanning with end-member modelling can serve as a tool to adequately extract the palaeoenvironmental narrative of sedimentary systems. Particularly in complex systems with multiple distinct sediment sources and significant changes in the depositional environment through time, end-member modelling is advantageous over more commonly used statistical methods applied to XRF data sets, such as clustering or principal component analysis (PCA).

The potential of using μ XRF records to explore climate change during the Younger Dryas period: challenges in interpreting elemental data.

Alice Carter-Champion^{1,2}, Ian P. Matthews¹, Adrian P. Palmer¹, David J. Thornalley²

¹Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom. ²Department of Geography, University College London, London, United Kingdom

Abstract

Investigation of the late Quaternary indicates that glacial terminations typically include abrupt millennial scale climatic changes, thought to play an important role in the mechanics of how deglaciations proceed. During the last deglaciation, the Younger Dryas (c. 12.9 – 11.7 ka BP) was a partial return to more glacial-like conditions across the North Atlantic region. Both the abrupt onset and rapid termination of the Younger Dryas have been the focus of palaeoclimate studies aiming to understand the cause and nature of these abrupt shifts in climate state.

Here we focus on Scotland, where the local expression of the Younger Dryas, the Loch Lomond Stadial (LLS), resulted in the growth of an ice-cap covering much of the Western Highlands and local valley glaciation in the eastern uplands. The timing of the advance and retreat of this ice-cap is the subject of much debate, with estimates for the onset of recession ranging from the mid-stadial (12.5 ka cal BP) to the very early Holocene (11.7-11.5 ka cal BP). The early deglaciation estimates are thought to be driven by the establishment of relatively warm dry summer temperatures leading to ice recession, while the late deglaciation hypothesis argues for the predominant signal in glacier advance being driven by changes in the precipitation-bearing westerly wind systems. In order to examine these competing hypotheses, high-resolution sites that are spatially comprehensive and beyond the LLS glacial limits are required alongside a range of palaeoenvironmental proxies which provide temperature and/or precipitation data. Several such sites exist across the region and these contain one or more proxies of temperature, but also require a detailed understanding of the sedimentary context which may in turn reveal information regarding landscape stability.

μ X-ray fluorescence (μ XRF) scans provide semi-quantitative down-core variations in a number of elements. These data have been used to understand how lake characteristics may have changed through time, with elemental variations acting as a proxy for a number of different environmental variables e.g. lake productivity, catchment erosion, and turbidity. These indicators are thought to reflect periods of stability and instability within lake systems and are ultimately linked with climatic variability particularly changes in snow melt and storminess. Here we present new μ XRF data from 5 lake sites across Scotland to explore the propagation and variability of environmental changes during the LLS, and to further examine the rapidity of environmental changes towards the end of the Last-Glacial Interglacial Transition. These records are paired with existing palaeoecological proxies to also assess the effect of site-specific sedimentological changes and whether these clarify or obfuscate the regional expression of climatic change.

Interpreting XRF-derived CaCO₃ records from the Agulhas Plateau during the past 150 ka: Surface ocean calcareous productivity vs CaCO₃ dissolution

Miros Charidemou^{1,2}, Ian Hall³, Martin Ziegler⁴, Suzanne MacLachlan^{1,2}

¹National Oceanography Centre, Southampton, United Kingdom. ²British Ocean Sediment Core Research Facility, Southampton, United Kingdom. ³Cardiff University, School of Earth and Ocean Sciences, Cardiff, United Kingdom.

⁴Utrecht University, Department of Earth Sciences, Utrecht, Netherlands

Abstract

Past variations of the Atlantic meridional overturning circulation are believed to have affected Pleistocene climate change by altering the patterns of oceanic heat transport (e.g., Lynch-Stieglitz et al., 2007, *Science*; Adkins, 2013, *Paleoceanography*) and by changing the quantity of respired carbon stored in the deep ocean (e.g., Freeman et al., 2016, *Nature Communications*). During glacial intervals, northern-sourced Atlantic deep waters are thought to have shoaled while southern-sourced deep waters expanded to fill a larger proportion the abyssal and deep ocean (e.g., Curry and Oppo, 2005, *Paleoceanography*; Marchitto and Broecker, 2006, *Geochemistry Geophysics Geosystems*). Differences in the carbonate ion concentration of northern- and southern-sourced deep waters result in changes in the carbonate saturation state of the ocean and variable preservation of CaCO₃ on the seafloor on glacial-interglacial timescales. Stratigraphic records of CaCO₃ can therefore act as a proxy for past changes of deep ocean circulation.

We present XRF core scanning data from sediment core MD02-2588 which was recovered from a calcareous contourite drift located on the southwestern flank of the Agulhas Plateau (41°19.90'S, 25°49.40'E, 2907 m water depth). Today, the core site underlies the Southern Ocean Subtropical Front and is situated within the transition zone between North Atlantic Deep Water and Circumpolar Deep Water. We examine the XRF data alongside records of bulk sediment geochemistry and stable isotopes and elemental ratios measured in foraminifera.

We find that the XRF-derived Ca record of sediment core MD02-2588 closely matches the downcore record of calcium carbonate content. Bulk sediment CaCO₃ content is controlled by a complex interaction between various environmental drivers, including surface ocean calcareous productivity, CaCO₃ dissolution on the seafloor, and dilution by other sediment components. In this study, we attempt to determine the relationship between CaCO₃ content, bottom water carbonate saturation state and surface ocean productivity at the MD02-2588 core site during the last 150 ka. We then examine XRF-derived Ca records from a suite of neighbouring sites to develop a regional interpretation of the temporal and spatial variability of surface ocean productivity and bottom water carbonate saturation state in the context of regional and global climate change.

Fe and Mn in lake sediments: spatiotemporal patterns and potential for redox reconstructions - a multicore study from Lake Łazduny (Poland)

Maurycy Żarczyński¹, Dirk Enters², Wojciech Tylmann¹

¹University of Gdańsk, Gdańsk, Poland. ²Lower Saxony Institute for Historical Coastal Research, Wilhelmshaven, Germany

Abstract

Changes in water oxygenation, especially recently emerging hypolimnetic anoxia, are potential threats for aquatic environments. Understanding past water mixing regimes is an important tool for mitigation of such human-induced changes. The utilization of geochemical proxies of past water-column oxygenation such as variations of the Fe and Mn content in lacustrine sediments is often limited due to their complex relationships with allochthonous inputs. These relations vary within different locations in the same basin. We use 31 surface cores from small and deep Lake Łazduny (Masurian Lakeland, NE Poland) to study spatiotemporal changes of selected elements to see if Fe and Mn concentrations are suitable proxies of past water oxygenation. Ongoing limnological monitoring (water column temperature and oxygen concentrations) indicates that the lake is either dimictic, monomictic or meromictic depending on the annual weather conditions. Sediment cores collected from different depths across the basin indicate that varves are preserved at depths greater than approximately 14 m. All the cores were analyzed with a μ XRF scanner to trace their elemental composition. A Robust Principal Components Analysis (RPCA) was performed on the μ XRF data to assess the internal relationships between elements. Additionally, material from the topmost 1 cm of the cores was used for the geochemical characterization of the surface sediments to determine spatial relationships between different components. Bulk elemental composition of these samples were measured by μ XRF analysis and with an elemental analyzer (CNS). Additionally, biogenic silica concentrations were determined. RPCA suggests that both Fe and Mn are mostly independent from the terrestrial inputs, as correlation with erosion proxies such as Ti or K is only incidental with no apparent depth-related pattern. Accumulation of allochthonous elements (Ti, K) are highest near the lake shores, while redox-dependent elements (Fe, Mn) dominate in the deeper parts of the lake despite low oxygen concentrations. This could be an effect of sediment focusing towards the deeper parts of the lake, where even low amounts of oxygen could prevent net loss of Fe and Mn. In this study we show that the interpretation of geochemical proxies could be challenging or misleading if spatial patterns between geochemical proxies are not known.

Disentangling climate and human factors in the settlement of the Maori in the North Island of New Zealand

Ronald Lloren^{1,2}, Paul Augustinus³, Nemiah Ladd^{1,2}, Nathalie Dubois^{1,2}

¹Department of Surface Waters Research and Management, Eawag, Überlandstrasse 133, CH-8600 Dübendorf, Switzerland. ²Department of Earth Sciences, ETH Zürich, Sonneggstrasse 5, CH-8006 Zürich, Switzerland. ³School of Environment, University of Auckland, School of Environment, University of Auckland, New Zealand

Abstract

Based on archaeological evidence, Maori landed on New Zealand around 700-800 cal BP. However, what caused Maori migration is still an open question and still has no direct evidence: was it the search of new resources brought about by human exploitation? Or was it climate induced? The cause could also be a human-climate-environment nexus.

Here we present down core leaf wax carbon and hydrogen isotopic record coupled with XRF data (Ti), Loss-on-ignition (LOI) based total organic carbon (TOC) and geophysical data (Magnetic Susceptibility) from Lake Pupuke in the North Island of New Zealand, spanning the past ~1700 years.

Ti showed an almost constant trend from 160 cm to 70 cm (~1700 to 700 yrs cal BP) then an overall varying increasing trend towards 15 cm (~200 yrs cal BP). It then showed an abrupt drop towards the top. Likewise, MS counts showed a slight overall decreasing trend from 160 cm to 70 cm (~1700 to 700 yrs cal BP) and then an overall varying increasing trend towards 15 cm (~200 yrs cal BP) similar to Ti. LOI based TOC showed an elevated concentration from 160 cm to 70 cm (~1700 to 700 yrs cal BP) compared to concentration from 70 cm (700 yrs cal BP to present) to the top of the core. LOI based TOC mirrors its overall trend of MS all through out the core.

The opposing overall varying increasing trends of Ti and MS data versus LOI based TOC from 70 cm to the top (700 yrs cal BP) may imply contributions from anthropogenic and climate-induced changes. Leaf wax carbon and hydrogen isotopic record would further our interpretation of the down-core data for the climate. These sedimentary footprints will help us to further define factors that triggered the arrival of early Polynesians on the North Island of New Zealand as well as possible implications of concurrent climatic changes.

Tephra and cryptotephra in the Ross Sea, Antarctica marine deposits, correlated with rapid, non destructive magnetic susceptibility and XRF fluorescence methods.

Alessio Di Roberto¹, Ester Colizza², Paola Del Carlo¹, Andrea Gallerani³, Federico Giglio³, Stefano Miserocchi³
¹Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy. ²Dipartimento di Matematica e Geoscienze, Università degli Studi di Trieste, Trieste, Italy. ³Consiglio Nazionale delle Ricerche-Istituto di Scienze Marine, Bologna, Italy

Abstract

Marine sediment sequences may contain deposits produced during large explosive volcanic eruptions i.e. tephra. These materials usually dispersed over regional to continental-scale areas, are isochronous marker horizons and can provide important time-stratigraphic information if geochemically fingerprinted and tied to a known, dated eruption, or used as cross-correlated time horizons between natural records, offering an accuracy difficult to achieve with other methods. Usually macroscopic/visible tephra are recognizable during the visual description of the sediment sequences by variation in sediment color or texture.

Sometimes volcanic ash is dispersed in the sediment records and does not form a continuous distinct horizon. These deposits known as cryptotephra, occur as layers of very fine ash (tens of μm) and offer the opportunity to register also smaller eruptions, and eruptions from more distal sources.

Cryptotephra could be identified using several different methods, most of which are time-consuming and sample destructive. Here we present an application of rapid, and non destructive scanning techniques (XRF core scanning and Magnetic Susceptibility), in order to recognize cryptotephra in marine distal sediment sequences, from the continental shelf of the Ross Sea (Antarctica). Sediments gravity cores has been collected in the framework of Italian PNRA TRACERS Project (TephRoChronology and mArker events for the CorrElation of natural archives in the Ross Sea, Antarctica) that aims to identify, characterize in detail (sedimentological characteristics, texture, mineral phases, geochemical fingerprint) tephra as potential regional markers.

Victoria Land has been the site of intense and recurrent volcanic activity since 500 ka which resulted in the deposition of several discrete tephra in sediment sequences from Drygalsky basin off the Victoria Land coast. The volcanoes of the Melbourne Volcanic Province are considered the most likely sources for these tephra layers on the basis of volcanological, geochemical and age constraints.

High resolution Magnetic susceptibility and XRF scan of sediment cores allowed us to recognize for the first time cryptotephra layers also in more distal basin (Joides Basin). Sediment cores (ca 6-8 m long) were run through the Avaatech XRF (3rd generation) core scanner at the Italian CNR- Ismar Institute with a sample spacing of 1 cm, at 10, 30 and 50 kV to obtain semi-quantitative geochemical composition. Magnetic Susceptibility was measured with 2 cm of resolution, using a Bartington MS2 system with loop sensor to acquire the concentration of ferromagnetic component.

In particular, the ratios of light element (Fe/K, Ti/K, Ti/Ca, Mn/Ca, Cu/K and Si/Ca) proved to be the most useful to mark the cryptotephra.

Drilling for insight on long-term ice history and landscape evolution in Antarctica with cosmogenic nuclide depth profiles

Andrew Hein¹, Ángel Rodés², David Sugden¹, Finlay Stuart²

¹University of Edinburgh, Edinburgh, United Kingdom. ²Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom

Abstract

The volume of the Antarctic Ice Sheet has varied greatly during glacial-interglacial cycles and with changes in global climate over millions of years. Many nunataks exposed above the ice sheet today have been periodically buried by ice, but have not been significantly eroded by it. These surfaces are problematic for typical exposure age studies that aim to date the most recent bedrock exposure because they contain nuclides inherited from exposure prior to the most recent glaciation. However, these surfaces do offer the possibility to explore a much longer history of ice cover, exposure and erosion, which can be exploited by measurement of noble gases and radioactive cosmogenic nuclides. Here, we present results from a pilot study conducted in the Ellsworth Mountains, West Antarctica. Cosmogenic ²⁶Al, ¹⁰Be and ²¹Ne concentrations were measured at six depths within a 2 m-deep core extracted from an ice-moulded bedrock surface ~100 m above the ice margin. The data indicated a multi-cycle exposure-burial history, and so the global marine isotopic record of climate change was employed as a basis for modelling an exposure-burial history that was compatible with the ²⁶Al, ¹⁰Be and ²¹Ne concentrations. The modelling constrains a $\delta^{18}\text{O}$ threshold for glaciation at the site, and indicates the bedrock was first exposed 3.5-5.1 Ma, and when exposed it eroded subaerially at a low rate of 1.5 m Ma⁻¹. The data indicate the warm-based glacial erosion of the bedrock occurred before the Quaternary, rather than during more recent glacial cycles. Future applications of this approach will be discussed in light of the pilot study results, with a view to understanding the potential of the technique to constrain long-term ice volume changes and landscape evolution in Antarctica.

Abstract

Following Milankovitch's theory the incoming insolation or summer energy at 65°N is typically analysed to predict the waxing or waning of land ice. We here use a model-based deconvolution of the LR04 benthic-d18O stack into land ice distribution (de Boer et al., 2014, Köhler et al., 2015) to verify if the latitudinal focal point of land ice dynamics has changed over the last 2 Myr or whether this choice of 65°N in orbital data is indeed well justified. We find that the 5°-latitudinal band which contributes most to land ice albedo radiative forcing ($\Delta R_{[LI]}$) is 70-75°N between 2.0-1.5 Myr, which is then until 1.0 Myr gradually substituted by 65-70°N. During the last 1 Myr both 60-65°N and 65-70°N dominate $\Delta R_{[LI]}$ and contribute approximately the same amount, while the relative importance of 70-75°N is shrinking. Our analyses illustrates that the choice of 65°N seems for the last 1 Myr to be well justified, while for earlier parts of the last 2 Myr the dominant land ice changes seems to have happened up to 10° further to the north.

Focusing on the last 800 kyr (the time for which precise data on atmospheric CO₂ concentration exists) we furthermore find that the multi-millennial land ice growth and proxy-based reconstruction of global cooling (= the glaciation) appear synchronously to each other and to decreasing obliquity, but diverge from CO₂. This suggests that the global cooling associated with Earth's way into an ice age as deduced in the reconstructions has to be mainly caused by the land ice albedo feedback, and is not dominated by the CO₂ greenhouse gas radiative forcing. One way of perceiving this CO₂-glaciation divergence in the reconstructions is that the reduced incoming insolation at high latitudes during phases of decreasing obliquity causes land ice growth (= sea level fall) and cooling, while there is a coexisting process that keeps CO₂ at a relatively constant level. Solid Earth modeling experiments have indicated that falling sea level might lead to enhanced marine volcanism (enhanced magma and CO₂ production) at mid-ocean ridges and at hot spot island volcanoes which might be a potential cause for this CO₂-glaciation divergence (Hasencler et al., 2017).

This CO₂-glaciation divergence needs to be considered, when using paleo data to quantify paleoclimate sensitivity: periods with diverging CO₂ and global temperature change should be filtered out when approximating the relationship between global temperature rise and CO₂ concentrations (Köhler et al., 2018).

P-1479

A conceptual model of the causes of a varying Eurasian ice sheet size during past glaciations

Henning A. Bauch¹, Robert F. Spielhagen²

¹AWI c/o GEOMAR, Kiel, Germany. ²GEOMAR, Kiel, Germany

Abstract

Varying fluxes of iceberg-rafted debris (IRD), as recorded in polar-subpolar marine sediment cores from the western European margin (British Isles to Fram Strait), provide ample evidence for the large-scale waxing and waning activity of ice sheets during major glaciations of the past 0.6 Ma. These marine data of iceberg discharge rates point to significant temporal changes in ice-sheet coverage over the NW Eurasian continent. A clear, stepwise decrease in IRD delivery is noted for the last 3 major glaciations (Elsterian/MIS12, Saalian/MIS6, Weichselian/MIS2-5), which matches well the pattern recognized on land, i.e., the southern and western spatial extents of moraines. By contrast, the North Eurasian shelf edge (Barents/Kara seas) remained rather inactive for a long time starting to deliver IRD into the adjacent Arctic Ocean only during Saalian times. This latter finding is somewhat at odds with field evidence from southern and eastern Russia where the existence of several major glaciations predate both the Weichselian and the Saalian. This asymmetry in terrestrial glacial development between the Arctic and the regions farther south calls for a systematic migration of southern glaciation limits towards the north on the one hand, and with it, for a western and northern shift of major glaciation centers on the other. These spatial shifts were likely forced by major changes in oceanic heat transport which essentially influenced the pathways of atmospheric moisture transfer thereby leading to the systematic changes of the Eurasian ice sheet since mid-Pleistocene times.

Using the history of the Antarctic Ice Sheet to reduce uncertainties in projections of global sea level rise

Steven Phipps¹, Jason Roberts^{2,3}

¹University of Tasmania, Hobart, Australia. ²Australian Antarctic Division, Kingston, Australia. ³Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia

Abstract

Ice sheet models are the most descriptive tools available to simulate the future evolution of the Antarctic Ice Sheet (AIS), including its contribution towards changes in global sea level. However, our knowledge of the dynamics of the coupled ice-ocean-lithosphere system is inevitably limited, in part due to a lack of observations. Furthermore, to build computationally efficient models that can be run for multiple millennia, it is necessary to use simplified descriptions of ice dynamics. Ice sheet modelling is therefore a poorly constrained exercise. The past evolution of the AIS provides an opportunity to improve the description of physical processes within ice sheet models and, therefore, to constrain our understanding of the role of the AIS in driving changes in global sea level.

We use the Parallel Ice Sheet Model (PISM) to demonstrate how past changes can be used to improve our ability to predict the future evolution of the AIS. A large perturbed-physics ensemble is generated, spanning uncertainty in the parameterisations of key physical processes within the model. A Latin hypercube approach is used to optimally sample the range of uncertainty in parameter values. This perturbed-physics ensemble is used to simulate the evolution of the AIS from the Last Glacial Maximum (21,000 years ago) until 5,000 years into the future. Records of past ice sheet thickness and extent are then used to determine which ensemble members are the most realistic. This allows us to use the known history of the AIS to constrain our understanding of its past contribution towards changes in global sea level. Critically, it also allows us to determine which ensemble members are most likely to generate realistic projections of the future evolution of the AIS. This enables us to use past changes in the AIS to reduce uncertainty in projections of future sea level rise.

Timing and Rate of Deglaciation of the MIS 2 Cordilleran Ice Sheet in Yukon Territory, Canada

Jeffrey Bond¹, Brent Ward², John Gosse³, Derek Turner⁴, Derek Cronmiller²

¹Yukon Geological Survey, Whitehorse, Canada. ²Simon Fraser University, Burnaby, Canada. ³Dalhousie University, Halifax, Canada. ⁴Douglas College, Vancouver, Canada

Abstract

The northern Cordilleran ice sheet (CIS) consisted of a series of quasi-independent ice lobes that coalesced during the last glacial maximum (LGM) to form a continuous carapace of precipitation limited ice over southern Yukon. Deglaciation of the northern margin of the CIS and its rate of recession from the LGM are poorly understood. We use cosmogenic nuclide exposure dating (10Be and 36Cl) on groups of 3-4 glacial erratics to reconstruct the timing and rate of deglaciation. Our sampling concentrated on the St. Elias, Cassiar and Selwyn lobes, as well as an independent glaciers in the Ogilvie Mountains and Ruby Range.

Boulders sampled up-ice from terminal moraines show that the initiation of deglaciation varied regionally. 36Cl ages from the Ogilvie Mountains indicate that deglaciation initiated by ca 23 ka. Deglaciation of the NCIS initiated first in the Coast Mountains and St. Elias lobes at 18.2 and 17.4 ka, respectively. Deglaciation of the Cassiar lobe initiated before 16.4 ka. For the Selwyn Lobe, two sites separated by ~150 km returned ages of 15.3 and 16.5 ka.

Rates of deglaciation are best constrained for the Cassiar Lobe with two transects along different flow lines. Multiple valley bottom samples in the mid-deglaciation setting at Whitehorse yielded ages of 13.7 ka, while one boulder from the adjacent ridge top 600 m above is 15.4 ka. In the accumulation zone, ice-free conditions occurred by 12.1 ka. The other transect has higher elevation samples in a mid-deglaciation setting in the Pelly Mountains that indicate deglaciation occurred by 13.7 ka. Samples taken from high elevation and valley bottom sites close to accumulation zones of the Cassiar Lobe yielded ages of 13.4 and 10.8 ka, respectively, indicating ice persisted in valley bottoms much longer than uplands.

These results provide a chronology for the style of deglaciation interpreted from regional mapping throughout Yukon: gradual initial retreat and thinning marked by moraines, followed by rapid downwasting and regional stagnation. Thinning of the ice to expose uplands in the Cassiar lobe was coincident with margin retreat. The increase in rates of deglaciation after 14 ka fits well with mapped evidence of regional stagnation. Early animal, and possibly, human migrants could have traveled along the uplands as these became ice free first. Early deglaciation of the Ogilvie Mountains may be a result of moisture starvation due to the Laurentide Ice Sheet reaching its all time maximum in the western NWT.

Abstract

Ice flow modelling studies targeting the last glaciation of the European Alps have so far relied on present-day precipitation and temperature pattern and seasonality. These studies yield interesting insight to the dynamics of this former ice cap. However, the modelled maximum ice extent is inconsistent with geomorphological reconstructions based on terminal moraines. More precisely, the ice flow models systematically overestimate the ice extent in the north-east of the Alps and at the same time underestimate it in the south-west. Furthermore, the modelled flow directions are inconsistent with the depositional locations of erratic boulders with known origin, in particular those carried by the Valais Glacier. Recently, output of a global climate model run for Last Glacial Maximum (LGM, 20,000 year before present) conditions has been downscaled to a resolution of 2x2 km over the European Alps with a regional climate model. This offers, for the first, time the opportunity to drive an ice flow model with a high-resolution climate forcing that is truly representative for this period.

Here we present some simulations of the Alpine Ice Sheet around the LGM utilizing this novel climate forcing. To model the ice flow and mass balance of the ice sheet, we use the Parallel Ice Sheet Model (PISM), which is a state-of-the-art ice sheet model. As only the climate at the LGM is available, we emulate a transient climate by applying a time-dependent temperature offset deduced from the EPICA ice core. We compare the modelled ice sheets with geological evidence such as terminal moraines and trajectories of erratic boulders. Preliminary results show that the new LGM climate forcing yields notable improvements between modelled and reconstructed ice extents. In particular, the ice distribution between south-west and north-east is significantly improved when compared to former simulations employing a climate forcing derived from present-day climate.

Abstract

Dronning Maud Land (DML) represents a critical gap in the empirical data collected for reconstruction of the East Antarctic Ice Sheet (EAIS). MAGIC-DML is an international collaboration with a focus on filling this data gap and reconstructing the timing and pattern of ice surface changes on the western DML margin using field data and ice sheet modeling. The ice-sheet margin in DML is characterised by a prominent escarpment about 200 km inland from the grounding line. The near-vertical cliffs of this escarpment constitute a major barrier between the polar plateau ice (Amundsenisen) and the downstream ice (Ritscherflya), resulting in up to 500 m differences in ice surface elevations. This topographic barrier causes substantial challenges for both empirical ice sheet reconstructions and ice sheet models. Within MAGIC-DML, 35 samples were collected from stable bedrock surfaces and isolated erratics for cosmogenic nuclide surface exposure dating along a coast-inland transect running roughly perpendicular to the escarpment at its westernmost extent in DML.

Here we present ¹⁰Be, ²⁶Al and ²¹Ne results from these samples. The highest-elevation bedrock samples yield ¹⁰Be and ²¹Ne concentrations indicating steady exposure in excess of 3 Ma, indicating that the ice sheet has not overridden the escarpment edge at those sites since at least the Pliocene. The dataset also contains Holocene apparent ¹⁰Be ages (6.9 ka and 4.3 ka) for erratics collected ~30 m above the present-day ice on a nunatak situated ~150 km downstream of the escarpment. We link the wide spread, and spatial variation in apparent exposure ages to the distinctly different topographic settings of our sample sites. The results highlight a decoupling of the ice sheet dynamics above and below the escarpment which has persisted throughout the Quaternary. This decoupling presents a significant challenge in the ice sheet reconstruction and highlights the need for the integration of cosmogenic nuclide results with ice sheet models in this region, and elsewhere along the Antarctic margin.

Timing and causes of MIS 4 and MIS 3 glacial advances in South Island, New Zealand

James Shulmeister¹, Glenn Thackray², Tammy Rittenour³, David Fink⁴, Nicholas Patton¹

¹University of Queensland, Brisbane, Australia. ²Idaho State University, Pocatello, USA. ³Utah State University, Logan, USA. ⁴Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

This poster summarises information on the timing and possible causes of glaciation in New Zealand prior to the LGM (26.5-19 ka). We recognise five regionally identifiable advances in MIS 4 and MIS 3 in South Island, NZ, including one which may mark the start of the LGM, but may also precede it. These advances, all secured by CRN and/or luminescence chronologies, occurred at 65 ± 3 ka, 47.5 ± 3 ka, 38.5 ± 2 ka, 31.5 ± 3 ka, and at 26.5 ± 2 ka. Not all advances have clear linkages to climate but some are coincident with periods of Southern Hemisphere insolation minima (65ka, and 31.5 ka advances), while another occurs during a notably cold phase (38.5 ka) and precipitation may play a role (65 ka and 26.5 ka advances). The timing of greatest glacial extent in the last glacial cycle is not simultaneous across New Zealand. The MIS 4 advance was the greatest in the southern South Island, while the MIS 3/2 advances (26.5-25 ka) were greatest in the central South Island. We attribute these spatio-temporal changes in the timing of maximum glaciation to precipitation changes related to a northward shift in the track of the southern-hemisphere westerlies.

Late Pleistocene deglaciation history of the SW British Isles: New evidence from Lundy and the Outer Bristol Channel

Chris Rolfe¹, Philip Hughes², Tony Brown¹, Mark Bateman³, Philip Gibbard⁴, David Fink⁵

¹Palaeoenvironmental Laboratory at the University of Southampton (PLUS), Geography and Environment, University of Southampton, Southampton, United Kingdom. ²Department of Geography, School of Environment, Education and Development, The University of Manchester, Manchester, United Kingdom. ³Department of Geography, University of Sheffield, Sheffield, United Kingdom. ⁴Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom. ⁵Australian Nuclear Science and Technology Organisation (ANSTO), Sydney, Australia

Abstract

The SW British Isles was glaciated by the British-Irish Ice Sheet during the Late Pleistocene. Glacial deposits are widely preserved in the Bristol Channel and are revealed in boreholes and geophysical data. Lundy, an island in the Outer Bristol Channel, displays unique terrestrial evidence of glaciation in the Outer Bristol Channel. The evidence is dominated by erosional evidence of ice-scouring, although there are wide spreads of erratic cobbles and pebbles several of which contain evidence of striae and faceting. In addition, subsurface thick silt-clay deposits are common on the island with clay mineralogy indicating limited weathering, in contrast to occasional pockets of strongly weathered granite (growan). These deposits are interpreted as subglacial in origin. Offshore of Lundy, especially to the E and NE, geophysical data reveals the presence of thick glacial deposits and dense fields of boulders. This suggests that an ice limit occurred between Lundy and the mainland. This allowed the drainage of the proto-Severn to drain between this ice limit and the mainland in Devon, and the course of this palaeochannel can be traced in bathymetry and geophysical survey data.

Periglacial activity after deglaciation is recorded by the presence of coversands, loess, ventifacts, scree slopes and associated colluvial deposits. Luminescence ages from colluvial sands on Lundy date to 24-26 ka indicating that this island was deglaciated by marine isotope stage (MIS) 2. This is consistent with deglaciation and exposure of the island in MIS 3 following glaciation in MIS 4 or possibly earlier. Previously obtained exposure ages from ice-scoured bedrock surfaces have been recalculated using the most recent production rate models and support this interpretation. In addition, a new programme of cosmogenic exposure dating of glacially-transported boulders and displaced tors will further test the previously obtained exposure age data from glaciated bedrock surfaces. In contrast to other weathered granite surfaces in the British Isles, Lundy has not experienced a prolonged weathering history through multiple glacial cycles. Whilst the precise timing of deglaciation is undergoing further testing, the current evidence overwhelmingly indicates that Lundy was eroded by an ice sheet during the Late Pleistocene. Morphometric analysis of weathering pits in the ice-moulded granite bedrock on Lundy supports this exposure history as do the OSL ages from sands overlying the bedrock surfaces. Evidence from elsewhere around the Celtic Sea indicates that the glaciation of Lundy most likely occurred in MIS 4 with ice retreating in MIS 3. However, during MIS 2 ice reached to the continental shelf in the Celtic Sea. This apparent paradox may be explained by a highly mobile Irish Sea Ice Stream which changed its configuration in response to fluctuating marine incursions in MIS 3 before exploiting the exposed continental shelf to the southwest during MIS 2.

Abstract

In the Iberian Peninsula, currently there are only small glaciers in the Pyrenees, but their number and extent has experienced large changes over the Late Quaternary. The existence of a wide range of glacial landforms and deposits across different Iberian mountain ranges is indicative of the occurrence of periods in the past with extensive glaciers covering large areas. We have reviewed all available absolute dates concerning the glacial activity in the Iberian mountains during the Late Quaternary, homogenizing the surface exposure dates following the most recent standard procedures with the purpose of summarizing the current knowledge on the spatial and temporal patterns of glacial activity. The chronological framework was divided in six periods: glaciations prior to the Last Glacial Cycle, Last Glacial Cycle, Termination-1, Holocene, Little Ice Age (LIA) and present-day. The data were geographically divided considering the mountain systems where glacial evidence exists: Pyrenees, Cantabrian Range, NW ranges, Central Range, Iberian Range and Sierra Nevada. During cold phases, more or less ice was stored depending on the combination of temperatures and moisture conditions. The ice accumulated in the head valleys and glaciers flowed down-valleys, but did not reach the surrounding lowlands. In some massifs, there is evidence of Middle Pleistocene glaciations, one potentially correlating with marine isotope stage (MIS) 12 and another correlating with MIS 6 with glaciation dated to ca. 130-170 ka. However, most glacial records correspond to the Last Glacial Cycle and subsequent Termination. The maximum glacial expansion of this glaciation occurred well before the global Last Glacial Maximum (LGM) between 30 and 60 ka in the Cantabrian Mountains and Pyrenees, at ca. 30 ka in Sierra Nevada and NW ranges, and (almost) synchronously to the LGM in the Central Range and Iberian Range. A massive glacial retreat occurred in all Iberian mountain ranges at 19-20 ka. The long-term deglaciation was interrupted by two cold periods, such as the Oldest and Younger Dryas, which favoured glacial expansion in the highest mountains. Higher temperatures recorded at the onset of the Holocene favoured the melting of glaciers, which only reappeared in the highest massifs during the coldest phases, such as the LIA. However, post-LIA warming started by 1850 led to glacier disappearance in the Cantabrian Mountains, Sierra Nevada and most massifs of the Central Pyrenees, together with an accelerated shrinking of the small glaciers still existing in this range at elevations near 3000 m.

A cosmogenic glacial chronology of Lake Judd, southwest Tasmania and latitudinal shifts in the Roaring Forties

David Fink¹, Klaus Wilcken¹, Krista Simon¹, James Shulmeister², Glenn Thackray³

¹ANSTO, Sydney, Australia. ²Uni of Queensland, Brisbane, Australia. ³Idaho State University, Pocatello, USA

Abstract

Limited attention has been paid to the glacial history of Tasmania (40-44 S). At the northern limits of today's Westerly storm track (the Roaring Forties), it experiences precipitation changes due to shifts in the Southern Annular Mode and ITCZ. Cosmogenic dating in southwest Tasmania (Kiernan 2010) highlights the marginal nature of its glaciation where small precipitation or temperature changes cause large changes in mass balance. This makes southwestern Tasmania an excellent location to study Westerly flow through the Last Glacial Cycle. The prevailing idea is that during glacial times, Westerlies expand northward to lower Southern Ocean latitudes, delivering increased rainfall to Tasmania, whilst during interglacials, their migration polewards reduces precipitation. Somewhat counterintuitively, from a Tasmanian perspective of increased Westerly circulation and wind strength, maxima glaciation should coincide with peak global glacials. Although well preserved, extensive last glacial cycle moraine sequences are not common, a series of more than 20 terminal moraine ridges have been mapped over 3 km concentric with the southern margin of Lake Judd, in the SW wilderness corner of Tasmania. Morphologically, the Lake Judd sequence is believed to represent three phases; pre MIS-6, MIS 5-3 and MIS 2 (LGM), representing substantially different volumes of ice accumulation. Our first field campaign collected 16 dolerite samples (³⁶Cl) from the three innermost concentric moraines adjacent to lake edge and 4 quartzite (¹⁰Be, ²⁶Al) samples from the most distal moraines. Our aim is to test correlation of the long-term glacial history with records of westerly fluctuations from NZ speleothems (Whittaker et al., 2011) to determine whether the latitudinal variation in Westerly winds in the Australasian region are zonal during glacial times as they are demonstrated to be in interglacial intervals (Fletcher and Moreno, 2012). Preliminary exposure age calculations on the full set of 20 samples are in poor agreement with Kiernan's age associations. The ¹⁰Be (and ²⁶Al) ages on the distal moraine indicate a most probable MIS 4/5 affiliation (>50 ka), significantly younger than expected. In contrast, the 16 dolerite samples from the 3 innermost proximal moraines at lake edge gave a complex set of ages that ranged from MIS 3 to MIS 4 affiliation (45-25ka), somewhat older than predicted. To add further complexity, these 16 ages show no intra or inter moraine age trends with respect to their morphologic positions and ice flow direction. These results contrast with those from other Tasmanian glacial records and reveal the need for a concrete effort to apply cosmogenic exposure dating to the numerous glacial deposits already mapped throughout Tasmania.

³Universitary Institut of Geology Isidro Parga Pondal, University of A Coruña, A Coruña, Spain. ⁴Department of Geology, University of Oviedo, Oviedo, Spain

Abstract

In calcareous mountains, karst caves preserve information about glacial evolution, delimiting its advances and retreats temporal and spatially. In the SW of Europe, Picos de Europa mountains with 2650 m maximum altitude is included in the Cantabrian Mountains-Pyrenees chain. Pleistocene glaciers occupied an extension of ~180-190 km² in Picos de Europa, with a local maximum around 45 ka and a subsequent general retreat after 37-39 ka, before the LGM advance. Our study aims to quantify this glacial advance and retreat based on sedimentary and paleontological record in karst caves. The study cave is located in the glaciated area around the Covadonga Lakes, a reference location for glacier research in the northern Iberian Peninsula. The study combines cave geomorphology, five OSL ages and two AMS radiocarbon dates, allowing us to define two alluvial sedimentary sequences: 1) a first sequence deposited at 84-65 ka, and 2) a second sequence deposited 36 ka ago. Both sequences present remains of fauna that is not adapted to cold environments, as those covered by glaciers. The remains corresponds to fragments of dental enamel of Arvicolinae, and bones of chamois (*Rupicapra pyrenaica*) dated in 34-32 ka cal. All this evidence allows us to conclude that: 1) after 65 ka, glacial fronts descended more than 450 m in vertical range in less than 20 ka and 2) glacier retreat began at 45-36 ka and the altitude of the glacier fronts rose more than 350 m in less than 9 ka, coevally with the second half of the MIS 3.

Continental sediments and the MIS-3 in mid-latitudes of South America (Uruguay): faunal records, paleoclimatic and environmental features

Martín Ubilla

Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay

Abstract

MIS-3 evidences from continental beds in South America are few and loosely dated. Fluvial sediments and paleosoils developed in northern Uruguay (the Sopas Formation) produced a ^{14}C AMS (fresh-water mollusk shells) and OSL set (15 samples) of ages encompassing the $33,560 \pm 700$ yrs BP (cal 36,089 – 39,426 yrs) to $39,900 \pm 1,100$ (cal 42,025 - 45,389 yrs) and OSL ages from $27,400 \pm 3,300$ to $71,400 \pm 11,000$ yrs (being more represented the 45-28 ka time interval). A correlation with the Marine Isotopic Stage 3 (MIS-3, 60-25 ka) seems to be confident. This unit outcrops in northern Uruguay alongside creeks and rivers with a patchy pattern of distribution. It yields medium-coarse sandy and conglomerate basal levels belonging to fluvial facies overlaid by brownish mudstones and siltstones related to floodplains deposits and paleosoils including bioturbation. The ongoing analysis of the faunal content could help to characterize this interval of time at these latitudes. It includes trace fossils, woods, fresh-water mollusks and vertebrates with mammals being the predominant taxon with more than 50 species recorded belonging to ca. 25 families. In the fossil assemblage are taxa related to open habitats, savannahs and woodlands including gallery forests and perennial rivers. Among the extinct taxa are indicators of open to semi-open environments, such as some glyptodonts, ungulates such horses, toxodontids and litopterns, among others. Living representatives of taxa indicate mostly tropical to temperate climates along with some taxa that suggests arid to semiarid environments (tapirs, coendus, coypus, capybaras, river-otters, some peccaries, some caviids, ocelots, and marsh-rats). In addition, seasonality indicators are also registered like southern bird migrants and worm aestivation chambers. This climatic and environmental pattern could have been modeled by millennial climatic changes that were prevalent in the MIS-3. The presence in the mammalian assemblage of tropical to subtropical representatives is difficult to explain under the postulated climatic characteristics of the MIS-3, which is in fact colder than the Last Interglacial and the current time. In order to explain this pattern could be invoked a replacement faunal model or alternatively a mixed faunal model, which is discussed here. The survival of these tropical to temperate mammals during the MIS-3 at this latitude could have been caused by the presence of refuge areas (perennial rivers, riparian forest and semi-forested areas) performing a mixed fauna. In fact, heterogeneous biomes in the Neotropical Region of South America have expression in the recent such as the “Cerrado” (southeastern Brazil). It is characterized by a mosaic of environments (open habitats, savannahs and dense woodlands including gallery forests alongside perennial rivers) developed in seasonal climate. In this biome forest species with non-forested species coexists and has high values of diversity. Contribution to CSIC (DT-MU) and Pedeciba-Biología.

Early to mid-Holocene vegetation history of South Korea inferred from pollen records

Sangheon Yi

Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of. University of Science and Technology, Daejeon, Korea, Republic of

Abstract

The sedimentary cores were obtained from the Gunsan and Bigeumdo sites in west coast and Goheung site in south ones of South Korea in order to understand the vegetation changes response to the early to mid-Holocene climate changes on the Korean Peninsula. The age-controlled palynological studies associated geochemical data indicated that the riverine wetland meadow between 12.1 and 9.8 cal kyr BP changed to subtropical and temperate deciduous broad-leaved forest in 9.8–2.8 cal kyr BP. Additionally, the cold climate conditions from 12.1–9.8 cal kyr BP became warmer from 8.5–7.3 cal kyr BP. Subsequently, another relatively cool period from 7.3–2.8 cal kyr BP was prevailed. The temperature changes were mainly in response to solar factors. However, two relatively humid periods from 12.1–9.8 cal kyr BP and 8.5–7.3 cal kyr BP, which arose for different reasons, were detected. The earlier humid period resulted from strong westerlies and a rapidly rising sea level. The later humid period was produced mainly by the strong East Asian summer monsoon and may also be linked to La Niña-like activity. The cold “Younger Dryas” event (12.0–11.4 cal kyr BP) and “8.2 kyr cool” event recorded in the study area may have been produced by teleconnection with a North Atlantic meltwater pulse. This would have reduced temperatures that were already low due to weak insolation, and the strong winter monsoons would have increased the precipitation.

Postglacial diatom-climate responses in a small lake in the Pacific northwest of North America

Joanne Egan¹, Timothy Allott², William Fletcher²

¹Edge Hill University, Ormskirk, United Kingdom. ²The University of Manchester, Manchester, United Kingdom

Abstract

Understanding the variability of ocean-atmosphere interactions in the Pacific Northwest (PNW) of North America is essential for climate forecasting, particularly variations in the El Niño-Southern Oscillation (ENSO) and Pacific Decadal Oscillation (PDO). Research suggests that global warming is increasing the frequency of extreme El Niño events, which can have global climatic impacts (e.g. disrupting global weather patterns, affecting ecosystems and agriculture and extreme weather events (flood, drought, bushfires)). A diatom record spanning 14,500 Cal yr BP from Moss Lake, Washington is used to assess Holocene climate change in the PNW including evidence for periodicities related to ocean-atmosphere interactions and/or variations in solar output, and is directly compared to the Moss Lake pollen record. Three climate phases were identified: 1) the Late Pleistocene (until 11,800 Cal yr BP), with a cold climate evidenced by the low abundance of diatoms; 2) the early to mid-Holocene (11,800 – 7500 Cal yr BP), with warm climate, longer growing seasons and shorter periods of ice cover, indicated by the increase of *Cyclotella pseudostelligera* and decrease of *Fragilaria* taxa; and 3) the mid-to-late Holocene from 7500 Cal yr BP onwards, with a cooler climate reflected by a decrease in *Cyclotella pseudostelligera* and an increase in *Fragilaria* taxa. These climate shifts correlate with the regional and local pollen record. Fluctuations in *Cyclotella pseudostelligera* and *Aulacoseira* taxa suggest climatic cycles of varying amplitude throughout. RedFit and Wavelet analyses revealed periodicities of approximately 2000 years, 1300 years, and 450 years. The 2000-year cycle is attributed to solar variation; the Hallstatt Oscillation. The 1300-year and 450-year cycles are attributed to ENSO and PDO like cycles. The 1300-year periodicity is evident throughout the Late Pleistocene and Holocene and reflects shifts from El Niño/positive PDO (weak wind intensity, warm temperature) to La Niña/Negative PDO (high wind intensity, cool temperature). Between 11,800 and 7500 Cal yr BP the cycle amplitudes are reduced and frequency increased reflecting the 450 yr periodicity. Diatom data from Moss Lake provide a sensitive record of climate-related limnological responses and refine our understanding of Holocene climate change in the PNW.

Multidecadal variability of air temperature over East-Central Europe in the last millennium

Krzysztof Bartoszek¹, Joanna Sławińska²

¹Maria Curie-Skłodowska University, Department of Hydrology and Climatology, Lublin, Poland. ²University of Wisconsin-Milwaukee, Department of Physics, Milwaukee, USA

Abstract

Novel simulations of past climates provide unique opportunity to separate external perturbations from internal climate anomalies and to attribute the latter to systematic changes in different types of synoptic scale circulation and distributions of high-frequency weather events. At the moment, there is a lot of information about the variability of thermal and humidity conditions on continents in the last millennium. They can be obtained i.a. from an extensive network of tree-ring, ice cores and coral records. Here we study the trends of changes of thermal conditions by employing the Last Millennium Ensemble (LME) of climate simulations carried out with the Community Earth System Model (CESM) at the U.S. National Center for Atmospheric Research, focusing in particular on decadal changes in air temperature over East-Central Europe from 850 to 1850. The forcings over this period are associated with volcanic eruptions, solar activity, the orbit of the Earth, land cover, greenhouse gas concentrations, and tropospheric ozone and aerosols. We have analyzed the occurrence of air temperature anomalies in relation to both stratospheric volcanic sulfate aerosol concentration and total solar irradiance (TSI). In addition, we compared the differences between thermal conditions in winter and summer during Medieval Warming Period (MWP) and Little Ice Age (LIA). The values of the air temperature during the two periods were also compared with the sea level pressure anomalies over the North Atlantic Ocean and Europe as well as the index of the North Atlantic Oscillation.

Changes in speleothem $\delta^{13}\text{C}$ through the deglaciation: a model-based study

Sandy P. Harrison¹, Laia Comas Bru¹, I. Colin Prentice²

¹University of Reading, Reading, United Kingdom. ²Imperial College, London, United Kingdom

Abstract

Stable carbon isotope measurements ($\delta^{13}\text{C}$) on most of the speleothem records that span the end of the last glacial period and the deglaciation, both in tropical and extratropical regions, show a trend towards more negative values. At some sites the trend is marked by rapid shifts towards more negative values, and some sites also show short-lived reversals broadly corresponding to the Younger Dryas interval. Speleothem $\delta^{13}\text{C}$ records are conventionally interpreted in terms of shifts in the relative abundance of C_3 and C_4 plants in the vegetation above the cave. However, the $\delta^{13}\text{C}$ composition of C_3 plants also reflects the stomatal conductance response to aridity and this should also be reflected in speleothem $\delta^{13}\text{C}$ records. Changes in the $\delta^{13}\text{C}$ composition of C_3 plants are a reflection of climate, but shifts in the relative abundance of C_3 and C_4 plants can be caused either by climate change or by changes in atmospheric CO_2 concentration – low CO_2 can favour C_4 plants even in relatively moist/cold climates. We use a process-based biogeography model (BIOME4) that explicitly simulates ^{13}C discrimination to explore the causes of observed deglacial changes in $\delta^{13}\text{C}$ at 25 speleothem sites worldwide covering the interval from 22-10 kyr from the SISAL (Speleothem Isotopes Synthesis and Analysis) database. The model reproduces the observed trends in $\delta^{13}\text{C}$, including rapid shifts, and also reversals. We show that the trend towards increasingly negative values is largely a reflection of CO_2 -induced changes in vegetation composition, particularly in the tropics where the change in climate is muted. In the extratropics, both climate warming (and increased water stress) and CO_2 -induced shifts in vegetation composition play a role in explaining the trend. Rapid shifts in $\delta^{13}\text{C}$ appear, within dating uncertainties, to correspond to intervals when the increase in CO_2 is steep. The reversal in the $\delta^{13}\text{C}$ associated with the Younger Dryas is largely a vegetation response to climate. As this study shows, process-based modelling can be used to explore and explain the causes of changes in speleothem $\delta^{13}\text{C}$.

Poleward shift of the subtropical jet linked to Heinrich Stadial 1 and future rainfall changes in China

Lei Huang¹, Liping Zhu¹, yongsong huang²

¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China. ²Department of Earth, Environmental, and Planetary Sciences, Brown University, Beijing, USA

Abstract

Expansion of the Hadley cell and poleward displacement of the subtropical jet are two crucial features of circulation change under global warming. Connection between rain band of Asian Summer Monsoon in China and such circulation changes is very poorly studied. We use a compilation of hydroclimate records and published transient model simulation results to assess the connection of Hadley cell's width and subtropical jet to monsoonal precipitation change in China during HS1. Records documented precipitation increasing in northern China and the eastern Tibetan Plateau but decreasing in southern China during this period, indicating monsoonal rain band moved northward. The model output shows that temperature in middle and high latitudes increased in summer as a transient response to radiative forcing changes during the last deglaciation, leading the Hadley cell expanding and the subtropical jet moving poleward. Poleward displacement of the subtropical jet drove the monsoonal front moving northward during HS1 summer, therefore, precipitation increasing in northern China but decreasing in southern China as geological records documented. A very similar mechanism is also apparent in the multi model simulations under IPCC RCP 8.5, lending confidence to the projection of a wet northern China in the future.

Earth and Ocean Dynamics. Universitat de Barcelona, Barcelona, Spain

Abstract

Future climate change scenarios suggest an increase of extreme climatic events in southern Europe, especially those associated with anomalous rainfall conditions (i.e., droughts and floods), which often cause major negative economic and social impacts. However, climate model simulations still include large uncertainties in the reproduction of flood and drought recurrences, partly due to the large internal variability that characterises the climate of the mid to high latitudes of the Northern Hemisphere. Therefore, it is necessary the use of hydrological reconstructions to: i) establish the baseline conditions prior to the current Climate Change and ii) investigate the previous analogous warm periods (e.g., Roman Warm Period and Medieval Climate Anomaly) to infer the future behaviour of extreme climatic events and provide clues under the prevalence of which large-scale atmospheric and oceanic patterns occur these extreme events. The most prominent atmospheric pattern in mid to high latitudes of the Northern Hemisphere is the North Atlantic Oscillation (NAO). Nevertheless, the NAO is not the only mode that affects the North Atlantic-European sector climate regime. Here, we present the hydrological balance of two southern regions of the North Atlantic European sector (i.e., Azores Archipelago and Iberian Peninsula) using lacustrine sedimentary records to determine the spatio-temporal evolution of hydrological extremes and their relationship with large-scale modes of climate variability. Our main hypothesis is that large-scale climate variability other than the NAO have modulated extreme climatic events in the North Atlantic-European sector during the Common Era. Our results make evident that different interactions between the NAO and other large-scale atmospheric and oceanic patterns explain local climate conditions and spatial differences during enhanced flooding and droughts periods. These lacustrine records show that above-average rainfall conditions are linked to the negative phases of both the NAO and the Atlantic Multidecadal Oscillation (AMO), while background and drought conditions preferentially occur under positive NAO and AMO phases. These results highlight that, although the hydrological regime in this area is clearly influenced by the NAO, the low frequency AMO also plays a key role at decadal to centennial time-scales. Moreover, other climate patterns, such as the East Atlantic (EA) and Scandinavian (SCA) patterns, could also modulate the geographical position of the NAO action centres, thus affecting the strength and latitudinal position of the dominant westerlies crossing the North Atlantic sector. Our results provide an evidence of the importance of considering other patterns than the NAO to explain palaeohydrological variability in the North Atlantic European sector

¹Institute of Global Environmental Change, Xi'an Jiaotong University, Xi'an, China. ²Climate Geochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany. ³Instituto de de Geociências, Universidade de São Paulo, São Paulo, Brazil. ⁴IRD-Sorbonne Universités (UPMC, CNRS, MNHN) UMR LOCEAN, Centre IRD, Bondy, France. ⁵Laboratory of Applied Geology and Geo-Environment, Agadir, Morocco. ⁶Institute of Geoscience, University of Mainz, Mainz, Germany

Abstract

The periods of enhanced Holocene North Atlantic ice-rafting (Bond events) have climate implications over distant regions, due to their coupling with large-scale ocean circulation and atmospheric modes. However, only a few proxy records replicate all the Bond events as climate anomalies. Hence, additional paleoclimate research is required from key sites to reconstruct potential teleconnections with the subpolar North Atlantic. Here, based on robust age models, we present three high resolution isotope speleothem records from the Western Mediterranean, a region under the direct influence of the westerly winds circulation through the North Atlantic Oscillation (NAO). We demonstrate that the rainfall variability in the Western Mediterranean is in phase with negative NAO-like conditions and solar minima, consistent with modern climate patterns. Furthermore, we provide proxy evidence for wet conditions in the Western Mediterranean during the periods of enhanced ice-rafted debris (IRD) throughout the Holocene. These findings are consistent with previous proxy and model results, which describe cooling and sea ice expansion over the North Atlantic and the resulting slowdown of the Atlantic Meridional Ocean Circulation (AMOC) as a response to reduced wind stress on the ocean. The latter is caused by southward shifts of the precipitation-bearing westerly winds, which resemble negative NAO-like conditions that bring moisture to the Western Mediterranean.

Quantitative climatic reconstruction in China during the mid-Holocene and the Last Glacial Maximum

Haibin Wu^{1,2,3}, Qin Li¹, Yanyan Yu^{1,2}, Aizhi Sun³, Yating Ling⁴, Wenqi Jiang¹, Yunli Luo⁵

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China. ³University of Chinese Academy of Sciences, Beijing, China. ⁴Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ⁵Institute of Botany, Chinese Academy of Sciences, Beijing, China

Abstract

Quantitative paleoclimatic reconstruction is crucial for understanding the operation and evolution of the global climate system. For example, a quantitative paleoclimatic reconstruction for the Last Glacial Maximum (LGM) and the mid-Holocene is fundamental to understanding the evolution of Earth's climate during the last glacial-interglacial cycle. Previous quantitative palaeoclimate reconstructions in China are generally based on statistical comparison of modern pollen assemblages and modern climate data. These methods are based on the premise that vegetation-climate interactions remain the same through time, and implicitly assume that the interactions are independent of changes in seasonality and atmospheric CO₂ concentration. However, these assumptions may not always be valid, which may affect the reconstructions. In this study, we present the results of a quantitative study of the LGM climate of China based on an improved inverse vegetation model which incorporates physiological processes combined with a new China Quaternary Pollen Database.

The results indicate that during the MH period, mean annual temperature (ANNT) in China were higher ~0.7°C than present, especially in the eastern China, but cooler in the northwest China. Winter temperature were generally higher ~1.0°C than today, but summer temperature only higher ~0.5°C than present. Mean annual precipitation (ANNP) were wetter ~230 mm than present, especially in the eastern China, which was due to the increase of summer rainfall. At the LGM time, mean annual temperature (ANNT), winter and summer temperature of the warmest month in China were lower by ~5.6°C, ~11.0°C and ~2.6°C, respectively, compared to today, and that the changes in ANNT were attributed mainly to the decrease of winter temperature. Mean annual precipitation was lower by ~46 mm compared to today, especially in northern China, which was due to the decrease in summer rainfall.

Comparison of our results with recent outputs from paleoclimatic modelling reveals that while the latter are broadly consistent with our estimated changes in mean annual climatic parameters, there are substantial differences in the seasonal climatic parameters. Our results highlight the crucial importance of developing seasonal simulation on paleoclimatic models, as well as the need to improve the quality of paleoclimatic reconstructions based on proxy records from geological archives.

Abstract

Loess-paleosol and dune sand-paleosol $\delta^{13}\text{C}_{\text{SOC}}$ values of soil organic carbon (SOC) can be used to reflect “annual-average” changes of floral habitat and $\delta^{13}\text{C}_{\text{SCC}}$ values of soil carbonate carbon (SCC) can be used to reflect summer habitat changes. However, variations of “annual-average” proxy of floral habitat is biased by seasonal precipitation. When summer precipitation is intense and fall/winter season is dry, the “annual-average” proxy tends to reveal more summer habitat variation. When fall/winter precipitation is persistent and summer is dry, the “annual-average” proxy tends to reflect fall/winter habitat. We argue that an equilibrium state between $\delta^{13}\text{C}_{\text{SOC}}$ and $\delta^{13}\text{C}_{\text{SCC}}$ values indicates wet summers and dry falls/winters and a disequilibrium state between $\delta^{13}\text{C}_{\text{SOC}}$ and $\delta^{13}\text{C}_{\text{SCC}}$ values indicates dry summers and wet falls/winters.

We explored this approach to a riverine dunefield that contains 10 incipient paleosol horizons formed narrowly between 10,800 and 7,500 calBP to discuss the evolution of the East Asian Summer Monsoon (EASM) circulation in the southeast Mu Us Desert in northern China. We also examined stable carbon isotopes from a loess-paleosol sequence for the last 20,000 years in the northwest margin of the Loess Plateau. We found that wet falls and dry summers more frequently dominated the early-Holocene, while wet summers and arid falls became overwhelming after 9000 calBP. We interpreted that the substantial warming in the Northern Hemisphere in early Holocene propelled the subtropical jet streams that carried heat and moisture from Indian and West Pacific Oceans in falls poleward causing northern China wet, while accelerated melting of ice sheet raised sea level and shifted Arctic Oscillation (AO) to a negative phase in summers, resulting in southern China wet and northern China dry. However, after middle Holocene the highest summer and lowest winter solar radiation and decrease of sea level rise favored a positive phase of AO, driving polar jet streams further poleward with less meridional meanders, intensifying EASM rainfall transfer aloft poleward, while colder/windier winters could extend drier/colder conditions to springs/falls. The interaction between the Rossby wave trains of polar jet troughs and ridges and subtropical jet streams that carry Indian Summer Monsoon and EASM heat/moisture supplies modulated the millennial scale climate and habitat changes in the northern China.

¹Northern Arizona University, Flagstaff, USA. ²Université Catholique de Louvain, Louvain-la-Neuve, Belgium.

³University of Wyoming, Laramie, USA. ⁴US Geological Survey, Reston, USA. ⁵Cornell University, Ithaca, USA

Abstract

The latitudinal temperature gradient (LTG) between the equator and the poles influences atmospheric stability, jet-stream strength, and extratropical cyclones. Recent global warming is weakening the Northern Hemisphere annual surface LTG by preferentially warming the high latitudes; however, the implications of these changes for mid-latitude climate remain uncertain. Paleoclimate archives spanning the Holocene provide an opportunity to evaluate the impact of orbitally driven changes the LTG on mid-latitude hydroclimate. We show that a weaker LTG (warming of the Arctic with respect to the equator) during the early to middle part of Holocene coincided with substantial decreases in mid-latitude (30°-50°N) net precipitation. We quantify the evolution of the LTG and mid-latitude moisture in both an extensive new compilation of Holocene paleoclimate records spanning from 10°S to 90°N, and in an ensemble of mid-Holocene climate model simulations (PMIP3, 6 ka time slice). The observed pattern is consistent with the hypothesis that a weaker LTG led to weaker mid-latitude westerly flow and decreased net terrestrial mid-latitude precipitation. Currently the northern high latitudes are warming at rates nearly double the global average, decreasing the equator-to-pole temperature gradient to values comparable with the early to middle Holocene.

P-1500

Western Pacific Ocean influences in East Asian summer monsoon since the mid-Holocene

Cheng Zhao, Can Zhang, Ji Shen

Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

Numerous paleoclimate records on precipitation isotopes have been published to infer past hydroclimate changes in Asian monsoon region. However, there are still debates on whether or not these reconstructed precipitation isotopes can represent changes in the amount of monsoon rainfall. In this study, we report a record of leafwax hydrogen isotope (δD_{wax}) for the past 5000 years inferred from a 6.67-m-long sediment core collected in Beilianchi (BLC) Lake in the Chinese Loess Plateau. To better understand the relation between precipitation isotopes and monsoon rainfall amounts in this region, we systematically analyze the modern instrumental observations on moisture sources, precipitation amounts, precipitation isotopes. We find that precipitation isotopes (δD_p) show distinct negative correlation with amounts of local summer (from April to September) monsoon rainfall in the southwestern Chinese Loess Plateau, with moisture mainly transported from the northwestern Pacific Ocean through the subtropical monsoon circulation. These observation are further verified by the agreement between instrumental precipitation and reconstructed high-resolution rainfall isotopes from regional lake sediments and speleothems over the past 60 years, and climate simulations on regional atmosphere circulations. Accordingly, our ~20-year resolution δD_{wax} data reveal a slight long-term decrease in monsoon rainfall amounts since the mid-Holocene, with multicentennial-scale increased monsoon precipitations at 4800-4200 BP and 1100-400 BP but decreased monsoon precipitations intervals at 3900-3500 BP, 3200-2600 BP, 1700-1300 BP, and 300-0 BP. These changes agree with the published speleothem $\delta^{18}O$ data from the nearby area and remote sea-surface temperatures in the western Pacific Ocean, and the simulated summer rainfall record from the Kiel Climate Model (KCM) which also suggests a Pacific-sourced moisture for this region. We conclude that precipitation isotopes, at least in some East Asian monsoon regions, can still represent changes in the amount of summer monsoon rainfall, and that East Asian summer monsoon likely be controlled by subtropical monsoon circulations originating from the western Pacific Ocean and connected with changes in sea surface temperatures and migrations of the ITCZ there.

Anti-phase variation of hydrology and in-phase carbon accumulations in two wetlands in southern and northern China since the last deglaciation

Xuefeng Yu¹, Haiyan Zhao²

¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China

Abstract

To examine the spatial patterns of hydrological variations in the southern and northern East Asia Monsoonal (EAM) region on millennial scales as well as to investigate the relations of hydrological changes on carbon accumulation in the regions with contrasting environmental backgrounds, we performed facies-based hydrological reconstructions at two wetlands, Midiwanwetland (37°39'N, 108°37'E) and Dahu wetland (24°45'N, 115°2'E), respectively, located in a semi-arid loess-desert transitional zone and humid southern China. Our reconstructions show that there is an anti-phase pattern of the precipitation in these two wetlands on a millennial scale. However, with the different responses to the contrasting hydrological conditions, the carbon accumulations at these two sites show in-phase patterns on a millennial scale. These results indicate that the carbon accumulations in the two sites are mainly controlled by the local hydrologic conditions. The wetlands in both southern and northern China were found to be expanding during the interval from 6 to 4 cal. ka BP (ka = kilo annum), as inferred by the higher total organic carbon content. For the Mystery Interval (MI, from 17.5 to 14.5 cal. ka BP), however, both hydrological conditions and carbon accumulations in these two sites showed an in-phase pattern.

A high-resolution Holocene speleothem record from NE Romania: the nexus of Arctic and North Atlantic atmospheric circulation systems

Silviu Constantin^{1,2}, Ali Pourmand³, Oana Moldovan⁴, Arash Sharifi³, Sevag Mehterian³, Peter K Swart³

¹Emil Racovita Institute of Speleology, Bucharest, Romania. ²CENIEH-Centro Nacional de Investigacion sobre la Evolucion Humana, Burgos, Spain. ³RSMAS, University of Miami, Miami, USA. ⁴Emil Racovita Institute of Speleology, Cluj Branch, Cluj-Napoca, Romania

Abstract

The Romanian Carpathians act as a geomorphological barrier between different atmospheric circulation systems over Central and Eastern Europe; the NW of Romania lies under the remote influence of the North Atlantic oscillation, while the NE is influenced by the Arctic climate. In NW Romania, previous stable isotope studies of speleothems have not yielded a clear account of abrupt climate oscillations during the Holocene. Here we present results from a stalagmite collected from the Taușoare Cave, located in NE Carpathians. The chronology of stalagmite T141 is based on 15 high-precision Th/U dates ranging between 32 and 1.1 ka with a continuous growth between ~13.3 and 1.1 ka. The portion of the record within the Holocene was analyzed for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ at a resolution ranging between 15 to 200 years/sample. The resulting $\delta^{18}\text{O}$ record captures the Younger Dryas (YD) event centered at ~12.9 ka, with $\delta^{18}\text{O}$ values about 4 ‰ more depleted than those corresponding to the Holocene Climatic Optimum. The 8.2 ka event appears to be also captured in the record, although less prominent. The T141 isotope record is significantly different when compared to coeval records measured in speleothems from NW Carpathians, which do not exhibit marked changes during the YD or 8.2 ka events. This is likely due to the contrasting effect of temperature and atmospheric transport on $\delta^{18}\text{O}$ signal in NW Romania. Within a distance of 200 km to the east, on the eastern flank of the Carpathian range, the $\delta^{18}\text{O}$ signal of the Arctic circulation appears to be more prominent and clearly exhibits a positive relationship with temperature changes.

Application of Avaatech X-ray fluorescence core-scanning in Sr/Ca analysis of speleothems

Dong Li, Liangcheng Tan, Fei Guo, Yanjun Cai, Youbin Sun
Institute of Earth and Environment, Chinese Academy of Sciences, Xi'an, China

Abstract

Application of X-ray fluorescence core-scanning (XRF-CS) analysis on both marine and lake sediments has achieved remarkable results. However, its application now has not been widely extended to the research of speleothems. In this study, we measure the Sr abundance and the Sr/Ca ratio of three stalagmites (two aragonite stalagmites, one calcite stalagmite) using the state-of-the-art fourth-generation Avaatech high-resolution XRF core scanner. Through comparisons among different scan paths and among different scan resolutions, as well as comparisons with inductively coupled plasma optical emission spectrometer (ICP-OES), Itrax XRF and Artax XRF results, we confirm that the Avaatech XRF core scanner could accurately, quickly and non-destructively analyze the high-resolution Sr abundance of speleothems. Furthermore, we also combine the stalagmite $\delta^{18}\text{O}$ record to try to explain the paleoclimatic significance of the measured stalagmite Sr/Ca.

P-1504

Pipi shells: a new high-resolution palaeoenvironmental archive for south-eastern Australia

Amy Prendergast¹, Vincent Chea¹, Michael Godfrey²

¹University of Melbourne, Melbourne, Australia. ²Independent researcher, Melbourne, Australia

Abstract

Oxygen isotope ratios from marine mollusc shells have been widely used to reconstruct sea surface temperature (SST) and seasonal shellfish foraging records from archaeological sites worldwide. However, the application of this technique to the Australian archaeological record has so far been limited to a few sites. Pipi shells (*Donax deltooides*) are common components of many archaeological sites in south-eastern Australia. One pioneering study in the 1980s (Godfrey 1988) employed oxygen isotope analyses of pipi shells to study the Holocene archaeological record of Discovery Bay in Victoria. However, this study was constrained by the technology and techniques of the time. Recent advances in mollusc shell growth increment analysis (sclerochronology) and high-resolution geochemical sampling as well as improvements in mass spectrometry technology have enabled the reconstruction of sub-monthly sea surface temperature records from intertidal mollusc shells, thus enabling more robust and reliable reconstructions. In light of these recent advances, we reassess the utility of *Donax deltooides* shells as archives for SST and seasonality information in south-eastern Australia.

To validate whether this species is a faithful year-round palaeoenvironmental recorder, we collected live *D. deltooides* from Discovery Bay, Victoria each month for a year. We analysed the intra-annual variability of $\delta^{18}\text{O}$ in modern live-collected shells and sea water and compared $\delta^{18}\text{O}$ -derived SST reconstructions with instrumental SST records. Shell-derived SSTs were highly correlated with instrumental SST records over the period of collection. This suggests that these shells are reliable palaeothermometers. This study demonstrates the utility of applying advanced sclerochronological techniques to Australian shell middens and shows that pipi shells hold great potential for reconstructing monthly-resolved SST records and seasonal foraging practices in south-eastern Australia.

Mid-late Holocene palaeoclimate reconstructions from speleothem and peatland high-resolution stable isotope records (the HOPES project)

Mohammed Allan^{1,2}, Nathalie Fagel², David P. Gillikin³, Neil.J Loader⁴, Sophie Verheyden⁵, Michel Crucifix¹

¹The Georges Lemaître Centre for Earth and Climate Research (TECLIM), Earth and Life Institute, UCL, Louvain-la-Neuve, Belgium. ²AGEs, Département de Géologie, Université de Liège, Liège, Belgium. ³Union College, Stable Isotope Laboratory, Department of Geology, Union St. Schenectady, USA. ⁴Department of Geography, College of Science, Swansea University, Swansea, United Kingdom. ⁵Belspo, Politique scientifique fédérale, Brussels, Belgium

Abstract

Among geological archives, speleothems (i.e. secondary carbonate deposits in caves) and peatbogs are now regarded as important continental archives of past climatic and environmental conditions, offering a number of advantages relative to other archives such as lake sediments, tree rings or ice cores. Both archives, available in Belgium, are potentially reliable environmental records of high interest due to their dating possibilities and their possibility to preserve multi-proxy records of environmental and climatic dynamics.

Here, we present a peat core and a stalagmite collected from the Clefaye peatland (Hautes-Fagnes Plateau) and the Père Noel cave, respectively, used to reconstruct Mid to Late Holocene climate. The Clefaye peat core covers 6.4 ka according to ²¹⁰Pb, ¹⁴C datings and the Père Noel stalagmite (PN) covers the last 12.7 ka according to U/Th datings. Trace elements concentrations and stable isotopes were analyzed in Clefaye peat core and PN stalagmite to assess local and regional climate changes. To compare the two records, this study focuses on the interval from 1.5 to 6.5 ka. High spatial resolution measurements of Mg, Al, Sc, Sr, Ba were done by using Laser-Ablation Inductively Coupled Plasma Mass Spectrometry at Royal Museum for Central Africa (Tervuren, Belgium). The $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of Clefaye peat cellulose and PN stalagmite were measured by Mass Spectrometer at the Department of Geography, Swansea University (UK) and at Union College (USA). Time series of elemental and stable isotope geochemistry were established for the 2 archives. Precipitation and humidity conditions over Belgium was reconstructed by result integration derived from the two continental archives.

Even diagenesis processes influenced the peat composition (i.e. peat decomposition), the stable carbon and oxygen isotope signals preserve the hydrological conditions. The similar patterns of $\delta^{18}\text{O}$, $\delta^{13}\text{C}$ in both archives suggests that they have the potential to provide high resolution insights into regional palaeoclimatic variability during the Holocene. The regional climate patterns are dominated by alternations of dry and wet episodes during the Mid-Late Holocene. Five distinct periods of wetter conditions were identified between 6000 and 5500, at 5200, 4650, 3250 and at 2100 cal. BP, along with three periods of drier conditions between 4900 and 4750, at 4150, and from 3000 to 2500 cal. BP. These climatic variations show some correlation with published records from different climatic archives studied in Europe and in the North Atlantic area. The results suggest that local and regional climate change in the mid-late Holocene has a potential to control the peatland and speleothem proxies in Belgium, although the reliability of these records will depend heavily upon the nature (quality, purity and preservation) of the sample material analysed.

P-1506

Sub-annual multi-proxy data reveals Pacific ENSO variability during the mid-Holocene

Cinthya Nava Fernandez¹, Sebastian Breitenbach¹, John Hellstrom², Amanda French³, Vasile Ersek⁴, Annabel Wolf⁴, Beth Fox⁵, Adam Hartland³

¹Institute for Geology, Mineralogy and Geophysics, Ruhr University Bochum, Bochum, Germany. ²School of Earth Sciences, The University of Melbourne, Melbourne, Australia. ³School of Science, University of Waikato, Hamilton, New Zealand. ⁴Department of Geography and Environmental Sciences, Northumbria University, Newcastle upon Tyne, United Kingdom. ⁵Department of Biological and Geographical Sciences, University of Huddersfield, Huddersfield, United Kingdom

Abstract

The Pacific El Niño-Southern Oscillation (ENSO) affects climate dynamics globally. A number of archives are at our disposal to gain insight into the natural variability of the ENSO system, the controls underlying these dynamics and the impact it exerts on other climate subsystems. However, only very few high-resolution time series are available to inform us about ENSO conditions during the Holocene Thermal Optimum (ca. 7-5 kyrs BP, Moy et al. 2002, Donders et al. 2008, Cobb et al. 2013).

Here we present preliminary results from a U/Th dated stalagmite from remote Niue Island in the tropical South Pacific that reveal palaeo-hydrological conditions and ENSO dynamics during the mid-Holocene (ca. 7,000 to 5,450 years BP). Caves on Niue Island are highly susceptible to environmental changes, with local infiltration being modulated by seasonal shifts in the South Pacific Convergence Zone, and at multi-annual scale by ENSO (Tremaine et al. 2016). The island receives most rainfall during austral summer, while during the austral winter and during El Niño events rainfall is significantly reduced (Rasbury & Aharon 2006).

The shallow epikarst above the study site supports a rapid response of the cave environment to infiltration changes and thus transfer of climatic signals into the cave at seasonal scale.

Stalagmite C-132 consists of calcite and is visibly laminated, with layers as thick as 800 μm . Stable oxygen and carbon isotope analyses are combined with laser ablation multi-element profiles to illuminate past local moisture conditions at seasonal scale. Stable isotopes and X/Ca ratios vary at sub-annual scale, highlighting the rapid response of the cave system to external conditions.

Prior calcite precipitation (PCP) dynamics in the epikarst are the most likely reason for $\delta^{13}\text{C}$ and X/Ca changes. Oxygen isotopes reflect changes in moisture source distance and amount. We use statistical analyses to extract PCP changes that are superimposed on seasonal variability in our proxies and controlled by ENSO dynamics.

20th century decreases in local effective moisture recorded by a Kangaroo Island speleothem

Bronwyn Dixon^{1,2}, Russell Drysdale², Jonathan Tyler³, Ian Goodwin⁴

¹University of Reading, Reading, United Kingdom. ²University of Melbourne, Melbourne, Australia. ³University of Adelaide, Adelaide, Australia. ⁴Macquarie University, Sydney, Australia

Abstract

Australian cities and agricultural areas have seen a decrease in rainfall over recent decades, with economic and social consequences. High-resolution palaeoclimate records present an opportunity to place these trends into a longer context and can shed light on the drivers of such change over time scales beyond the instrumental coverage of the 20th century. This study presents outcomes from a five-year monitoring program and a new speleothem derived palaeoclimate record from Kangaroo Island, South Australia. The site is strategically located because it is situated in a location with few palaeoclimate reconstructions, as well as being climatically 'upstream' from major population and agricultural centres.

The monitoring program reveals the primary controls on rainfall and cave dripwater $\delta^{18}\text{O}$ as well as drip counts. Precipitation $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_p$) is controlled by rainfall amount on daily and monthly time scales. However, seasonal $\delta^{18}\text{O}_p$ values reflect seasonal changes in moisture source, with winter rainfall originating from the Southern Ocean and summer rainfall originating from the tropical Indian Ocean. Yearly $\delta^{18}\text{O}_p$ reflects seasonality of the rainfall, with winter rainfall currently dominating the average $\delta^{18}\text{O}_p$ values. Dripwater $\delta^{18}\text{O}$ values reflect the yearly weighted average $\delta^{18}\text{O}_p$ values.

Calcite $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values, in addition to a suite of trace element concentrations, were measured in a ~103-year-old speleothem from Kelly Hill Caves on Kangaroo Island. The $\delta^{18}\text{O}$, $\delta^{13}\text{C}$, and trace element results (Mg/Ca, Sr/Ca, Ba/Ca) corroborate wetter conditions in the early part of the record and drying in the most recent decades. Increases in Mg/Ca, Sr/Ca, and (to a lesser extent) Ba/Ca are driven by prior calcite precipitation and are used to identify dry periods in the palaeoclimate record. Comparison of these proxies with Kangaroo Island instrumental observations supports a rainfall interpretation; however, temperature may have played an important role in decreasing effective moisture, and thus triggering the increases in $\delta^{13}\text{C}$ and Mg/Ca since ~1970.

Outcomes of the monitoring investigation indicate that rainfall amount and moisture source influence rainfall $\delta^{18}\text{O}$ values, but interpretation of the speleothem record suggests that temperature also plays an important role on longer time scales. Overall, this study demonstrates that Kangaroo Island speleothems can preserve records of regional climate variability, and analysis of additional, older, speleothems from Kelly Hill Cave will assist in understanding the interplay of rainfall and temperature in southern Australian hydroclimate variability.

Abstract

The future frequency and magnitude of the El Niño – Southern Oscillation (ENSO) in a world with global climate change is still highly uncertain and topic of intense debate. High resolution records from sedimentary archives can aid our understanding of ENSO variability under changing climates on the true 2-7 year El Niño timescale. One of the most detailed continuous records of Holocene El Niño dynamics from a terrestrial setting is the Laguna Pallcacocha record from Cajas National Park, Ecuador. Previous analysis revealed hundreds of El Niño-driven light-coloured inorganic, clastic laminations, in the dark organic lake sediments which reflect increased frequency of El Niño events during the past 5000 years, with millennial-scale oscillations. While used worldwide as a key record of ENSO variability, it is essentially a local record with potential complexity in interpretation. High resolution pollen analyses represent a more regional source area that aid the development of our understanding of ENSO intensity through time. We present the first high resolution Holocene pollen record from Laguna Pallcacocha that reveals clear expanses of the montane forest belts to phases of high ENSO frequency. Additionally, an ultra-high resolution pollen analysis of the last century permit to calibrate interannual changes in pollen deposition to variability in regional precipitation and temperature variability forced by ENSO on the true 2-7 year timescale. Application of this approach to an interval during the early Holocene will for the first time detect annual-scale vegetation responses during a phase of proposed reduced ENSO intensity.

Using elemental mapping of Mg/Ca ratios to cheaply screen seasonal limpet records for SST changes and vital effects

Niklas Hausmann^{1,2}, Amy Prendergast³, Demetrios Anglos^{1,4}

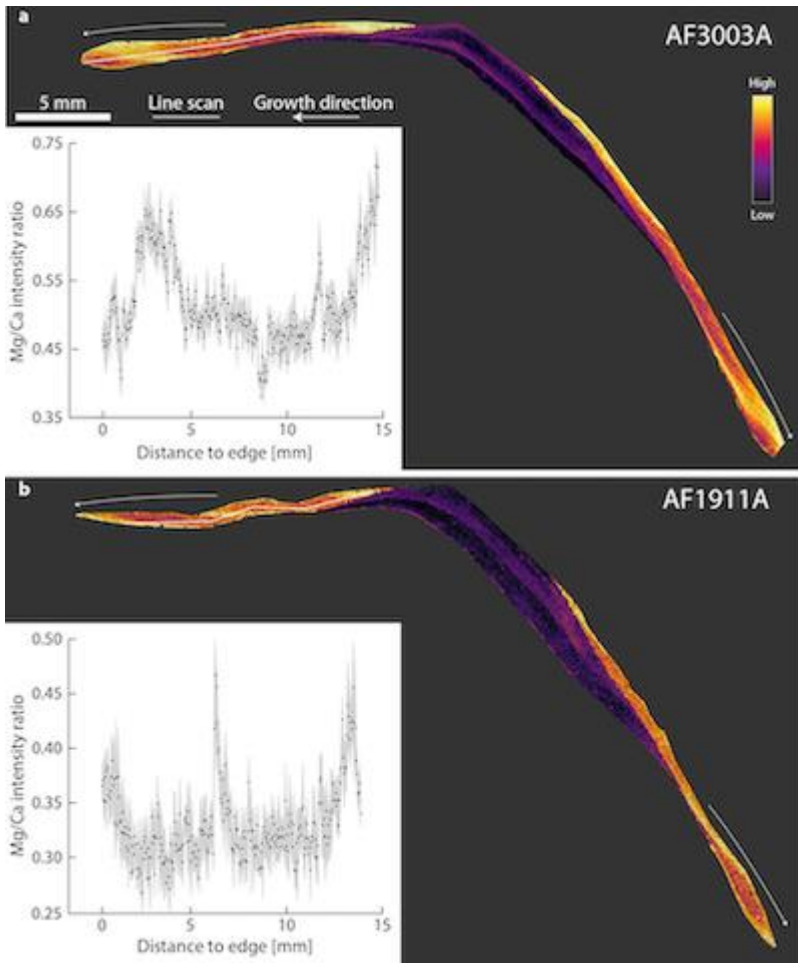

¹Institute of Electronic Structure and Laser, Heraklion, Greece. ²University of York, York, United Kingdom. ³University of Melbourne, Melbourne, Australia. ⁴University of Crete, Heraklion, Greece

Abstract

Elemental analysis of biogeochemical archives is an established technique used to study climate in a range of applications, including ocean circulation, glacial/interglacial climates, and anthropogenic climate change.

Data from mollusc archives are especially important because of their global abundance and sub-annual resolution. Despite this potential, they are underrepresented among palaeoclimate studies, due to enigmatic physiological influences skewing the elemental record. Understanding the patterns behind these influences will improve data interpretation and lead to the development of new climate proxies.

Here, we apply extensive mapping of multiple mollusc specimens using the rapid method of Laser Induced Breakdown Spectroscopy (LIBS) across a wider region to compare and resolve enigmatic patterns within the elemental record caused by physiological influences.

Mg/Ca ratios displayed as maps and line scans for two modern limpet shells collected in spring (top) and autumn (bottom).

2D elemental (Mg/Ca) maps of whole limpet shells (*Patella caerulea*) from across the Mediterranean revealed patterns of variability within individual mollusc records as well as within isochronous parts of specimens. By registering and quantifying these patterns, we established previously uninterpretable correlations with sea surface temperature (SST): $R^2 > 0.8$.

We additionally found that the resulting SST equations were specimen specific and would require additional calibration using other methods (i.e. $\delta^{18}\text{O}$). We thus present a combined approach of fast and cheap LIBS screening and subsequent isotopic analysis of seasonal minima and maxima only.

This approach thus presents the means to assess annual temperature ranges using oxygen isotope analysis requiring only 2 samples per shell and season of capture, important for archaeological studies, entirely without oxygen isotope analysis.

Revealing interannual variability in the Indian monsoon with sub-mm lipid biomarker and elemental measurements over the past 200 years

Tiffany J. Napier¹, Lars-Peter Wörmer¹, Jenny Wendt¹, Andreas Lückge², Kai-Uwe Hinrichs¹

¹Organic Geochemistry Group, MARUM – Center for Marine Environmental Sciences, Department of Geosciences, University of Bremen, 28359 Bremen, Germany. ²Bundesanstalt für Geowissenschaften und Rohstoffe (BGR), 30655 Hannover, Germany

Abstract

Sub-decadal to annual climate oscillations are particularly relevant to human climate perception, including such well-known phenomena as seasonal tropical monsoons and the Pacific El Niño-Southern Oscillation (ENSO). To assess the variability of these oscillations in the past, proxies for climate variables that are influenced by these oscillations (e.g., temperature, precipitation) and geologic materials with a temporal resolution able to record them are both needed. However, even in settings where these two criteria are met, the sample size needed for laboratory analysis can limit temporal resolution.

Recently, a mass spectrometry imaging technique, matrix-assisted laser desorption/ionization coupled to Fourier transform-ion cyclotron resonance mass-spectrometry (MALDI-FT-ICR-MS), has been developed to measure and map distributions of climate-relevant biomarkers (e.g., GDGTs, alkenones) from intact sediment core surfaces in 100- μm increments, unlocking the ability to reconstruct sub-annual paleoclimate (Wörmer et al., 2014, 2019; Alfken et al., 2019). The same sediment sample surfaces can also be analyzed with micro-XRF mapping, enabling congruent examination of complementary elemental- and biomarker-derived paleoenvironmental proxies at ultra-high spatial resolution both down-core and along-lamination.

Nearshore Pakistan Margin (northeastern Arabian Sea) marine sediments provide excellent, continuous archives of past climate and oceanographic conditions that can be used to reconstruct the variability of the Southwest (summer) and Northeast (winter) monsoons of India. These sediments are composed of alternating light and dark layers—laminae couplets—that together record the deposits of a single year. The sub-mm-thick layers consist of organic-poor terrigenous clays associated with river-runoff after heavy rainfall events, and organic-rich layers associated with high primary productivity.

Using the congruent micro-XRF and MALDI-FT-ICR-MS techniques, we measured elemental abundances and lipid biomarkers in Pakistan Margin sediment core SO90-58KG in continuous 100- μm increments, resolving 8 to 14 discrete time intervals per year over the past ~200 years. We present a precipitation proxy for south-central Pakistan based on detrital, siliciclastic elemental abundances, and sub-annual $U_{37}^{K'}$ and CcAT (a GDGT-based proxy; Wörmer et al., 2014) sea surface temperature (SST) proxy records for the northeastern Arabian Sea. Precipitation may be linked with the Southwest monsoon, and cooler winter SSTs are due to convective mixing by the Northeast monsoon. We apply spectral analysis to identify dominant cycles in precipitation and SST reconstructions and periodicity changes through time. We compare our sub-annual precipitation and SST proxies with instrumental and satellite data, and other records of Southwest and Northeast monsoon variability and ITCZ position.

Hydrological change in subtropical Australia from 80–40 kyr

Cameron Barr¹, John Tibby¹, Melanie Leng^{2,3}, Jonathan Tyler¹, Haidee Cadd¹, Lee Arnold¹, Jonathan Marshall⁴, Glenn McGregor⁴

¹University of Adelaide, Adelaide, Australia. ²British Geological Survey, Nottingham, United Kingdom. ³University of Nottingham, Nottingham, United Kingdom. ⁴Queensland Government Dept of Environment and Science, Brisbane, Australia

Abstract

There are very few continuous palaeoclimate records of the period when humans first colonised Australia 60–50,000 years (60–50 kyr) ago, or during the extinction of Australia's megafauna between 51 and 40 kyr. The studies that exist primarily employ palynological techniques; however, the interpretation of terrestrial vegetation records becomes complex within the nexus of combined human, fire, climate and mega-herbivore influences. An incomplete understanding of Australian climates during this period means questions remain regarding the relative influence of Northern and/or Southern Hemisphere forcing of Australian climate variability and the role of climate in the extinction of megafauna. Here we present a palaeohydrological record from Welsby Lagoon, a wetland in subtropical eastern Australia that was recently discovered to be over 100,000 years old. We use the oxygen isotopes of aquatic cellulose preserved in the sediment – which reflect the isotopic composition of the lake water – to infer hydrological variability between 85 and 40 kyr independent of changes in terrestrial vegetation.

Our results demonstrate substantial hydrological variability occurred during this period, with apparent links to both Antarctic temperatures and North Atlantic Heinrich events. We propose that this is due to the combined influence of sea-surface temperature variability and the impacts of ITCZ migration on the prevalence of south-easterly trade winds in transporting moisture to the study region. We find evidence of a notable shift towards drier climates during the megafauna extinction window at around 45 kyr, aligning with findings from elsewhere on the continent. Though the magnitude of this shift is not exceptional in our record, it does imply that, in the subtropics at least, climatic change may have played a contributing role in the demise of the megafauna.

⁵Department of Atmospheric Sciences, Cochin University of Science and Technology, Kochi, India. ⁶Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan

Abstract

Variations in oxygen isotopes in speleothems are often interpreted to reflect variations in the amount of precipitation controlled by changes in climate phenomena such as the monsoon or ENSO. However, this amount effect has recently been questioned, favoring other mechanisms such as moisture source(s), rainout history, shifts in climate patterns or front systems, or the influence of local convection. A more than 5 years long daily resolved precipitation and $\delta^{18}\text{O}$ record from southern Thailand allows the relationship between precipitation patterns and rainwater $\delta^{18}\text{O}$ to be examined. Rainfall at the Krabi station was highly irregular with rain events ranging from 0.1 mm to nearly 150 mm per day. Rainwater $\delta^{18}\text{O}$ values vary from -17.50 to 8.24 ‰, with a long-term average close to -5 ‰. We demonstrate that while daily and amount weighted seasonal $\delta^{18}\text{O}$ values show no correlation with rain amount, the amount weighted monthly values display a significant correlation with monthly rainfall. Statistical comparison to atmospheric parameters reveal a strong correlation to outgoing longwave radiation, suggesting that local convection rather than precipitation amount control variations in rainwater $\delta^{18}\text{O}$ in this region. Comparison to a short cave drip water record suggests that the atmospheric $\delta^{18}\text{O}$ signal is recorded with a muted amplitude in the drip water, and with a lag of one to two weeks.

The link between Asian summer monsoon, polar and tropical regions during the Quaternary

Zeke Zhang^{1,2}, Gaojun Li², Zhisheng An¹

¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²Nanjing University, Nanjing, China

Abstract

A long-term decreasing trend in the Asian summer monsoon (ASM) during the Quaternary has been proposed to be associated with increasing ice volume, decreasing $p\text{CO}_2$ and global temperature based on observations of changes on glacial-interglacial time scales. However, the long-term evolution of the ASM intensity during the Quaternary is still highly debated. The debate is mainly caused by the paucity of continuous geological records that cover the Quaternary and a lack of fidelity of paleo-proxies that could faithfully reflect monsoon intensity.

To understand this question, here we use a new proxy based on oxygen isotopic compositions of pedogenic carbonates from the Chinese Loess Plateau to reconstruct the ASM intensity over the past ~2.6 million years, which shows an increasing long-term ASM intensity, rather than a weakening trend. Then, we review the current geo-biological archives from ASM region to confirm our result. Afterward, we integrate the records from polar and tropical regions to explore the inter-regional processes from a global perspective.

P-1518

Aridity timeseries for 10 selected key regions of the global climate system during the last 60 000 years

Florian Fuhrmann, [Frank Sirocko](#)

Department of Geoscience, Johannes-Gutenberg-University, Mainz, Germany

Abstract

Teleconnections existed at least from ~ 60 000 to ~ 48 000 yr b2k and from 25 000 to 15 000 yr b2k (LGM) from North Atlantic over Central Europe, Arabian Sea to China. Strong aridity can be shown during LGM (25 000 to 15 000 yr b2k) for Cariaco Basin, Central Europe, France, Portuguese Margin, NW-Africa, Mediterranean Sea, Arabian Sea and China. Early marine isotope stage 3 (MIS3, 60 000 – 48 000 yr b2k) was warm and Humid in Cariaco Basin, NW-Africa, Central Europe, Arabian Sea and China.

Published literature on the dust content in terrestrial and marine sediment cores is synchronized with terrestrial and marine pollen data and speleothem growth phases on a GICC05 time scale for ten selected key areas of the global climate system during the last 60 000 years. Records have different time resolution and are dated by different methods, but still are brought to a synthesis for each of the regions. All regions show speleothem growth during the early MIS3, sometimes continued into the middle MIS3, but mostly confined to interstadial times only. Dust is common during the entire MIS2, but dust deflation in some regions start in the middle MIS3. It is not always apparent if the dust deflation is confined to stadial phases only, because the time resolution is often not sufficient to resolve the stadial / interstadial phases precisely. A major problem for the middle and early MIS3 are the limitations of ^{14}C dating. Finally, we detect only few regions where a MIS3 synthesis of dust, vegetation and speleothem growth results in coherent pattern. With all information of the ten regions combined, a newly developed Aridity Index is estimated. This Index reveals strong aridity patterns throughout the northern hemisphere. The regions show synchronous changes in vegetation, speleothem growth and Aeolian dust and in result Aridity, which can be explained by atmospheric teleconnections of the regions.

¹Institute of Geosciences, Johannes Gutenberg University Mainz, Mainz, Germany. ²Höhlen- und Heimatverein Laichingen, Laichingen, Germany. ³Institute of Geology, University of Innsbruck, Innsbruck, Austria. ⁴GFZ German Research Centre for Geosciences, Potsdam, Germany. ⁵Max Planck Institute for Chemistry, Mainz, Germany

Abstract

Speleothems, such as stalagmites or flowstones, are unique continental archives of past climate and environmental dynamics. Past climate records can be established and precisely dated by a variety of independent proxies (such as $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) and U-series disequilibrium methods, respectively.

Here we present new speleothem $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ time series from a 1.3 meter-long calcite flowstone core (BÄ-1) drilled in the Bärenhöhle, Swabian Alb, Southern Germany. The 200 m long Bärenhöhle developed in Upper Jurassic limestone in the Pliocene and Early Pleistocene under epiphreatic conditions. Cave sediments and speleothems in the Bärenhöhle can be subdivided in at least 13 periods of speleothem growth, which reveal several accumulation and erosion processes during the early and middle Pleistocene. The location of Bärenhöhle can be strategically used to reconstruct past changes of mid-European hydroclimate and associated Northern Hemisphere (NH) mid-latitude atmospheric pattern highlighting the potential of speleothems from Bärenhöhle to gain a better understanding of mid-latitude climate variability.

The morphology of the flowstone core shows a succession of several growth periods, suggesting a discontinuous formation of BÄ-1. This is for example indicated by five thin sand layers and two soda straw layers (up to 3-4 cm thick) where no flowstone formation occurred, related to a stream that flowed through the cave, possibly during deglaciation periods. A first set of U-Th ages and the correlation of the BÄ-1 $\delta^{18}\text{O}$ time series to the benthic stack $\delta^{18}\text{O}$ time series and a benthic $\delta^{13}\text{C}$ time series reveal that the upper half of the flowstone core grew from c. 83 kyrs to 530 kyrs. Based on these preliminary analyses we find that the flow stone core includes several glacial-interglacial cycles during the last 530 kyrs, but did not grow during peak glacial conditions during MIS 12, 10 and presumably 6.

Absolutely dating of the bottom half of the flowstone core is not possible due to the secular equilibrium of U- and Th-isotopes, but U-isotope ages, the history of cave sediments in Bärenhöhle and a first magnetic record of BÄ-1 suggest that it grew between 530 kyrs and about 1.4 million years before present. However, both $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values from the bottom half of BÄ-1 show pronounced changes of several per mil that partially follow the benthic $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ time series, which suggest that some glacial-interglacial cycles are recorded.

In summary, our preliminary set of analyses on BÄ-1 emphasise the high potential of speleothems from Bärenhöhle to reconstruct Northern Hemisphere mid-latitude climate and environmental variations on long time scales that can be compared to other climate reconstructions from high (ice cores) and low (e.g. speleothem based monsoon reconstructions) latitudes. This will allow for a better understanding of interregional relationships/teleconnections on various time scales.

Abstract

Situated at the intersection between of Africa and Eurasia, the Southern Caucasus is a key region in understanding hominin dispersal and behaviours during the Pleistocene. Specifically, the occurrence of a wide range of biomes and steep topographic gradients over small geographic area create an ideal locale to examine multi-scalar models of hominin-environment interactions. The Ararat Depression is a large intermontane basin located in Armenia and Turkey, bounded by the volcanic centres of Ararat and Aragats. Presently, the basin is drained by the river Arax; however, during the Quaternary there were several intervals in which lakes persisted in the area. Exposed on the surface today are the relict shorelines and deposits associated with these lakes, in addition to at least 200m of interbedded lacustrine and volcanogenic deposits representing the basin fill. Limestone escarpments outcrop on the eastern side of the depression, in which karstic cave and springs created thick travertine deposits. Several of these caves have yielded Palaeolithic archaeological remains, with further artefact surface scatters also identified. The wide range of depositional environments in the area offers enormous potential for the development of a high resolution chronological and environmental framework in this area.

Here we present preliminary results from ongoing investigations in the Armenian sector of the Ararat Depression as part of the Fritz Thyssen Foundation funded 'Pleistocene Hunter-Gather Lifeways and Population Dynamics in the Ararat (palaeo-lake) Depression, Armenia' project. We focus specifically on the results from extensive geomorphic mapping, deposit modelling and archaeological surveys undertaken, highlighting the ongoing chronological (OSL, U-Th, ¹⁴C, tephrostratigraphy) and multiproxy environmental work currently being undertaken. It is envisaged that the results of this work will significantly expand our understanding of Pleistocene hominin population dynamics and environmental change in the Southern Caucasus and enable its articulations within the wider context of Southwest Asia.

New loess deposits in the southern Caucasus - On the way towards an interregional loess-stratigraphic scheme

Daniel Wolf¹, Tilmann Wolpert², Lilit Sahakyan³, Hayk Hovakimyan³, Kristina Sahakyan³, Jenni Sherriff⁴, Keith Wilkinson⁴, Markus Fuchs², Dominik Faust¹

¹Technische Universität Dresden, Dresden, Germany. ²Justus-Liebig-University Giessen, Giessen, Germany. ³National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia. ⁴University of Winchester, Winchester, United Kingdom

Abstract

In the framework of a research project funded by the German Research Foundation (DFG), much work is being conducted on the Sevkar loess record, NE-Armenia, in order to explore it as a reliable and meaningful archive of palaeoenvironmental conditions. This work includes detailed stratigraphic analyses, extensive luminescence dating, sedimentological, mineralogical, geochemical, micromorphological, and clay mineral analyses, as well as terrestrial mollusc, biomarker, and pollen analyses. Although most of the work is still in progress, we are already able to provide a local to regional stratigraphic model for the Sevkar area (Tavush region) (see Wolf et al. 2016) based on the correlation of four individual loess sections, each of them with a thickness between 22 and 42 meters.

In the most recent past, we were successful in discovering further and not yet described loess and dust deposits in the Hrazdan area (Kotayk and Gegharkunik regions) as well as in the area of Stepanakert, Maghavuz in the Republic of Artsakh (Nagorno-Karabakh). Deposits in the latter area are similar to the loess in the Sevkar area, situated at the eastern foothills of the Lesser Caucasus at the transition to the Transcaucasian depression. Contrary, deposits close by Lake Sevan are located to the west of the main ridge of the Lesser Caucasus Mountains. This fact, together with the different character of the deposits as well as differing stratigraphic appearances, suggests disparate sediment sources and probably disparate conditions of dust formation, deposition, and post-sedimentary overprinting.

On the poster, a first stratigraphic overview of the different loess sites will be given together with observed similarities and differences. In addition, we will present some key sites that will be visited in the course of the post-conference excursion following the International Symposium on "Loess deposits as archives of environmental change in the past" that will take place from September 15th to 23th, 2019 in Yerevan (Armenia).

P-1603

Evidence of long ice-free conditions during MIS 3 in northern Finland

Pertti Sarala

Geological Survey of Finland, Rovaniemi, Finland. Oulu Mining School of the University of Oulu, Oulu, Finland

Abstract

Northern Finland has been repeatedly in the centre of the Fennoscandian Ice Sheet during Late Pleistocene. Till stratigraphy is composed of several till beds having stratified sand and fines inter-till layers and sometimes organic material; peat and gyttja. However, many of them were dated in 1970s and 1980s using radiocarbon method, which gave unreliable ages 45 ka or more i.e. indicating the limit of the dating method to be reached (e.g. Hirvas 1991).

From the beginning of this century, many of the earlier stratigraphical key sections were re-examined and dated by Optical Stimulated Luminescence (OSL). Many of the inter-till layers have been dated back to Eemian or Early Weichselian (e.g. Mäkinen, 2005, Auri et al. 2008; Lunkka et al. 2015), but there were also indications of the Middle Weichselian ages and ice-free conditions during MIS3 (Salonen et al. 2014, Sarala et al. 2010, Johansson et al. 2011). Particularly, several new observations of the inter-till stratified sections with OSL dates supported the idea (e.g. Sarala & Eskola 2011, Sarala et al. 2016). The best section and the key site locates in Kaarreoja, northern Finnish Lapland, where the most well-preserved and representative sedimentary deposit including organic peat and wood pieces were studied and dated (Sarala et al. 2016). It is confirmed that during MIS3, in the middle of the most recent ice age, some 30,000–50,000 years ago, birch and coniferous forests grew in Lapland, Finland.

Nowadays, there are more than 100 reported OSL ages from northern Finland. The determined ages of Weichselian age form three groups: old 115-70 ka (MIS 5), middle 53-67 ka and young 21-46 ka (MIS 3). New dating results prove that the extent of glaciers and the length of glaciations were mostly short through Weichselian in Finland. During Early Weichselian, there were three short stadials, which occurred only in the northernmost Finland. Middle (MIS 4) and Late Weichselian (MIS 2) stadials lasted longer, and according to Sarala (2005) and Salonen et al. (2008) they were probably the only stages when glaciers covered central and southern Finland. Instead, during the MIS 3 northern Finland seems to be ice-free for a long time and the OSL ages (21-25 ka) from Veskonieni, close to Inarinjärvi Lake, indicate rapid build-up of continental ice to LGM limits (MIS 2). These observations support the recently strengthened idea of a variable climate within ice ages and the relatively short duration of glaciation cycles, as well as the rapid growth and melting of ice sheets during ice ages.

P-1604

Global chronostratigraphical correlation table for the last 2.7 million years, version 2019 QI-500

Kim M. Cohen¹, Phil L. Gibbard²

¹Utrecht University, Utrecht, Netherlands. ²University of Cambridge, Cambridge, United Kingdom

Abstract

This poster shows the 2019 version of a table showing chronostratigraphical subdivisions of late Cenozoic geological time, aligned to key geological records from marine, glacial and terrestrial environments around the world. As did earlier versions (Gibbard & Cohen 2008; web updates, Bern 2011, Nagoya 2015), the chart aims to provide scientists, students, professionals and the general public with a ready reference to stratigraphical terms and schemes in use in different areas for similar periods. The chart received substantial updates, comprising the status of Quaternary chronostratigraphic subdivision (e.g. Head & Gibbard 2005; Walker et al. 2018), the combined age-modelled geomagnetic and isotope records from ocean drilling records (Channell et al. 2009, 2016), and revisions in regional correlation schemes, notably for eastern Europe (e.g. Shik 2014). The chart and a description text are to be published in the celebratory issue 500 of Quaternary International, to appear in open access at the time of the Dublin congress (Cohen & Gibbard, 2019) and will be distributed via stratigraphic commission websites (IUGS' ICS SQS: www.stratigraphy.org; INQUA SACCOM: www.inqua.org).

Coiling ratio of *Globorotalia truncatulinoides*: a robust stratigraphic tool in the North East-Atlantic during the Holocene.

Linda Rossignol, Frédérique Eynaud, Salomé Ducos
UMR EPOC Bordeaux University, Bordeaux, France

Abstract

Coiling ratios of planktonic foraminifera are commonly used in paleoceanographic studies to build stratigraphic sequences (e.g. *Neogloboquadrina pachyderma* sinistral form). Bolli (1950, 1951) noticed that such an exercise is especially possible with the species *Globorotalia truncatulinoides* because the ratio of sinistral vs dextral shells strongly varied in time and space. In Holocene sequences of the North East Atlantic ocean, authors usually use coiling ratio of *G. truncatulinoides* to identify a warm period (between 6 and 10 ka) marked by increases of sinistral form occurrences (Pujol 1980, Auffret et al., 1996, Zaragosi et al., 2000).

In this study, we consider changes in the coiling ratio of *G. truncatulinoides* over the last 15 000 years thanks to a collection and combination of ten marine sediment cores distributed from the Rockall trough to the southern Iberian Peninsula. This regional compilation aims to improve the precision of this stratigraphic as the work done by Ducassou et al. 2018 in the Gulf of Cádiz, especially in the definition of *G. truncatulinoides* events (TE1, TE2 and TE3). Preliminary results allow us to identify a marked change in *G. truncatulinoides* populations at 10 ka, with sinistral forms reaching up to 80% (TE3). This transient event which can extend to the mid Holocene depending on the considered site is characterized by a multi-step structure. Accurate datings of this interval will allow obtaining a robust stratigraphic tool for the Holocene. The *G. truncatulinoides* events TE1 and TE2 are not observed along all cores. These results bring us to understand more finely reasons of changes of coiling ration of *G. truncatulinoides*.

As counts of the two coiling forms of *G. truncatulinoides* are quite easy and do not imply high instrumental costs, such a study demonstrates that a robust stratigraphic framework can be efficiently obtained for Holocene marine archives on this basis.

P-1606

Chronology and deltaic development of the Nakdong River delta area, southeastern Korean Peninsula

Jin Cheul Kim¹, Daekyo Cheong², Dong-Geun Yoo¹, Jooah Choi¹, Seok Hwi Hong¹, Seungwon Shin²

¹Korea Institute of Geoscience and Mineral resources, Daejeon, Korea, Republic of. ²Department of Geology, Kangwon National University, Chuncheon, Korea, Republic of

Abstract

Optically stimulated luminescence (OSL) dating was performed on Late Quaternary deltaic sequences from five long cores in the Nakdong River estuary, Korea. OSL ages obtained from chemically separated fine (4-11 μm) and coarse (90-250 μm) quartz grains ranged from 14.0 ± 0.8 to 0.4 ± 0.04 ka, revealing clear consistency between the grain-size fractions. The D_e values from the standardized growth curve (SGC) are consistent with those from the single-aliquot regenerative-dose (SAR) procedure, which suggests that the SGC is valid for the Nakdong deltaic sediments. However, different samples from different sites did not share dose-response characteristics. The ^{14}C ages of shells and wood fragments ranged from 11 to 2.9 ka, demonstrating reasonable agreement with the OSL ages, within the error range. OSL ages obtained by high-resolution sampling show down-section variations in the depth-age curve, indicating the occurrence of rapid changes in sedimentation rate. The Nakdong deltaic sediments were divided into five units based on sedimentation rate. The lowest (unit 5) shows a break in sedimentation between the last glacial maximum (LGM) and the Holocene. The sedimentation rate increased in units 4 and 3, presumably corresponding to the early to middle Holocene sea level rise and high stand. Unit 2 shows a gradually decreasing sedimentation rate following the regression of the shoreline, until about 2 ka. The progradation of the Nakdong River delta resulted in the rapid accumulation of unit 1 during the last 2000 years.

Tephrostratigraphy of the Middle Paleolithic (MIS5-3) in southern Italy: the Infreschi and Grotta del Cavallo records

Giovanni Zanchetta¹, Biagio Giaccio², Monica Bini¹, Fabio Martini³, Lucia Sarti⁴

¹University of Pisa, Pisa, Italy. ²IGAG-CNR, Rome, Italy. ³University of Florence, Florence, Italy. ⁴University of Siena, Siena, Italy

Abstract

Near or beyond the limit of radiocarbon dating (~54 ka), chronology of Middle Paleolithic archeological sites is challenging. This amplifies the ambiguity in correlating archeological successions among them and with paleoclimate archives, so limiting our understanding of historical processes and of the environmental context of archeological remains. Southern Italy archeological successions are important archives to reconstruct stratigraphy and chronology of Early to Middle Paleolithic technocomplexes thanks to the presence of tephra layers mostly originated by Campanian volcanoes (Giaccio et al., 2008; Zanchetta et al., 2018). In the last years the stratigraphy, chronology and the geochemical fingerprinting of these layers have been clarified allowing detailed correlation (Giaccio et al, 2017). In this contribution, we discuss the tephrostratigraphy of two marine caves filled by sediment containing prevailing Middle Paleolithic remains (Musterian) located ca. 200 km apart in southern Italy (Grotta di Infreschi and Grotta del Cavallo). In particular, we highlight the importance of the X-6 tephra marker at regional scale for the chronology of Musterian layers.

P-1608

Tephrostratigraphy of the basaltic Izu-oshima volcano during last 20,000 years using radiocarbon ages and distal tephras, off Tokyo Pacific Ocean

Takehiko Suzuki¹, Satoshi Terayama²

¹Tokyo Metropolitan University, Tokyo, Japan. ²terayama-satoshi@ed.tmu.ac.jp, Tokyo, Japan

Abstract

The Izu-oshima volcano (110 km SSW of Tokyo) in northern Izu-Bonin Arc, is one of the most active Quaternary volcanoes in Japan. This volcano originating from basaltic magma has frequently erupted; that is, 12 times of major eruptions occurred after 2 ka. Studies of its eruption history have been carried out by Nakamura (1964), Kawanabe (2012) and so on. However, precise ages of eruption preceding the caldera formation occurred at 1.8 ka have not been determined. Here, we re-examine the chronological framework of eruption history of the Younger Edifice of pre-caldera.

Fall-out tephras are typically exposed along so-called Great Cut of Beds in SW part of the island. Previous studies by Tazawa (1990) and Uesugi et al. (1994) have described this outcrop, numbering each tephra layer using serial numbers (O1–95 and Osb96–127). All tephras except O55 and O58 are proximal fall-out tephras composed of scoriaceous lapilli and/or scoriaceous ash. Due to the large number of tephras and lithological similarity, it is difficult to confirm each tephra defined by previous studies except several characteristic ones such as O95, O58, and O55. O55 and O58 are rhyolitic tephras from Nijima island and Omuro-dashi submarine depression, respectively (Saito et al., 2007). Uesugi et al. (1994) estimated the age of the lowest tephra to be 25 ka or older by using 15 radiocarbon ages. However, this estimation is not reliable because it was determined using two oldest conventional radiocarbon ages (non-calibration) of 14–13 ka for the same horizon (just above O64) and under the assumption that the frequency of the tephra occurrence is constant.

In this study, radiocarbon dating was performed for organic tephric loess collected from 14 horizons under O58 and 11 above O58. The oldest radiocarbon age is 18,598–18,287 cal BP, determined at the horizon 4 m below O95. The age of O95, the most prominent scoria fall deposit, is most likely to be 16–17 ka judging from several radiocarbon ages. It is 2400–3700 years younger than the estimated age (19.4–19.7 ka) by Uesugi et al. (1994). We also recognized widespread K-Ah tephra using volcanic glass geochemistry. Two radiocarbon ages determined at 45 cm above and 55 cm below K-Ah are 6882–6747 cal BP and 8167–8021 cal BP, respectively. These ages are concordant with revised age of K-Ah (7307–7196 cal yrs BP; McLean et al., 2018), indicating the age of horizon detected K-Ah is older than estimated age of 6,330±85 yBP by Uesugi et al. (1994). These results indicate that the interval between O95 and K-Ah is shorter (67–75%) than previous estimation, suggesting higher frequent occurrence of the eruptions in this period.

P-1609

Do visible Holocene tephra from Mt. Churchill, Alaska, display varying geochemistry across their distributions?

Lauren Davies, Britta Jensen
University of Alberta, Edmonton, Canada

Abstract

Mt. Churchill, located in the Wrangell volcanic field close to the Alaska/Yukon border, is the suggested source of the late Holocene White River Ashes (WRAn and WRAe). These eruptions are separated in time by ~700 years and have geographical distributions related to their dominant plume directions (north and east, with some overlap). Visible tephra deposits are found up to 300 to 1500 km from Mt. Churchill with cryptotephra correlations extending 1000 to 7000 km (distances for WRAn and WRAe respectively).

Both eruptions have been geochemically characterised using proximal material (e.g. Preece et al., 2014) but their major element geochemical data, most commonly used to correlate and/or provenance distal tephra, show the eruptions produced two very similar rhyolites with only slight differences in their range of wt.% SiO₂. This considerable overlap means additional information (e.g. stratigraphy, chronology, associated mineral Fe-Ti oxide data) is required to interpret which tephra is present where only one is found. Trace element geochemical data is also similar between eruptions, with broad ranges of values measured for several elements.

While distal samples of the WRAe have relatively constrained major element geochemical data across large distances (e.g. Jensen et al., 2014) there are comparatively fewer distal samples of WRAn analysed. The little data collected over several years on a limited number of widely-distributed WRAn samples at the University of Alberta show a more complicated geochemical picture for this older eruption - samples have variable wt.% SiO₂ ranges, some have bimodal rhyolitic populations. It is not clear if this relates to the eruption of a heterogeneous/zoned magma column or, potentially, multiple closely spaced eruptions.

Here, new samples collected from Haines Junction (YT) to Tok (AK) on a transect of 460 km moving from east to north of Mt. Churchill are geochemically characterised to investigate any variation with sample location/distance from source and to improve mapping of the known visible limits of each eruption/plume. Samples were analysed at the University of Alberta, Edmonton, producing major and trace element glass analyses and Fe-Ti oxide analyses of magnetite and ilmenite.

Abstract

Timor, a southerly island east of Wallace's Line in SE Asia, preserves extensive Quaternary gravel deposits that have yielded fascinating fauna remains such as the highly dwarfed *Stegadon timorensis* and a larger *S. trigonocephalus*. The age of the older fossil-bearing gravels remain in question, with only one age determination of >130 ka derived from six ²³⁰Th-²³⁸U dates on a tusk fragment found in the Raebia area. However, two tephra deposits were found bracketing these gravels near Raebia, a *S. timorensis* fossil locality 8 km northeast of Atambua city. Here we present the full geochemical and age characterization of these two tephras. Both tephras are high-silica rhyolites, but trace-element geochemistry suggests they originate from different regions in the Sunda-Banda volcanic arc north of Timor. The upper tephra (Raebia Tuff 1; RT1) has a greater enrichment in LREE and a steeper La/Yb profile, suggesting this unit is from a larger island in the arc (i.e. thicker crust), while the lower tephra (RT2) has a notably flatter profile. Biotite and zircons for ⁴⁰Ar/³⁹Ar and laser ablation U-Pb dating were extracted from RT1, and zircons from the lower unit RT2. RT1 had zircons with two distinct age populations, but the youngest yield a ²³⁰Th deficiency corrected ²⁰⁶Pb/²³⁸U age of 665 ± 19 ka, (2s, n = 23, MSWD = 0.81), consistent with the ⁴⁰Ar/³⁹Ar age 614.9 ± 16.4 ka (2s, full external precision). Preliminary zircon dates on RT2 are more problematic, providing a large range that suggests inheritance by xenoliths and/or locally-sourced detrital zircons. However, a single zircon yielded ²³⁰Th deficiency corrected ²⁰⁶Pb/²³⁸U age of 708 ± 66 ka (2s, n=17, MSWD = 0.41). RT2 has now also been correlated to a tephra at IODP Site U1483 on the northwest Australian margin, which offers an independent age verification. The identification of RT2 in U1483, and the geochemistry of RT1, shows that these two newly described tephras are regionally distributed and will likely be important stratigraphic horizons for this portion of Southern Wallacea and into the Indian Ocean. They also push the age for these fossils back by ~500,000 years.

P-1611

Tephra evidence for the explosive eruptions of Changbaishan volcano

Chunqing Sun, Jiaqi Liu

Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

Changbaishan volcano is known for its Millennium eruption (ME, AD 946; VEI 7) and the ME tephra has been detected in Greenland ice cores ~9000 km from the vent. However, the pre-Millennium (pre-ME) and post-Millennium (post-ME) eruptions are still poorly characterized. Combining field exposures with tephra layers recorded in lake sediments, detailed explosive eruptions of Changbaishan volcano were characterized. A pyroclastic fall deposit (more than 1 m thickness, and well sorted pumice lapilli) with an age older than 31 ka was found at its eastern flank. Tephra layers from Yuanchi lake ~30 km to the east of Changbaishan volcano illustrate that the tephra Qixiangzhan eruption can be traced from this lake to Suigetsu lake in central Japan, and the age of the controversial Qixiangzhan eruption (dated to 88 ka to 4 ka previously) can be constrained to ~8100 cal a BP. There are no tephra at around 4 ka in Yuanchi lake, which implies that the age of Tianwenfeng eruption should be more older than previous thought. Tephra from ME can be found about 700 km north to Changbaishan volcano, and the geochemical composition of glass shards from this eruption is different between south (east) and north (west) directions. Tephra from those historical documents recorded eruptions referred as post-ME eruptions (e.g., AD 1668, AD 1702) can be found at eastern flank of Changbaishan volcano, and even in the Sihailongwan lake sediments from Longgang volcanic field ~120 km west to the Changbaishan volcano.

Converging tephra community effort to establish best-practices for data collection, analysis, and reporting

Kristi Wallace¹, Marcus Bursik², Stephen Kuehn³, Andrei Kurbatov⁴

¹U.S. Geological Survey/Alaska Volcano Observatory, Anchorage, USA. ²University of Buffalo, Buffalo, USA. ³Concord University, Athens, USA. ⁴University of Maine, Orono, USA

Abstract

A renaissance in tephra research, involving volcanology, petrology, geochemistry, tephrochronology and tephrostratigraphy, is motivated by studies of environmental/climate change, sediment transport and deposition, archaeology, anthropology and natural hazards. During workshops in 2014 and 2017, the tephra research community concluded that it is crucial for future progress and advances in tephra studies to develop unified requirements for tephrochronological data collections. Proposed best practices in tephra data collection and reporting aim to establish a new research philosophy that is necessary to coordinate, simplify and broaden data contributions from various scientific disciplines. Using common, accessible mechanisms for tephra data archiving and retrieval, major advances are expected. By standardizing protocols for the collection, analysis and reporting of tephra field and laboratory data across and within disciplines, all relevant tephra information will be more easily shared through common databases while maintaining data uniformity and completeness.

An important aspect of data sharing is related to open access for standardized data and metadata. This element is remarkably well aligned with major data sharing initiatives and requirements that research and funding agencies are trying to establish (e.g., NSF, USGS).

While the community understands the value of open data access, it is important to develop mechanisms to ensure that original investigators receive credit, and that data users comply with data sharing licenses and policies established by the users. A similar framework is well established in the open source software community, but is often misused or misunderstood by the scientific community.

We present the latest community vision and initiative that will help to:

1. consistently collect and share data produced by various disciplines using tephra,
