Abstract

This study suggests that cold-ice processes may be more widespread than previously assumed, even within temperate glacial systems. We present the first systematic mapping of cold-ice at the snout of the temperate glacier Midtdalsbreen (Norway) using ground penetrating radar data. Results show a 40 m-wide cold-ice zone within the majority of the glacier snout. We interpret ice to be cold-based across this zone, consistent with basal freeze-on processes involved in the deposition of moraines. We also find at least two zones of cold-ice up to 15 m thick within the ablation area, occasionally extending to the glacier bed. There are two further zones of cold-ice up to 30 m thick in the accumulation area, also extending to the glacier bed. Cold-ice zones in the ablation area tend to correspond to areas of the glacier that are covered by late-lying seasonal snow patches that reoccur over multiple years. Subglacial topography and the location of the freezing isotherm within the glacier and underlying subglacial strata likely influence transport and supply of supraglacial debris and formation of controlled moraines. The wider implication of this study is the possibility that with continued climate warming, temperate environments with primarily temperate glaciers could become polythermal in forthcoming decades with i) persisting thinning and ii) retreat to higher altitudes where subglacial permafrost could be and/or become more widespread. Adversely, the number and size of late-lying snow patches in ablation areas may decrease and thereby reduce the extent of cold-ice, reinforcing the postulated change of thermal regime.

Assessing the erosivity and deglacial thinning history of the southeastern Laurentide Ice Sheet using *in-situ* cosmogenic ^{10}Be and ^{14}C

Christopher T. Halsted¹, Jeremy D. Shakun², Lee B. Corbett¹, Paul R. Bierman¹, P. Thompson Davis³, Brent M. Goehring⁴, Alexandria J. Koester⁵, Marc W. Caffee⁵

¹University of Vermont, Burlington, VT, USA, ²Boston College, Chestnut Hill, MA, USA, ³Bentley University, Waltham, MA, USA, ⁴Tulane University, New Orleans, LA, USA, ⁵Purdue University, West Lafayette, IN, USA

Abstract

A lack of empirical data constraining the thinning history and erosion patterns of the Laurentide Ice Sheet has resulted in uncertainty about volume changes and dynamics – information critical to understanding its contribution to sea level rise, influence on paleoclimate, and response to the changing climate of the deglacial period. To provide insight about ice sheet history and behavior, we collected 120 samples for *in-situ* ^{10}Be and 10 samples for *in-situ* ^{14}C cosmogenic exposure dating from various elevations at numerous mountains in the northeastern United States and southern Quebec, Canada. By calculating ages of exposure at different elevations across this region, we will reconstruct the lowering paleo-ice surface of the southeastern Laurentide Ice Sheet. Using radionuclide pairs at critical locations, we will also investigate the erosion that took place during glaciation.

Presently, we have processed 62 samples for ^{10}Be concentrations. Mountain-top exposure ages located within 150 km of the southeastern Laurentide Ice Sheet terminal moraine indicate that near-margin thinning began early in the deglacial period (~19.5 to 17.5 ka), coincident with the slow initial margin retreat indicated by varve records. Exposure ages from several mountains further inland (>400 km north of terminal moraine) were collected over ~1000 m elevation spans and record ice thinning between 14.5 and 13 ka. Ages within each of these vertical transects are similar within 1σ internal uncertainty, indicating that ice thinning was rapid. This rapid thinning occurred at approximately the same time that varve records indicate accelerated ice retreat during the Bølling-Allerød warm period (14.6–12.9 ka), providing evidence of substantial ice volume loss during this period from the southeastern Laurentide Ice Sheet.

Higher elevation (>1200 m a.s.l.) samples contain high ^{10}Be concentrations that yield simple exposure ages older than the LGM. *In-situ* ^{14}C ages from one of the high-elevation locations yield younger exposure ages, indicating that these high ^{10}Be concentrations are likely due to ^{10}Be inherited from previous periods of exposure rather than continuous exposure. At the highest elevations (>1600 m a.s.l.), samples contained high ^{10}Be concentrations (simple exposure ages ~33 – 75 ka) and *in-situ* ^{14}C concentrations at or near saturation, possibly indicating early exposure (>25 ka) following cover by non-erosive ice. The lack of summit erosion suggests that the paleo-ice surface of the Laurentide Ice Sheet was never significantly higher in elevation than the tops of these mountains, inhibiting meltwater formation and basal sliding above ~1200 m a.s.l.

Cosmogenic surface exposure dating of the deglaciation of Finnmark and northern Finland

Johanna Anjar^{1,2}, Naki Akçar³, Thomas Lakeman⁴, Eiliv Larsen⁴, Martin Seiler¹

¹National Laboratory for Age Determination, NTNU University Museum, Trondheim, Norway, ²University of South-Eastern Norway, Bø, Norway, ³Institute of Geological Sciences, University of Bern, Bern, Switzerland, ⁴Geological Survey of Norway, Trondheim, Norway

Abstract

The northern coast of Finnmark county, northern Norway, forms the northernmost edge of mainland Europe. During the Last Glacial Maximum (LGM) this region was covered by the Fennoscandian Ice Sheet (FIS), which coalesced with the Barents Sea Ice Sheet (BSIS) off the coast. The region is thus important for our understanding of the dynamic interactions between the BSIS and the FIS, but despite this it remains one of the least dated regions covered by the FIS.

We present 23 cosmogenic surface exposure ages (¹⁰Be) from eight localities sampled along a 240 km long north-south transect ranging from the outer coast of the Nordkinn peninsula (Norway) to Lake Inarijärvi (Finland). Based on these we discuss implications for the pattern and timing of ice sheet retreat in the region. The samples were prepared at the Institute of Geological Sciences, University of Bern and were the first geological ¹⁰Be samples measured at the National Laboratory for Age Determination, Trondheim (Seiler et al. 2018).

We were particularly interested in the deglaciation age at the outer coast, where the previously suggested deglaciation ages have varied widely. Seven of the samples were therefore taken at the outer coast of the Nordkinn peninsula. After excluding three questionable samples (two outlier ages at 55.1±5.1 ka and 19.5±1.8 ka and one sample taken below the marine limit), the remaining samples gave a mean age of 14.5±0.4 ka, which we consider the best estimate of the deglaciation at the outer coast of Nordkinn. For the southernmost part of the transect, three samples from the streamlined terrain around Lake Inarijärvi indicate a deglaciation 11-10 ka ago.

Highlights

- Twenty-three cosmogenic surface exposure ages (¹⁰Be) from eight localities in northernmost Norway and Finland.
- For the outer coast, our new exposure ages suggest a deglaciation around 15-14 ka, which fits with a deglaciation during early Bølling.
- The study presents the first geological ¹⁰Be samples measured at the National Laboratory for Age Determination, Trondheim.

The impact of glacial lake-outburst floods on the meltwater-drainage system of northern central Europe during the Middle Pleistocene glaciations

Jörg Lang¹, Petteri Alho², Elina Kasvi², Nils Goseberg³, Jutta Winsemann¹

¹Institut für Geologie, LUH Hannover, Hannover, Germany, ²Department of Geography and Geology, Turku, Finland,

³Leichtweiß-Institut für Wasserbau, Braunschweig, Germany

Abstract

The formation and drainage of ice-dammed lakes along the southwestern margin of the Middle Pleistocene (Saalian) Fennoscandian ice sheet had a major impact on the regional meltwater-drainage system and the landscape evolution. The advances of the Middle Pleistocene ice sheets repeatedly led to the blockage of the fluvial- and meltwater-drainage systems and the formation of extensive ice-dammed lakes. The drainage of the meltwater along the southwestern margin of the Middle Pleistocene ice sheets was controlled by the ice-dammed lakes in river valleys and lowland areas from the Lower Rhine Embayment in the west to the continental drainage divide between the Atlantic and the Black Sea in eastern Poland. The location and extent of these lakes depended on local topography and the presence of ice dams. The retreat of the ice margin changed the lake configuration and opened lake overflows, leading to a successive drainage of the lakes. Glacial lake-outburst floods occurred when large overflows were suddenly opened. The restoration of the drainage routes towards the west and northwest required the successive opening of the ice dams and the drainage of the ice-dammed lakes.

At least three major outburst floods from different ice-dammed lakes in northwestern and central Germany have been reconstructed. These floods were triggered by the failure of ice dams in bedrock-outlet channels and released ~20 to ~200 km³ of water. The drainage routes are characterised by erosional features like plunge pools, trench-like channels, megaflutes, scour pools and streamlined hills. Depositional features include large sand and gravel bars, and fields of sandy bedforms deposited by supercritical to transcritical flows.

Numerical flood simulations were conducted to better understand flood inundation and quantify the flow characteristics. Reconstructed flood hydrographs indicate peak discharges between 166,000 and 673,000 m³s⁻¹. 2D numerical simulations of the flood inundation provide estimates of the spatial and temporal evolution of flow depth, velocity and bed-shear stress.

The incision of deep and broad channels by the glacial-lake outburst floods strongly impacted the meltwater-drainage system by providing an efficient drainage network. The channels initiated by the lake-outburst floods became a crucial part of the ice-marginal drainage system during the decay of the Saalian ice sheet and subsequent re-advances. Some of the flood-related channels became part of the fluvial drainage system after deglaciation.

Run-up sediments as (palaeo-)hydraulic indicator

Juergen Herget¹, Paul Carling², Pavel Borodavko³, Sergey Parnachov³

¹Dept. of Geography, Bonn University, Bonn, Germany, ²School of Geography, Southampton, United Kingdom, ³Dept. of Geology and Geography TSU, Tomsk, Russian Federation

Run-up sediments can be found in river channels and floodplains in front of local obstacles like trees trunks, bridge piers or bedrock cliffs. Upstream of the obstacle, the flow velocity of the current decreases resulting in a locally elevated water surface due to the transfer of energy from kinetic to potential energy. Transported suspension load might be deposited at a higher level in front of the obstacle or mark the higher water level to one side or either side of the obstacle.

Run-up effects as special feature of flood debris lines were first mentioned by Costa in the context of debris flows, but were not investigated in detail. Along the pathway of the Pleistocene ice-dammed lake outburst floods in the Altai-Mountains, Siberia, run-up sediments are located at numerous valley obstructions in front of local bedrock ridges. The clue of the interpretation is not their sedimentological structure or texture, but the configuration of their deposition and especially their elevation in relation to undisturbed flood stage indicators upstream of the obstruction. Typically, they generate a relatively thin layer of deposited suspension load in front of the obstruction.

They indicate the amount of energy transfer and can be used to conclude on the mean flow velocity of the current upstream of the obstruction. According to the energy equation by Bernoulli, energy can only be transferred from kinetic to potential energy as pressure energy is negligible for open channel flow. Hence, once a current is blocked its kinetic is transferred into potential energy indicated by a risen water level. As the amount of the water level differences upstream and in front of the obstruction can be measured in the field – or surveyed of suspension load marks and deposits for palaeofloods – the unknown variable of mean undisturbed flow velocity can be estimated. This principle previously was applied for flow velocity measurements in small channels.

P-3827

The geomorphological significance of Quaternary fluvial deposits and mega-boulders in the Tamatert Valley, High Atlas, Morocco

Madeleine Hann, Jamie Woodward, Philip Hughes
University of Manchester, Manchester, United Kingdom

Abstract

In the Tamatert Valley, near the village of Imlil (1800 m.a.s.l.) in the High Atlas of Morocco, a defining feature of the valley floor is a spread of enormous boulders pointing to the occurrence of a catastrophic geomorphological event (or events) in the recent geological past. The headwaters of this catchment were glaciated during the Pleistocene. Mega-boulders are present on the bed of the steep active channel and within exposed Quaternary fluvial and colluvial deposits. Fieldwork has been carried out to establish the spatial distribution, lithology, size, and geomorphological context of these boulders. Key aims are to determine their age, provenance, and the processes responsible for their transport and present disposition. The largest boulders are not derived from the local bedrock in the lower valley. The timing of emplacement will be established through optically stimulated luminescence dating of associated deposits and via cosmogenic dating of the boulders themselves.

The Tamatert Valley and adjacent valleys were glaciated periodically during the Quaternary. The timing and extent of the glaciation has been well constrained with over 50 cosmogenic isotope dates. Optically stimulated luminescence dating of the Quaternary fluvial and colluvial deposits near the village of Imlil will shine a light on the influence of glaciation, as well as the catastrophic events, on the river record in this steepland setting.

More broadly, understanding the specific impact of glaciation, as part of cold stage climate, may be key to a better understanding of landscape evolution and contemporary fluvial system behaviour in steep mountain settings and must therefore be an important part of fluvial geomorphological research in the Mediterranean and North Africa.

New geochemistry evidence for the Yellow River intrusion into the Huaihe River (east China)

Lei Zhang^{1,2}, Xiaoguang Qin², Daogong Hu¹, Jiaqi Liu^{2,3}

¹Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China, ²Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ³University of Chinese Academy of Sciences, Beijing, China

Abstract

The sediments of the Huaibei Plain in semi-humid mid-eastern China represent valuable geological records with respect to eolian–fluvial interactions, depositional environments, and climate change in east China. The lower course of Yellow River has flooded many times throughout history with documented recordings of more than 1000 floods over the past 4000 years and at times has invaded the Huaibei Plain. However, the existence of prehistoric incursions of the Yellow River into the Huaihe River drainage basin is still poorly understood. This is a significant scientific question for understanding the evolution of Huaibei Plain and Yellow River.

In this study, an 8-m core from Huainan (HN, 32°50.123'N, 116°30.167'E) in the center Huaibei Plain and a set of loess samples from northern and southern China were analyzed for major, trace, and rare earth elements (REEs). Results were compared to determine the samples' provenance. The major, trace, rare earth elements contents, and grain size distribution were found to fluctuate widely in the 2–8 m section of the Huainan core and more narrowly closer to the surface (0–2 m). This suggests a provenance shift at a depth of 2 m. The $\text{TiO}_2/\text{Al}_2\text{O}_3$, $\text{SiO}_2/\text{Al}_2\text{O}_3$, Th/Nb, La/Nb values and REE patterns in the upper core (0–2 m) are similar to those found in samples from the Chinese Loess Plateau (CLP). These results suggest that the CLP in northern China is likely to be the primary origin of the upper part (0–2 m) of the Huainan core. And the upper part (0–2 m) is Yellow River flood sediments. According to the ^{14}C dating, the age is ~13.2 ka at 2 m depth in the HN core. The sediments may have been transported from the CLP to Huainan as Yellow River flood events, probably during the last deglaciation (~13.2 ka) as a result of increased precipitation, along with glacier and snow melt in the upper reaches of the Yellow River catchment during this period. This suggests that the Yellow River may have migrated into the Huaihe River catchment much earlier than the earliest historical records (361 BCE) suggest. This result significantly improves our understanding of the influence of the Yellow River in the formation and shaping of the Huaibei Plain.

Development of the north-central Nile Delta in the Holocene, based on examination of the barrier Blorus Lake sediments, Egypt

Leszek Marks^{1,2}, Fabian Welc³, Barbara Woronko², Jarmilla Krzywińska⁴, Jerzy Nitychoruk⁵, Marcin Szymanek², Alaa Salem⁶, Jakub Holuša⁷

¹Polish Geological Institute – National Research Institute, Warsaw, Poland, ²University of Warsaw, Faculty of Geology, Warsaw, Poland, ³Cardinal Stefan Wyszyński University, Institute of Archaeology, Warsaw, Poland, ⁴Polish Geological Institute – National Research Institute, Marine Branch, Gdańsk, Poland, ⁵John Paul 2nd State Higher School, Faculty of Economic and Technical Sciences, Biała Podlaska, Poland, ⁶Kafrelsheikh University, Faculty of Science, Kafrelsheikh, Egypt, ⁷Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic

Abstract

Development of the Nile Delta in the Holocene was dependent on three major factors: sea level fluctuation, Nile sedimentary activity and subsidence of the delta front. In turn, landscape and accretion of the delta itself had a great impact on the ancient Egyptian state, especially in the pharaonic times. The modern Blorus (Burullus) Lake is located in a north-central part of the Nile Delta, east of the Rosetta branch. It is the second largest natural lagoon in Egypt, characteristic for its numerous environments including salt marshes, mudflats and sand plains, with high sand dunes on the shores. The lake is about 54 km long, 6-21 km wide and to 2 m deep, longer axis runs parallel to the delta sea-front and its area is about 462 km². The western part the lake is deeper and mostly freshwater, the eastern sector is more shallow and saline due to the Bughaz Canal that connects the lake with the sea. The Blorus Lake was fed in the Holocene by the Sebennytic branch of the Nile and its transformations stimulated predynastic settlements, laying foundations of the ancient Egyptian civilisation.

A drilling BO-1 was done in 2014 at the northern shore of the Blorus Lake within the frames of the project funded by the National Science Centre in Poland (decision no. DEC-2012/05/B/ST10/00558). The collected core, 11 m long, was sampled for high resolution lithological, sedimentological and faunal analyses, including also microscopic studies (SEM/EDS), magnetic susceptibility measurements, radiocarbon dating and correlation with geoarchaeological data. The basal fine-grained sand (11.0 – 10.7 m depth) of the Late Pleistocene Mit Ghamr Formation was deposited by the Nile in a dry climate. It is overlain by well-sorted sand with interbeds of silty clay, inserts of organic matter and mollusc shells deposited in a brackish lake with water-level fluctuations and varied interaction of fluvial and marine environments in the Early Holocene. A sea ingression at ca 6.9 – 6.5 cal kyr BP in a shallow brackish lagoon is indicated by a silty clay with water-soluble ions and organic matter. Since that time, the predominant angular quartz grains in the sediments are replaced by the subrounded ones. It is followed by periodical input of the Nile and a sea ingression at ca 2.9 – 2.7 cal kyr BP, reflected by sand deposited in a shallow brackish lagoon with a marsh margin. Since ca 2.5 cal kyr BP there were numerous short sea ingressions and after 2.0 cal kyr BP the lagoon was generally cut off from the Nile but more grains of sand gained the aeolian sculpture.

P-3830

Physical property characterization of Quaternary sediments in the vicinity of the paleo-Seomjin River, the South Sea, Korea

Gil Young Kim, Ki Ju Park, Gwang Soo Lee, Dong Geun Yoo, Gee Soo Kong
Korea Institute of Geoscience and Mineral Resources(KIGAM), Daejeon, Korea, Republic of

Abstract

Thirty-two core samples were collected from the continental shelf area of the South Sea, Korea. They have been used to characterize physical properties in relation to sedimentary units (interpreted from seismic and core data) and to interpret physical property variation as a function of burial depth. The physical property data were readily classified into sedimentary units: Units S1, S2, S3, S4, and S5, in descending order. The variations in physical properties reflect well the relative characteristics of sedimentary units (equivalent to seismic units). Moreover, the relationships between physical properties are well grouped by each sedimentary unit. In addition, the distributions of physical properties match well with the grain size distribution and bathymetry of the study area. In particular, the lithology (e.g., grain size) plays an important role in the variation of physical properties. These results suggest that the physical properties of these sediments are mainly controlled by depositional processes in the vicinity of the paleo-Seomjin River, and that sea-level change specifically was a dominant sedimentary processes in the study area during the Quaternary. In particular, the physical properties of Unit S2 do not show transitional characteristics between Units S1 and S3, although it belongs to the transition zone in sequence order. This finding is attributed to the fact that compared with the sediments of Units S1 and S3, Unit S2 is composed of more coarse-grained sediments with abundant shell fragments.

P-3831

The geomorphic and climatic affinity of Holocene mega-floods in the western Himalaya, India

Shubhra Sharma¹, Anil Shukla²

¹IISER Mohali, Mohali, India, ²Physical Research Laboratory, Ahmedabad, India

Abstract

Sedimentological evidence of Holocene mega floods are investigated in the Satluj river valley and its trans-Himalayan tributaries. The idea is to understand the geomorphic and climatic processes responsible for the generation of the mega floods in the western Himalaya. Based on the sedimentological and textural criteria ~16 flood events of increasing magnitude are dated which cluster in two major time domains. The older phase (seven events) occurred before ~11 ka while the younger phase (nine events) is dated between ~8 and 6 ka. The younger flood phase is regional in nature (catchment wide) but does not overtop the older flood phase (>11 ka) in the para-glacial zone of the Spiti river implying that the former were either of lesser magnitude or did not originate in the trans-Himalayan region. The former seems to be the likely possibility as indicated by the ^{87/86}Sr ratio and major element data suggesting dominance of higher Himalayan crystallines in the flood sediment. Climatically, we ascribe the younger phase to the phases of negative Arctic Oscillation (-AO) and negative North Atlantic Oscillation (-NAO) during which a coupling between the moisture-laden monsoon circulation and southward penetrating mid-latitude westerly troughs occurred. As a consequence, the floods were triggered by the extreme precipitation events causing slope instability leading to the Landslide Lake Outburst Floods (LLOFs) particularly in the higher Himalaya (orographic barrier)- a conducive geomorphic setting for cloud condensation and torrential precipitation. On the other hand the events in older phase seems to be triggered by melting of glaciers/rain on snow and GLOFs generated thereof by rising temperatures in early Holocene.

Late Holocene Environmental Change at Math-Pimpri: A New Ancient settlement discover on the Sina River Valley in Deccan region, India

SOURAV MUKHOPADHYAY¹, Pandurang Sabale¹, Manoj Jaiswal², Sharad Rajaguru¹

¹Department of Archaeology; Deccan College, Post-graduation and Research Institute, Pune, India, ²Department of Earth Sciences; Indian Institute of Science Education and Research, Kolkata, India

Abstract

Math-Pimpri, the ancient settlement town of Satavahanas dynasty, is a key site for understanding the complex alluvial environment of the upper Sina River valley which is located in the semi-arid parts of the Deccan Trap region, western part India. The beginning of the Satavahana rule is dated variously from 271 BCE to 30 BCE. Satavahanas dominated the Deccan region from the 1st century BCE to the 3rd century CE. The dynasty reached its zenith under the rule of Gautamiputra Satakarni and his successor Vasisthiputra Pulamavi. The Puranas and inscriptions remain important sources for the history of Satavahanas. Among the inscriptions, the Nasik and Naneghat inscriptions throw much light on the reign of Gautamiputra Satakarni. Renewed archaeological excavations (2013-14) allied to geomorphological works on the ancient river environment are attempting to establish the nature of the local and regional landscape before, during, and after the occupation of the settlement. For the first time, Optically-Stimulated Luminescence (OSL) and archaeological datings have been combined on the fluvial archives. This database helps us to understand better the chronostratigraphy and the evolution of the palaeo-environments. A complete bankfull cross-section of the Math-pimpri branch has been obtained. Thus, we get 3 important characteristics of the main branch: the width, the depth, and the palaeo-discharge records. In order to get an idea of the palaeo-processes information provides additional insights into the nature of the local environment during the period of occupation.

P-3833

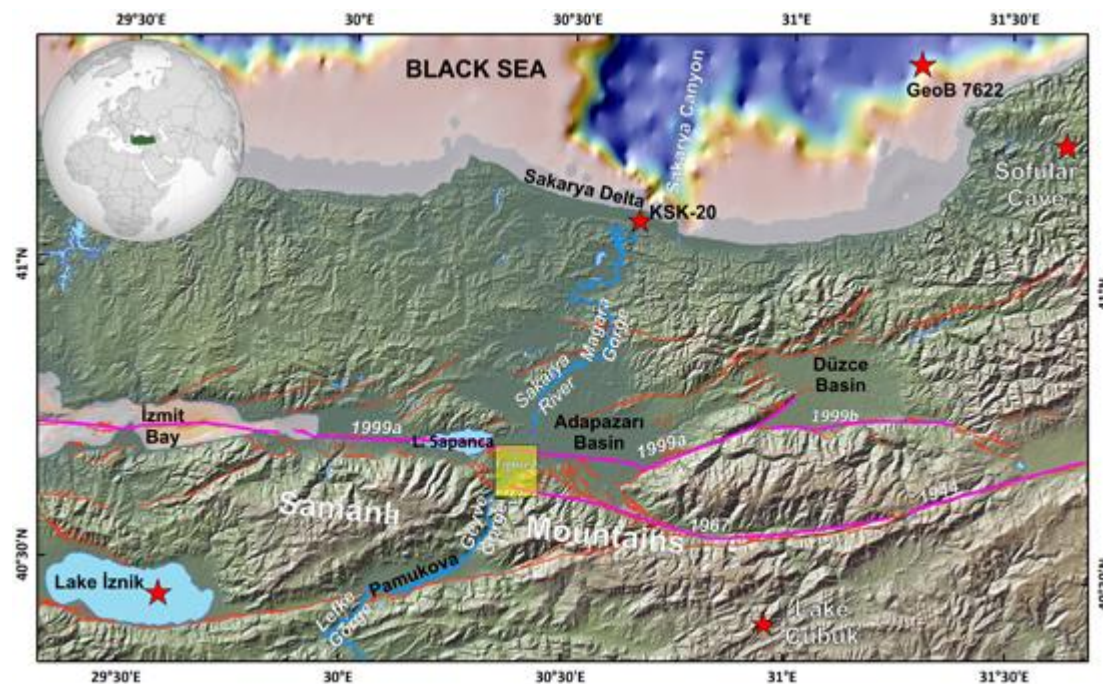

Investigation of Holocene palaeo-hydrological changes using fluvial archives: A case study for Sakarya River terraces, NW Anatolia.

Hilal Okur¹, Mehmet Korhan Erturaç¹, Damase Mouralis²

¹Sakarya University, Sakarya, Turkey, ²Rouen University, Rouen, France

Abstract

Holocene climate changes of the NW Anatolia is well-resolved by means of high resolution speleothem (Sofular Cave) and sedimentary (Iznik, Çubuk Lakes and Black Sea) records. The Sakarya River, the major fluvial system of the region, comprise 3 stepped depositional terrace staircases located just to the south of the North Anatolian Fault at the Adapazarı Basin. These terraces provide sedimentary record from 9-1.8 ka (T2), 1.2-1 ka (T1) and 0.7 ka-recent (T0) evidenced by luminescence and radiocarbon dating.

Physiographic map of NW Turkey and the location of the study area (yellow shaded area). Pink lines represent surface ruptures along the North Anatolian Fault during the last 100 years. Stars present the locations of the adjacent climate records

The sections are fully exposed due to excessive sand-mining, and formed of fine grained flood plain deposits exhibiting a layered stratigraphy. Despite the hiatus(s), these deposits have a potential to record and reflect the hydrological changes at the Sakarya River throughout the Holocene.

In order to construct an event stratigraphy, we detail the sections exposed at the terrace steps and map the changes in grain size, geochemistry and charcoal percent etc. By using this multi-proxy approach, we aim to detect the rapid climate changes (such as 8.2 and 4.2 ka events) evidenced in regional paleoclimatic records and also the critical hydrological events (such as frequent flooding periods) for the region.

This study is supported by TUBITAK 115Y132 and 117Y426 grants.

P-3834

Luminescence Chronology of Late Holocene Palaeofloods records in the Upper Kaveri Basin, India: Flood-Climate relationship

Kartika Goswami¹, Maha Dev¹, Manoj Kumar Jaiswal¹, Vishwas. S Kale²

¹Department of Earth Sciences, Indian Institute of Science Education and Research , Kolkata, India, ²Formerly at the Department of Geography, Savitribai Phule Pune University, Pune, India

Abstract

Palaeoflood records from upper Kaveri were identified and provided with Optically Stimulated Luminescence (OSL) dates to reconstruct the past flooding events generally associated with climatic transitions. The river gauge data from the Kaveri basin were substantiated with the preserved sedimentary records, emphasizing on the importance of sedimentary records in climate studies. Rainfall record of 100 years (1901-2002) is also considered to understand the flood dynamics of the study region. The objective is to look for palaeoflood records and ascertain their periodicities on decadal to millennium scale and to observe the association of extreme flood events with climatic changes. Upper Kaveri receives Indian summer monsoon and flows through rocky terrain. It is joined by many tributaries on its way, thus, is expected to carry mixed sediments coming from weathering of local host rocks. Therefore, extent of bleaching and thus feasibility of OSL dating in such environment was checked. Age models were applied to compute the ages successfully, complemented by existing flood records. The study shows changes in the climatic pattern can be associated with more frequent occurrences of extreme flood events. The flood clusters (~50 years BP, ~90 years BP, 160-220 years BP, ~700 years BP, ~2.1 ka and ~2.3 ka) are observed during major climatic shifts. No high magnitude floods are observed when the monsoon climate was relatively consistent for a long time. The study throws light on luminescence characteristics, bleaching status and helps to reconstruct the past fluvial history of the upper Kaveri river, generally associated with climatic transitions.

P-3835

Geomorphologic indications of the Mediterranean and Black Seas capturing presently the endorheic plains and plateaus of Central Anatolia

Catherine Kuzucuoğlu

Laboratoire de géographie Physique (LGP, HMR 8591) / CNRS, Meudon, France, Paris 1 University, Paris, France

Abstract

Since Late Miocene in Anatolia, uplift, faulting and sliding have generated the encircling of a central zone limited south by the Taurus highlands with summits reaching today 3000 m to >4000 m along the Mediterranean sea. Meantime, the uplift of the central zone reached 1000-1500 m asl while major strike-slip fault zones, sheared and faulted block systems. Uplift of the highlands encircling Anatolia caused the incision of valleys and deep canyons radiating from the highlands in direction of the seas surrounding the peninsula, while central Anatolia formed a more or less high depression at 1000-1500m asl. This central zone presents today patches of (i) plateaus and low hills corresponding to remains of erosion and structural surfaces truncating carbonate deposits, and (iii) volcanic massifs constructed after Late Miocene.

During and after uplift, thick series of emerged carbonates were subjected to dissolution producing a high variety of surface and underground karstic features. In the highlands, stages in the deepening of the underground karst (eg. forming stepped floors separated by sloped to vertical tunnels) record slowing phases in the uplift. In parallel, the slower uplift of central Anatolia protected the central plateaus from incision, allowing karstic features to remain superficial, with low Plio-Pleistocene limestone plateaus alternating with poljes. As a result, the hydrography of central Anatolia is mostly endhoreic (ie. no outflow to the sea) with depressions often corresponding to faulted poljes in which water occurrences mostly occur as karstic springs, and freshwater to salty marshes and lakes.

Recent interpretation of three large depressions bordering the northern slopes of the Taurus from the Isparta Angle (Beydağları poljes and Burdur to Beyşehir-Suğla poljes) to the Aladağlar range (Konya-Ereğli, Tuz Gölü and Sultansazlığı plains) evidence, together with hydrogeologic monitoring of underground water, that these closed depressions are being captured today by Mediterranean and Black Sea exhoreic drainage. This capturing is controlled by both the tectonic regimes that has affected Anatolia during Pleistocene, and by the karstic processes dissolving the carbonates. The result of these observations is that the combination of tectonics and karstic dynamics is opening a new stage in the dismantling of the endhoreic central Anatolia. In eastern Anatolia where the uplift is more recent and active, connections between underground and surface erosion processes are not as much developed. In this latter region, "capture-to-be" locations exist where (i) tectonically-controlled lines concentrate surface erosion in limestones (fault lines, canyons), and (ii) surface and deep karst features develop actively in limestone massifs separating tectonically mobile watersheds.

P-3836

Holocene and historical morphodynamics of the Lower Mesopotamian waterscape: a multi-sensor remote sensing approach

Giulia Iacobucci, Paolo Mazzanti, Salvatore Milli, Davide Nadali, Francesco Troiani, Marta Zocchi, Luca Forti
Sapienza University, Rome, Italy

Abstract

During the Holocene the Tigris-Euphrates river system, at the lower sector of the Mesopotamian Plain (Iraq), has been characterized by a complex morphodynamics in response to climate fluctuations and the extensive construction of artificial canals, dug since the first River Valley Civilizations. During the early Holocene, the sea-level rise caused a general and rapid northward shifting of the Persian Gulf shoreline, after which the general progradation of the Tigris and Euphrates delta system accounted for the shoreline regression up to the present position. Several studies focused on the Mesopotamian waterscape to identify, among others: i) the position of the shoreline during the maximum Holocene marine ingression (i.e., 6,000 yr BP); ii) the effect of the Tigris and Euphrates paleo-delta progradation during mid and late Holocene; iii) key features useful for distinguishing natural river channels from anthropogenic canals. In this context, this study aims to enhance the knowledge on the Holocene and historical morphodynamics of the Lower Mesopotamian waterscape and, specifically, on the paleo-hydrology of the ancient fluvial system. This study provides new geomorphological data useful for better comprehending the mechanisms and rates of the complex interactions between the dynamics of the natural waterscape and the distribution, shifting and abandonment of historical settlements and artificial canals.

A multi-sensor remote sensing approach has been adopted to identify the main geomorphological features and describe the associated morphogenetic processes. Optical and multi-spectral Landsat 8 satellite images have been processed for computing NDVI and Clay Index, as well as to extract Regions of Interest (ROIs). The spectral signatures of the ROIs have been extracted and compared among them. This analysis has been integrated with the investigation of the micro-topography obtained through the re-classification of different DEM sources: i) C-band interferometric SRTM and Sentinel-1 (ground resolution of 30 and 15 m); ii) optical ALOS datasets (ground resolution 30 m).

Remote sensing multi-spectral analysis revealed useful to identify and delineate the geomorphological features associated to the Holocene progradation of the ancient Tigris and Euphrates delta system, past flood-events along the main distributary channels, surficial effects of channel migrations and marshes distribution. Especially, past flood-events have been identified by depositional and erosive landforms due to avulsion processes and the associated crevasse splays, other than by the position and planar pattern of artificial canals. In fact, these latter were essential for managing hydrological extreme events and, on the other hand, to take advantage from them (i.e. field irrigation system). Micro-topography analysis, integrated by the study of distribution of ancient settlements and the planar configuration of ancient distributary channels and artificial canals, allow to preliminary discern the geomorphological effects of the Holocene sea-level variations and the associated variations of the river morphodynamics.

Improving the understanding of the lower Guadalhorce fluvial landscape development: first dates on the river terrace staircase and alluvial fans

Jeroen Schoorl¹, Tony Reimann¹, Alice Versendaal², Tom Veldkamp³

¹SGL Wageningen University, Wageningen, Netherlands, ²NCL, Wageningen, Netherlands, ³ITC Twente University, Enschede, Netherlands

Abstract

Quaternary fluvial archives such as river terraces and alluvial fans are the most important, potentially to be dated, landforms in the unravelling of quaternary landscape development and climate changes. This is even more true for the western Mediterranean where terrestrial climate records are not abundant. One of the so far poorly studied areas is the around 160 km long Guadalhorce river is situated in the province of Malaga, Andalucía in the south of Spain. Its source is located in the Sierra de Alhama and it dominantly flows west, draining the Antequera tectonic basin before turning south in the El chorro area towards the Mediterranean - Alboran Sea, having its mouth near the town of Malaga. The catchment has undergone a complex geologic – tectonic development history, and shows evidence of an extensive human occupation history.

The principal investigated area is the Lower Guadalhorce valley with a flight of terraces situated between the El Chorro canyon and the beginning of the Malaga Basin. In this area a total of 10 terrace levels can be distinguished, from T0 (current river bed) to T9 (supposing the highest and oldest terrace level). A total of 11 locations were sampled in vertical exposures of fluvial terraces or alluvial fan settings ranging from 1 to 20 meter above present day river level. Sampled sediments of the sand fraction were analysed with the latest quartz OSL techniques and IRSL feldspar methods.

The results indicate burial ages, inferred as important aggradation phases, in MIS 4, 5d and 6. The same holds true for the 2 sampled alluvial fans, indicating fan buildup activity, interfingering with fluvial activity in MIS 4 and 6. Consequently, fluvial aggradation seems, in analogue to NW Europe, to be linked to the so called cold stages, although there is no direct evidence for real (peri)glacial conditions in the Western Mediterranean lower river basins. The mechanism therefor is probably linked to wetter conditions (can be in both precipitation amounts and lower temperatures, evaporation conditions). Remarkably, there is no terrace level found yet for the MIS 2 cold stage. Finally, the lowest and youngest terrace level, although with poor reliability, points towards a historical aggradation phase of only 600-100 years ago. Not surprising, the incision that formed these lowest - youngest terrace levels is clearly linked to the installation of the reservoir lakes just upstream of the El Chorro area, trapping the upstream sediments and providing more controlled clean water discharge.

Sediment provenance indicated by magnetic susceptibility and inorganic geochemistry in the Baker-Martínez fjord system (Chile, 48°S)

Matthias Troch¹, Sebastien Bertrand¹, Benjamin Amann¹, Dawei Liu¹, Juan A. Placencia², Humberto E. Gonzalez³, Carina B. Lange^{3,4}

¹Renard Center of Marine Geology, Ghent University, Gent, Belgium, ²Departamento de Química Ambiental, Facultad de Ciencias, Universidad Católica de la Santísima Concepción, Concepción, Chile, ³Centro de Investigación Dinámica de Ecosistemas Marinos de Altas Latitudes (IDEAL), Universidad Austral de Chile, Valdivia, Chile, ⁴Centro de Investigación Oceanográfica COPAS Sur-Austral, Departamento de Oceanografía, Universidad de Concepción, Concepción, Chile

Abstract

Patagonian fjord sediments are increasingly used as high-resolution archives of past climate and environmental change, including variations in glacier mass balance, flood frequency, and seismic activity. To accurately interpret these proxy records, it is crucial to comprehend modern day sedimentation processes and determine the provenance of the sediments. With this in mind, the main objective of this study is to identify parameters that can be used to reconstruct sediment provenance in the fjords of Chilean Patagonia. We focus on the Baker-Martínez fjord system, which is located between the Northern and Southern Patagonian Icefields and seems particularly sensitive to climate change. This fjord system connects the terrestrial ecosystems of Patagonia with the SE Pacific Ocean, and most of its sediment originates from glacier-fed rivers draining either the Patagonian Batholith (PB; Baker and Huemules rivers) to the north, or the Eastern Andes Metamorphic Complex (EAMC; Bravo and Pascua rivers) to the south. Eighteen surface sediment samples from across the Baker-Martínez fjord system and 44 suspended sediment samples from two sequential (Baker fjord) and one continuous (Steffen fjord) sediment trap were investigated. In addition, we analyzed suspended sediment samples collected at the mouths of the four main rivers that drain the PB and EAMC to define end-members. We focus on mass-specific magnetic susceptibility (MS) and inorganic geochemistry, which seem to be particularly promising in this fjord system dominated by lithogenic sediments (97–85 wt%). Our results indicate that sediments derived from the PB are characterized by high MS, Ti/Al, and Fe/Al values, reflecting the granodioritic nature of the batholith (rich in pyroxene and amphibole). In contrast, sediments from the southern EAMC-derived rivers have significantly lower MS, Ti/Al, and Fe/Al values. The sediment trap results reveal MS values that increase with increasing Baker river discharge, either during the summer melt season, or during high precipitation events (rain-on-snow) in winter. Likewise, the MS, Ti/Al and Fe/Al values of the fjord surface sediments are also directly related to sediment provenance. In fjords fed by only one river (e.g., Martínez channel), however, the MS is significantly correlated with mean grain size ($r = 0.90$; $p < 0.01$) and with the proportion of lithogenic particles ($r = 0.73$; $p < 0.05$). The latter observation means that future research is needed to correct the MS and geochemical data for grain-size before using them as quantitative provenance indicators. This study suggests that, after grain-size correction, MS and inorganic geochemistry (Ti/Al and Fe/Al) can be used to reconstruct sediment provenance within the Baker-Martínez fjord system. Ultimately, applying these provenance indicators to long sediment cores from the same fjord system will allow us to reconstruct variations in the behavior of outlet glaciers from both icefields independently.

Sub-annual flood dynamics during the last Saharan humid period: clues from a laminated record from the Nile deep-sea fan

Cecile Blanchet¹, Rik Tjallingii¹, Jens Mingram¹, Martin Frank², Achim Brauer¹

¹GFZ-Potsdam, Potsdam, Germany, ²GEOMAR, Kiel, Germany

Abstract

Paleoenvironmental reconstructions have revealed the occurrence of large-scale changes in precipitation dynamics in North Africa during the Holocene. Evidence from modelling approaches and sedimentary records suggests that these changes were linked to modifications of rainfall seasonality, which likely exerted direct control on fluvial dynamics. There are, however, few continuous records of changes in seasonality, which hinders our understanding of underlying forcing factors.

Here we propose to use a unique 5 m-thick section of finely laminated sediments deposited on the Nile deep-sea fan during the last Saharan Humid Period. The core was retrieved at 700 m water-depth and sedimentation rates during sapropel deposition are in the order of several mm per year. Microfacies analysis and elemental micro-XRF scanning indicate that couplets of alternating dark- and light-coloured layers represent seasonal deposits of Nile discharge and marine hemipelagic sedimentation, respectively. Preliminary lamination counts suggest that couplets were deposited at an annual rate for most of the record, except during a short interval of bi-annual deposition between 9 and 8.8 ka (i.e., 2 couplets/yr). Increases in layer thickness is observed around 9.5 and 9.1 ka BP, followed by a gradual decrease until 8 ka. Careful examination of lamination structure and time-series analysis of layer counts will permit to further explore sub-annual changes in flood dynamics during the Saharan Humid Period. Finally, due to its high temporal resolution, our record has the potential to link reconstructions of Nile discharge to other regional archives of hydrological changes (e.g., speleothems, lakes) and thereby identify overarching forcing mechanisms.

Late Holocene Glacial Lake Outburst Floods (GLOFs) in Chilean Patagonia: evidence from Valle Grande floodplain sediments (47 °S)

Elke Vandekerkhove¹, Sébastien Bertrand¹, Brian Reid², Dmitri Mauquoy³, Krystyna M. Saunders⁴, Dave McWethy⁵, Sarah Stammen¹, Fernando Torrejón⁶

¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium, ²Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Universidad Austral de Chile, Coyhaique, Chile, ³School of Geosciences, University of Aberdeen, Aberdeen, United Kingdom, ⁴Australian Nuclear Science and Technology Organisation, Lucas heights, Australia, ⁵Department of Earth Sciences, Montana State University, Bozeman, USA, ⁶Centro EULA, Universidad de Concepción, Concepción, Chile

Abstract

Glacial Lake Outburst Floods (GLOFs) constitute a major threat in glacierized regions. These catastrophic events occur when a lake dammed by a glacier or moraine empties, resulting in abrupt flooding. In Patagonia, this issue is particularly pronounced in the Baker region (47–48°S), where 21 GLOFs have been documented in the last decade. All recent GLOFs resulted from the emptying of Cachet 2 Lake into Colonia River, a tributary of the Baker River. During such events, Baker River, which is the largest in Chile draining most of the eastern side of the Northern Patagonian Icefield, triples in discharge. Due to backwater flooding, the water level in the Valle Grande floodplain, which is located along Baker river immediately upstream of Colonia River, rises by 4 to 6 meters, resulting in its complete inundation. Although GLOF frequency seems to have increased worldwide in the last decades, there is currently no reliable scientific evidence supporting this claim, largely due to a lack of flood records on timescales that extend beyond gauged river-flow datasets. To examine changes in GLOF frequency in Patagonia, four sediment cores were collected in the Valle Grande floodplain. The cores were scanned on a Geotek MSCL at 2 mm resolution for magnetic susceptibility (MS), gamma density, and sediment color (spectrophotometry). Loss-on-ignition was measured continuously at 5 mm resolution and radiocarbon ages, ²¹⁰Pb concentrations, and charcoal counts were obtained to establish a core chronology. All cores indicate the occurrence of fine-grained organic-poor material with high MS and density values, alternating with organic-rich deposits. It is hypothesized that the fine-grained material is deposited during floods, whereas the organic-rich soils represent periods of quiescence. The records seem to display three periods rich in floods during the last 2500 years. Once precise age depth models are constructed, the results will be compared to historical records of climate and glacier variability to assess the possible relationship between GLOFs and climate change.

P-3841

Geochemical Study of Holocene Sediments of The Mahi River Estuary, Implications To Palaeoweathering and Depositional Environment

shazi farooqui, Anupam Sharma

Birbal sahani institute of palaeosciences, Lucknow, India

Abstract

The Mahi River (~600km long) is one of the major west flowing rivers in India. The Mahi basin lies in horst segment and host 300 m Quaternary sediments, which is sitting over the tertiary rocks (Mehr 1993, Maurya et al 1995). The Mahi River originates in Madhya Pradesh and starts flowing, initially in NW direction and takes a southwesterly turn in Rajasthan and finally debouches in the Cambay Gulf. In lower reaches, where the river forms an estuary, the sediment package preserves signatures of the complex interplay of fluvial and estuarine processes, sea level changes and tectonics. In the present study a 17.28 m long sediment profile was taken from Chokari village to delineate different depositional environments and weathering in the sediments. The upper ~8 m sediments of the profile are estuarine in nature, whereas the lower part is fluvial and intercalated by 1 m thick gravel bed. The upper part is moderately sorted; unimodal and silt dominated indicating that it is formed under very low energy depositional environment which is also supported by the Herring-bone structure as noticed by earlier workers also (Maurya et al. 2000). Low carbonate content (4.2%) and dominance of smectite clay mineral in the sediments further support that the upper facies sediments are most likely deposited in the estuarine environment. The CIA value in the upper part varies from 53 – 60, and in lower part it range between 59-65 indicating that the upper part sediments are chemically immature compared to the lower part sediments. All these attributes reinforce that estuarine sediments may have deposited due to marine intrusion in the drowned river valley on account of sea level increase during the early Holocene time. The ~ 2 ka age deduced by the OSL dating technique in the upper part of section also suggests that sea level must have been more compared to the present and area was submerged (Maurya et al. 2002). Contrary to this, the sediments of lower part are poorly sorted and bimodal with alternate sand-silt layering. The occasional occurrence of cross bedding indicates fluvial deposition (Maurya et al. 2000). Relatively higher carbonate values (~12%) in lower part also indicates oxidizing conditions and relatively higher CIA (59-65) values suggest that the sediments are chemically more mature and may be linked to the terrestrial environmental conditions. A 1 m thick gravel bed (CIA- 44) sandwiched between the upper and the lower sections indicate enhanced precipitation or tectonic activity in the catchment area. The lower CIA (~44) and geochemical composition of sediments indicate tholiitte dominance also indicates that the Deccan basalt is the main source of sediments as also observed by Sharma et al. (2013).

Chronology of the Sakarya River Terraces: Fluvial response to climate change, tectonic uplift and to the Black Sea level changes

Mehmet Korhan Erturaç¹, Azad Sağlam-Selçuk², Eren Şahiner³, Alper Gürbüz⁴, Hilal Okur¹

¹Sakarya University, Department of Geography, Sakarya, Turkey, ²Van YY: University Department of Geology, Van, Turkey, ³Ankara University, Institute of Nuclear Sciences, Ankara, Turkey, ⁴Nigde Ömer Halisdemir University, Nigde, Turkey

Abstract

Sakarya River forms a prominent river system draining a large portion of Anatolia (~63544 km²) to the Black Sea. Along its 824 km course, the river runs through the high relief of the Pontide Mountain range and as well as the North Anatolian Shear Zone (NASZ).

The Sakarya River Basin and the distribution of studied terrace staircases. We studied the terrace staircases formed within the Sakarya River Basin (40-40.45°N and 30-32.15° E) by means of mapping, high resolution measurement surveys and systematic luminescence dating. The spatially scattered terrace formation has a potential to reveal interaction of various forces of the Earth, such as climatic events during the glacial and interglacial periods (such as extreme/rapid or long duration) leading to flow regime and sea level changes and also differential tectonic uplift observed along the southern block of the NAFZ.

We aim to reveal the initiation and termination of depositional/erosional periods, calculation of the vertical uplift rate and finally the timing and extend of the fluvial response to the Black Sea level changes. Each terrace staircases

exhibit at least four steps, enhancing our interpretation through time, from Holocene to late Pleistocene and beyond.

This study is supported by TUBITAK 115Y132 and 117Y426 grants.

Settlements in a dynamic fluvial environment – a multi-proxy approach to investigate the landscape history around Kom el-Gir (Nile Delta, Egypt)

Martin Seeliger¹, Marina Altmeyer¹, Andreas Ginau¹, Robert Schiestl², Jürgen Wunderlich¹

¹Faculty of Geosciences, Goethe-University Frankfurt, Frankfurt, Germany, ²Department of Ancient History, LMU Munich, Munich, Germany

Abstract

Settlement activity in the Nile Delta is strongly linked with the shifting of branches of the river Nile. Nearly all major ancient settlements were founded in close relationship to waterways. The constant shifting of these Nile branches - coming either too close or moving too far away – was a fundamental challenge for settlements.

This holds especially true for Kom el-Gir situated in the north-western Nile Delta and settled between Late Ptolemaic and Late Roman times (2nd century BC – 7th century AD). Remains of a temple, most likely founded in the Ptolemaic period, a late Roman fort, and the proximity to Tell Buto (Tell el-Fara'in), which has a much longer settlement history (with interruptions between 4th millennium BC to 7th century AD), made this site worth to be studied. The reasons for this comparatively short settlement period remain unclear so far. Did the general environmental conditions prevent settlers from populating this spot and how did these conditions change over time? How far was the distance to the nearest river arm? Had shifting river branches eroded an older settlement? Therefore, the questions on the proximity and the layout of the nearby river system are essential ones for deciphering the story of Kom el-Gir.

The region around Kom el-Gir was intensively investigated by a multi-disciplinary team under the umbrella of the German Archaeological Institute Cairo, in cooperation with the Goethe-University Frankfurt and the Ludwig-Maximilians-University of Munich and included the analyses of historic maps and satellite images, surface surveying, magnetic prospection, electric-resistivity measurements, auger core drilling, geochemical analyses of sediment samples, and the creation of a digital terrain model based on TandemX data.

Based on these applied methods, this paper presents first results dealing with the landscape evolution of the area and allows to: (1) deciphering the fluctuations of river arms in the surroundings of the Tell (especially in the eastern part); (2) detecting possible artificial channel systems for freshwater supply and drainage; (3) detecting the palaeorelief at Kom el-Gir itself to finally; (4) approach an answer to the question why we do not find settlement remains of the periods before the 2nd century BC in contrast to Tell Buto.

Floods of the Adige River and community resilience in the Venetian Plain (Italy) between the Medieval Climate Anomaly and LIA

Paolo Mozzi¹, Silvia Piovan², Elisa Corrò³

¹University of Padova, Department of Geosciences, Padova, Italy, ²University of Padova, Department of Historical and Geographic Sciences and the Ancient World, Padova, Italy, ³Ca' Foscari University of Venice, Department of Humanistic Studies, Venice, Italy

Abstract

Analyzing the interaction between settlements and floods of the past allows relevant insights on the dynamic behavior of communities that face critical climatic phases and/or adjustments of the fluvial network to changing environmental conditions and human impact. More specifically, it can provide clues to test the long-term capability of an urban system or community to adapt to flood hazard through “resisting or changing in order to reach an acceptable level of functioning, organization and structure” (Batista and Gourbesville, 2016), i.e., to develop and maintain an effective resilience to floods. Building societal resilience to flood hazard is central in the development of risk mitigation strategies in Climate Change scenarios of the future (Jeroen et al., 2014).

Here we present a case of resilience to flood hazard and floodplain silting-up in the city of Adria and along the Adige River, between the southern margin of the Venetian Plain and the northern Po River delta. Between the 10th and 15th century AD, recurrent floods hit the Adria and led to the burial of its 9th century church by overbank sediments (Corrò et al., 2017). The church now lies at about 2 m depth under the modern city cathedral. These floods were due to the opening of two crevasse channels on the right bank of the Adige River, the Castagnaro and Malopera rivers, that funneled sediments along the Tartaro River down to Adria (Mozzi et al., 2018). A first major event of floodplain aggradation clusters around the 10th century AD, during the Medieval Climate Anomaly, in a period of enhanced flooding recorded in Northern Italy, in the Alps and the Mediterranean basin. Extensive peat sedimentation followed between the 11th and 14th century AD, indicating a decrease of overbank flooding and silting by the Tartaro River due to early management of the crevasses, more proximal sediment accumulation, and better regional climatic conditions. Following events of floodplain sedimentation took place in the early 15th century due to the reactivation of the Castagnaro and Malopera crevasses. This was possibly related to the climatic deterioration of the Little Ice Age but also to the artificial deepening and enlargement of the channel for allowing small-boat navigation.

A more efficient management of the crevasses was actuated by the Venetian Republic during the 16th and 17th century, through the building of wooden and earth sluices. This resulted in a drastic decrease of floods in Adria. However, flood hazard along the Adige River kept on being very high, as documented by the occurrence of more than 80 events of channel overflow, embankment infiltration and formation of fountains at the foot of the levees on an 80-km long river tract between 1604 and 1882 (Bondesan et al., 2003).

P-3845

The post-LGM incised valley of Concordia: a fluvial archive of the alluvial plain of Tagliamento River (NE Italy)

Livio Ronchi¹, Alessandro Fontana¹, Kim M. Cohen², Timme H. Donders², Esther Stouthamer²

¹University of Padova, Padova, Italy, ²Utrecht University, Utrecht, Netherlands

Abstract

The Tagliamento River is one of the major alluvial systems in the Venetian-Friulian Plain (NE Italy) and its megafan is characterized by several incised valleys formed since the Late Glacial and now almost completely filled. Among these features, the most investigated is the one identified in a first time near the city of Concordia Sagittaria.

A dataset consisting of almost 2000 cores, integrated with several geotechnical tests and a lidar topography, was used in order to characterize this incised valley. In particular, more than 1500 cores were realized with hand augers since 2012 by the Physical Geography students of the Utrecht University during a series of fieldwork activities organized in the area.

Our dataset allowed to reconstruct the buried morphology of this incised valley, which can be traced for a length of almost 25 km and was characterized by a width up to 1.2 km and a maximum depth of about 20 m below the top surface of the LGM alluvial plain.

A detailed characterization of the infilling led to the recognition of three main depositional units.

The lower one is the result of the direct activity of the paleo Tagliamento River within the valley. It consists of a 10 m thick gravelly unit, deposited after 19.5 ka cal BP and capped by an organic-rich layer with an age ranging from ca. 9.5 to 6.5 ka cal BP.

The middle unit can be linked to the Holocene marine transgression, which led to the formation of a lagoon environment within the incised valley and the consequent deposition of a 15 m thick unit of muds between ca. 8.0 and 2.0 ka cal BP. The absence of an evident riverine input suggests an upstream diversion of the paleo Tagliamento River. The presence of some peat horizons within this unit indicates a pulsating freshening of the lagoon, which may be the consequence of phases of enhanced freshwater discharge. Nevertheless, whether the peat formation was fostered by fluvial (upstream) rather than marine (downstream) controls is still matter of debate.

The upper unit is represented by alluvial sediments deposited by the Tagliamento River in a renewed phase of activity in the area. The formation of this unit started after ca. 2.0 ka cal BP, but some major floods occurred between 6th and 8th century AD and deposited up to 6 m of sediments that sealed the incised valley.

This study provides a detailed description of a fluvial archive that encompasses almost the entire post-LGM history of the Tagliamento River, allowing the paleoenvironmental reconstruction of the area and providing new data on the fluvial evolution and on its interplay with the marine processes that occurred in the Venetian-Friulian Plain during the Holocene.

Obtaining extreme flood series by the combination of flow data and historical floods reconstruction: the Upper Garonne River (Spain-France)

J. Carles Balasch¹, Jordi Tuset², Xavier Castelltort¹, Mariano Barriendos³, David Pino^{4,5}

¹University of Lleida, Lleida, Spain, ²RIUS Fluvial Dynamics Research Group. University of Lleida, Lleida, Spain,

³University of Barcelona, Barcelona, Spain, ⁴Universitat Politècnica de Catalunya, Barcelona, Spain, ⁵Institut d'Estudis Espacial de Catalunya (IEEC-UPC), Barcelona, Spain

Abstract

Traditionally, the Val d'Aran (Spain) has been considered the headwaters of the Garonne River, a river that flows through Spain, goes into France and heads towards its mouth in the Atlantic Ocean after a journey of more than 647 km. Flow data of the Garonne River are recorded in Bossost, near the outlet of the Aran Valley (647 km² of the basin), but the series cover a relatively short period (from 1965 to the present) and prudence must be exercised when extrapolating flows associated to high return periods. One possibility to reduce the uncertainty when carrying out the frequency analysis is to complement the flow data series with data obtained from the reconstruction of historical floods.

In the French town of Saint Béat (Haute-Garonne), about 19 km downstream of the town of Bossost (Val d'Aran) and in the French part of the basin, the marks reached by the waters in different episodes are available for different floods (flood marks) since the year 1778. This information is not available in the Spanish territory of the Garonne. Therefore, the maximum discharges of the historical floods were obtained by the reconstruction of these episodes using the flood marks registered in Saint Béat. In each historical flood, the role of the snowmelting in the headwater as a contributory mechanism to the precipitation in the flood runoff generation has been analyzed simultaneously.

The peak flows of the historical floods in the town of Saint-Béat (673 km² of the basin) have been reconstructed with the help of the hydraulic model HEC-RAS v. 4.1.0 on a DTM with a resolution of 1m x 1m, in which the morphological changes of the bed and the floodplains and their roughness from the old cartography have been considered. Also cadastral plans and detail photographs were used to reconstruct the land uses and the vegetation occupation of the flooded areas in each period.

The historical reconstructed peak flows from the floods of the last 250 years clearly surpass those obtained in the flow systematic series of the last 50 years, indicating the lack of extreme values contained in these series. Its inclusion in flood frequency analysis allows reducing the uncertainty of an insufficient time series and improving the prediction of low recurrence quantiles in flood risk planning.

Provenance of western Patagonian river sediments (44–48°S): A critical evaluation of mineralogical, geochemical and isotopic tracers

Dawei Liu¹, Sébastien Bertrand¹, Tania Villaseñor², Nadine Mattielli³

¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium, ²Department of Geology, Universidad de Chile, Santiago, Chile, ³Université Libre de Bruxelles, ULB, Laboratoire G-Time, Brussels, Belgium

Abstract

Western Patagonian rivers supply a considerable amount of sediments to the eastern South Pacific via adjacent channels and fjords. Sediments deposited in those basins are increasingly used to reconstruct Quaternary paleoclimate, paleoceanographic and paleoenvironmental changes. To improve our interpretation of the regional sediment records, we evaluate the efficacy of four commonly used provenance tracers including bulk mineralogy, major and rare earth element (REE) geochemistry, and $^{87}\text{Sr}/^{86}\text{Sr}$ and ϵNd . Our results demonstrate that the ability of the investigated tracers to differentiate sediment sources varies widely. Bulk mineralogy is a powerful tool to distinguish volcanic soils from the batholith, but its ability to differentiate metamorphic and volcanic bedrock lithologies is limited, largely due to lack of mineralogical data on the source rocks. In contrast, the major element composition of the source materials in Northern Patagonia is abundantly documented. Major elements however suffer from compositional overlap between different sources and their use for provenance reconstruction is therefore very restricted. The REE patterns normalized to the Upper Continental Crust clearly allow distinguishing volcanic soil materials from the bedrock, but they are inadequate to distinguish among lithologies. Among the investigated tracers, $^{87}\text{Sr}/^{86}\text{Sr}$ and ϵNd are the most suited to reconstruct provenance. They are well differentiated among potential sources since all source materials have different ages. $^{87}\text{Sr}/^{86}\text{Sr}$ and ϵNd were therefore used to estimate the relative contributions of volcanic soils and various types of bedrock lithologies in sediment samples from the six rivers that reach the Pacific Ocean in northern Chilean Patagonia (44–48°S). Isotope-based mixing model results suggest various degrees of contribution from the bedrock compared to the regional volcanic ash soils, which we interpret as different vulnerabilities of soils covered by deciduous and evergreen forest to erosion. This study constitutes a strong basis for the interpretation of sediment archives from the eastern South Pacific. Our results should be particularly useful to test the different postglacial drainage routes that have been proposed in the recent literature.

Understanding the long-term flood variability in Western Mediterranean: A view from spanish lake records

Juan Pablo Corella^{1,2}, Bruno Wilhelm², Gerardo Benito³, Blas L. Valero-Garcés⁴, Anne-Catherine Favre²

¹Department of Atmospheric Chemistry and Climate, Institute of Physical Chemistry Rocasolano, CSIC, Madrid, Spain,

²Universite Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE, Grenoble, France, ³Geology Department, National Museum of Natural Sciences, CSIC, Madrid, Spain, ⁴Pyrenean Institute of Ecology CSIC, Zaragoza, Spain

Abstract

Society is becoming more vulnerable to extreme climate events through increasing exposure of people and infrastructure. Notably, floods are among the most destructive natural disasters, and robust knowledge about their future trends is therefore crucial for the sustainable development of societies worldwide, particularly in sensitive areas such as Western Mediterranean. FLOODARC MSCA project (2019-2021) aims to provide a more comprehensive understanding of the long-term variability of hazardous (high-impact) floods at different temporal and spatial scales. Preliminary results show large dissimilarities in flood-related sediment yield in different Western Mediterranean areas highlighting a large spatio-temporal flood variability during the last millennia. These dissimilarities seem to be controlled by the hydroclimate variability at the regional scale as well as by land use changes in different areas of the Iberian Peninsula. Future state-of-the-art statistical tools applied to the flood database will allow us i) to evaluate, for the first time, the causes of non-stationarity in the long-term flood pattern evolution at a sub-continental scale ii) to decouple the climate vs anthropogenic signal in the lacustrine flood record and; iii) to investigate the role of the climate variability on the high-impact flood patterns at centennial to millennial time-scales in Western Mediterranean.

³Archéorient, UMR 5133, University of Lyon 2-CNRS, Lyon, France, ⁴Institut für Geo und Umweltnaturwissenschaften - Sedimentologie, University of Freiburg, Freiburg im Breisgau, Germany

Abstract

The sedimentary provenance investigations contribute to improve the understanding of fluvial palaeo-dynamics at different spatial and temporal scales. Conventional approaches for source to sink studies are usually based on the physical, mineralogical, geochemical, magnetic or isotopic properties of sediments. Efficient, accurate and relatively less time-consuming than the conventional fingerprinting techniques, Mid-Infrared Spectroscopy (MIRS) is an alternative method for tracing the origin of fine sediments. The research objectives of this study are (i) to use the MIRS method to discriminate the origin of fine alluvial sediments, by using multivariate statistics on a large set of reference samples from three different sedimentary basins (Rhine, Ill, Vosges tributaries) in the Upper Rhine area, (ii) to verify whether the IR spectra signatures of sediments are influenced by the geomorphological deposition context (bars *versus* banks), and, to some extent, by high organic matter content in the samples and thereafter (iii) to apply the MIRS method to study the fluvial palaeo-dynamics and to determine the source of palaeo-channel infillings in the Upper Rhine alluvial plain. The three sedimentary basins have been characterized by 196 reference samples of sub-recent alluvial deposits from 78 collecting sites. Discriminant analysis revealed a strong discriminating capacity by classifying correctly the samples by their origin without any inter-groups overlap, independently from the geomorphological context (bars *versus* banks), slight changes in organic matter contents or sediment texture. Combining MIRS technique and multivariate statistics for palaeo-channel infilling determination, complemented by radiocarbon ¹⁴C dating and mineralogical data, allowed to understand local morpho-sedimentary dynamics over the last ca.12 millennia.

Keywords: Fine sediment provenance, Mid-Infrared Spectroscopy, Discriminant analysis, palaeochannel filling evolution.

Palaeoflood records for adaptation of infrastructure and civil engineering design in ephemeral rivers with scarce hydrological data: Ugab River, Namibia.

Gert Cloete¹, Gerardo Benito², Tamir Grodek³, Naomi Porat⁴, Yehouda Enzel⁵

¹Consulting Engineer, ADHOC Civil Engineering, Windhoek, Namibia, ²National Museum of Natural Sciences, CSIC, Madrid, Spain, ³Department of Geography, The Hebrew University of Jerusalem, Mt Scopus, Jerusalem, Israel, ⁴Geological Survey of Israel, Jerusalem, Israel, ⁵The Fredy and Nadine Herrmann Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel

Abstract

Palaeoflood investigation provides valuable data for designing the upgrade of a MR76 road bridge on the large (21,500 km²) Ugab River, northwest Namibia. A review of the regional road network requires this road to be upgraded to asphalt surfaced road standards with a double lane bridge, able to accommodate a 1% exceedance probability flood without overtopping.

Hydraulic modelling indicates that the current bridge can only accommodate a 2000 m³sec⁻¹ flood without overtopping. Local flood models predict the 1% flood between 3000- 5000 m³s⁻¹. However, in the Kuiseb River, 300 km south of the Ugab River, similar procedures are thought to overestimate flood peaks. Given the size of the investment for upgrading the road and bridge, a simple comparison between the two catchments could not be justified. Based on the available flood model results, the existing bridge needed to be demolished and replaced with a larger structure at a cost of N\$50 million (€ 3 million). As this is a data poor area and doubts were put on the estimations, a palaeoflood study was sponsored by the Roads Authority to determine the actual flood peaks at the bridge. The reason for this study was simple; if the bridge could accommodate the 100 year flood based on the additional data and analyses, the existing structure would be sufficient with a significant cost saving.

Palaeoflood studies were performed at two reaches with preserved sedimentary evidence: one site 20 km upstream, and another 7 km downstream from the bridge. As expected in this arid region with little bioturbation, evidence of floods, up to 1260 years old, are well preserved. Evidences were also obtained from tree log lines defining high-water marks. The oldest (and highest) was emplaced at AD 1135. The composited and better palaeoflood evidence is from the downstream site. It shows 14 palaeofloods since AD 757. The largest flood reaches a minimum discharge of 1130 m³s⁻¹.

A flood frequency analysis for the Ugab River at the bridge, based on palaeoflood data spanning 1300 years, indicates that the 100-year flood is 820 m³s⁻¹. This is much lower than the estimations by other procedures based on sparse data that proved overestimations. This outcome brings about a significant cost saving to the Roads Authority since the existing bridge complies with the standards for flood risk.

Atmospheric variability related to large summer floods in the upper Hasli-Aare catchment (Swiss Alps) from AD 1300 to 2010

Juan Carlos Peña¹, Lothar Schulte²

¹Meteorological Service of Catalonia, Barcelona, Spain, ²Department of Geography, University of Barcelona, Barcelona, Spain

Abstract

The paper explores the summer paleoflood variability in the alpine Hasli-Aare catchment (Swiss Alps), regarding the external forcing (e.g. Total Solar Irradiance – TSI) and atmospheric variability from the AD 1300 to 2010. Paleoflood series were recorded from alluvial sedimentary records and documentary sources. Paleoclimate modelling was applied to the sea level pressure anomalies (SLP). The grid database for modelling was provided by the CESM Paleoclimate Working Group at NCAR, which processed the experimental series of the Last Millennium Ensemble Project (LME).

Paleoflood series shows fourteen flood pulses since AD 1300. Ten flood pulses occurred during periods of negative anomalies of TSI/cold climatic phases: around AD 1310, 1390-1400, 1440, 1460, 1560, 1660, 1690, 1720-1730, 1800-1840, and 1920-1930. On the other hand, three flood pulses are related to positive anomalies of TSI/warm climatic phases: around AD 1780, 1860-1890, and 1970 to present. Furthermore, some of these pulses are modulated by volcanic activity. The cooling effect by volcanic forcing is visible during flood periods with positive anomalies of TSI, e.g. around AD 1600, showing the principal divergence between the temperature (negative anomalies) and the TSI (positive anomalies) since AD 1300.

The simulated SLP composites of summer flood clusters related to low-solar activity exhibited an atmospheric circulation pattern close to the negative phase of the summer North Atlantic oscillation (SNAO), with the low-pressure trajectories southward of its habitual location, in a temporal state almost permanent during these pulsations. We propose the name of paleo-SNAO to define this decadal atmospheric variability related to summer floods in the upper Hasli-Aare catchment. However, the results also showed evidences of the atmospheric circulation pattern of the flood clusters during high-solar activity and warm periods (i.e. current global warming), was related to positive phase of SNAO.

The results presented in our study using LME to detect similar interannual patterns of atmospheric variability related to flooding since 1300 in the upper Aare catchment, contribute to the understanding of past and future climates and their impacts. The results also improved the knowledge-base for some aspects of climate change impacts and to reduce the uncertainty about future outcomes. In this way, there are strong evidences that large paleofloods in the upper Aare catchment occurred not only during low solar activity/cold climate pulses but also during high solar activity/climatic warm climate phases. For example, the 1762 climate flood during positive solar activity was equal or even larger in the Hasli-Aare catchment than the 2005-flood (Global Warming), and several cold climate floods except the catastrophic 1480, 1550, or 1831 events. Therefore, the warm pulse 2005 flood is not unprecedented and might not directly connected with the anthropogenic influence on climate, but with pattern of atmospheric variability.

How extreme floods can trigger river avulsion beyond delta plain limits

Harm Jan Pierik¹, Tim Schuring¹, Esther Jansma², Esther Stouthamer¹, Willem Toonen³, Wim Hoek¹, Kim Cohen^{1,4}
¹Utrecht University, Utrecht, Netherlands, ²Cultural Heritage Agency, Amersfoort, Netherlands, ³KU, Leuven, Belgium, ⁴Deltares, Utrecht, Netherlands

Abstract

In lowland fluvial environments such as delta plains, rivers can create new branches through avulsion. This causes reorganizing of discharge diversion over the delta, in cases breaching former limits of floodplains to annexate new areas. Avulsions show a phased development, beginning with crevasse splay formation during floods, eventually maturing into a new single meandering river channel. This overall process can take several centuries and is affected by the flooding regime of the river. Periods of intensified flooding are thought to initiate avulsions, push ephemeral overflow routes to become permanent, and cause crevasse complexes to evolve into single channels. This means that studies of the pacing of geomorphological change can benefit from palaeohydrological studies focusing on the timing of larger flooding events.

Here we show the role of major flood events in fluvial morphology for the Gelderse IJssel case in the eastern Netherlands. This 100 km long river resulted from a major avulsion in the Rhine delta that occurred in the first millennium AD. It annexed a peat filled brook valley and debouched into the Central Netherlands lagoon. This downstream valley hosts a unique geological dataset to track the phasing of avulsion, while the upstream delta has a complete record of major flood events. These flood events have been independently identified in sedimentary and dendrological palaeohydrological records.

Triggering of the avulsion occurred while increased fine-sediment loads doubled due to deforested hinterland and when flooding intensified from the 6th to the 8th century AD. From the 7th century onwards a crevasse complex had permanently breached the rim of the former floodplain. A final extreme flood (c. AD 784/5) appears to have triggered maturation into a single meandering channel, that by 1000 AD was fully developed. These dates are in agreement with geological data upstream and with abundant archeological and historical evidence along the river, such as the rise of the cities of Deventer and Zutphen. This case highlights the importance of extreme flood events for fluvial morphology, delta-network evolution and the impact on people living in the delta.

Climate Hazards and Extremes (CHEX) – palaeoflood reconstructions from southernmost Norway

Johannes Hardeng^{1,2}, Jostein Bakke^{1,2}, Eivind Støren^{1,2}, Willem Van der Bilt^{1,2}

¹University of Bergen, Bergen, Norway, ²Bjerknes Centre for Climate Research, Bergen, Norway

Abstract

Climate Hazards and Extremes (CHEX) is an interdisciplinary research project within the Bjerknes Centre for Climate Research. CHEX seeks to provide policy-relevant information through improved projections of climate hazards and extremes, by integrating long-term time series from proxy records with numerical model output and Earth observation data. Climate hazards are climatically induced events that may have a significant impact on society, such as strong winds, storm surges, rapid sea level change and floods. Projections for future climate scenarios are typically modeled using observed data and instrumental records as data input. However, such data records are typically no longer than a few decades and hold little information about the most extreme and hazardous events with recurrence intervals for several hundred years. To gain data on these events we have to rely on records obtained from palaeoarchives such as lacustrine sediments.

The hydroclimate of southernmost Norway is highly influenced by changes in the westerly winds and the North Atlantic atmospheric circulation. Holocene flood records from this region may provide an important tool for the prediction of future flood events, and how land use planning should be conducted in light of present and future climate change. As a contribution to the project we, use lacustrine sediment records to investigate palaeoflood activity in lakes in the region. Sediment thickness and distribution have been mapped using Chirp Sonar and Ground Penetrating Radar (GPR). A multi-proxy approach has been applied to fingerprint the sediments, which includes X-ray fluorescence (XRF), computed tomography (CT-scanning) and magnetic susceptibility (MS). This yields high-resolution data of geochemical properties throughout the core, as well as high-resolution 3D X-ray imagery.

Lacustrine sediment records from both western and eastern Norway have been studied quite extensively, whereas no such records have been presented from the southernmost region. Subsequently, this region represents a knowledge gap concerning Holocene climate change and is an important link between the coastal climate of western Norway and the more continental eastern region.

Postglacial incisions-infill cycles in fluvial headwaters of NE Borisoglebsk Upland: base level vs landscape conditions variability signal (Central European Russia)

Vladimir Belyaev¹, Katerina Garankina¹, Ilya Shorkunov², Yulia Shishkina¹, Pavel Andreev³, Alexey Rusakov³, Elena Sheremetskaya¹, Tatyana Verlova³

¹Lomonosov Moscow State University, Moscow, Russian Federation, ²Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation, ³Institute of Earth Sciences, Saint-Petersburg State University, Saint-Petersburg, Russian Federation

Abstract

Borisoglebsk Upland is one of a number of the Moscow glaciation marginal zone uplands in the Russian Plain center. Evolution of its fluvial network began since the last deglaciation. It is generally accepted that the density of glacialfluvial network and its penetration into interfluves significantly exceeded those of modern fluvial systems. However, our knowledge on the postglacial incision-infill cycles, their drivers and timing is very limited, especially at the local scale. In this study, we attempt to reconstruct the Northeastern Borisoglebsk Upland fluvial systems development over the last 150 ka and determine its past extents at different stages based on palaeoarchives comparison from presently inactive interfluve headwaters, contemporary gullies and small valleys. Interdisciplinary research within the ≈ 15 km² case study area involved detailed description of cores and sections, analysis of grain size, chemical and organic contents, pedogenic and microstructural properties of associated deposits, dating, investigations of the present-day and buried topography, remote sensing data interpretation, and DGPS survey.

Integrating the available results, at least four distinct fluvial incision stages were determined while network extent has significantly changed through the Late Pleistocene. Three – Late Moscow (Saalian), Late Valdai (Weichselian) and Late Holocene – can be generally associated with the Nero Lake level decrease and accompanying isolation of the 130, 100-105 and 95-98 m ASL terraces respectively. For the late incision, human impact has also been an additional trigger. The Late Moscow and Late Valdai incisions mostly determine general outlines of modern fluvial systems while the latter appears to be most expansive. The Late Valdai gullies cut only middle reaches of the initial fluvial network and eastern slopes of highest hills. In contrast, the Early-Middle Valdai incisions of limited distribution and problematic causes were most likely associated with permafrost degradation impacting surface runoff formation.

Incision stages were separated by landscape stability or aggradation periods. Upper parts of the Late Moscow depressions and fluvial incisions were gradually infilled and smoothed by Valdai lacustrine sediments and Late Valdai-Holocene colluvial deposits. In contrast, in middle parts of the fluvial network, two complex periods included heterogeneous aggradation interrupted by stabilization and smaller but prominent incisions. For the Mikulino (Eemian) interglacial prolonged lacustrine sedimentation was altered by stabilization and incision in the middle (partly eroded peats with tree logs). For the most of Holocene at least some of superimposed colluvial infills and local incisions can be attributed to short-term events as forest fires.

It is particularly important to note that most of the detected incision stages were asynchronous between headwaters and middle reaches and spatially non-uniform. Thalwegs of major Late Moscow incision and local incisions during the Mikulino interglacial generally do not coincide with the following Late Valdai and Late Holocene incisions.

Landscape changes, terraces and deposits of the river Pulvar (Fars, Iran): new perspectives and new chronology derived from OSL dating.

Jean-Baptiste Rigot¹, Sébastien Gondet², Kourosh MOHAMMADKHANI³, Edit Thamó-Bozsó⁴

¹Tours University/CITERES-CNRS, Tours, France, ²ARCHEORIENT-CNRS/Lyon2 University, Lyon, France, ³Shahid Beheshti University, Teheran, Iran, Islamic Republic of, ⁴Mining and Geological Survey of Hungary, Budapest, Hungary

Abstract

This work is implemented in the frame of an Iranian-French archaeological project focusing on the area of Pasargades, an Achaemenid capital founded in the middle of the 1st mill. BC, located in an intermountaneous flooding plain in the Zagros. The goal of the project is to understand the regional human occupation, consequently deeper study of the large-scale Holocene landscape dynamics is necessary. This project is implemented under the agreement of the of the Iranian Centre for Archaeological Research (ICAR) with the support the Pasargadae World Heritage Site Office, the Shahid Beheshti University, the French National Agency for Research (ANR), and the French Foreign Ministry.

Critical results concerning landscape changes in mountain environment has been produced. Especially for the Holocene river dynamics, three main phases have been characterized corresponding to three alluvial terraces (T1 to T3) mapped and analyzed over the whole studied area.

A large scale phase of alluvial deposits occurred from the beginning of the Holocene until middle or even recent Holocene. It is characterized by a thick fine sediment layer visible throughout the region which fills plains and valleys. This deposit was cuted as terrace 15 meters up to the river (T1). The controlling factors of this accumulation appears to be climate and geological structure. Holocene climatic optimum (8000-5000 BP) increased the erosion of previous levels and especially sandy-marly quaternary deposits. This would explain both the high carbonate content and the fineness of the particles, because the quaternary deposits consist partly on the same type of sediment. Furthermore the increase of the precipitations and the vegetation covering could explain the strong cutting of the T1 terrace. An Achaemenid dam built over the T1 terrace gives a relative date to this phenomena (at least 500 BC). OSL dating (results to be received during the first 2019 semester) will precise this event.

The thickness and granularity of the sediments in T1 are striking, in such an environment. The steepness of the side slopes, the former Pleistocene deposits and the presence of intermountain plains downstream of the studied section (Tang-e-Bolaghi gorge) could have played a decisive role.

The second terrace (T2) is linked to reactivation of the alluvial dynamic, with coarser deposit in a context that seems relatively wet. The obtained C14 dates refer to the Islamic period as also demonstrated by a ceramic sherd found in a sequence in the plain of Pasargades.

Third terrace (T3) is less visible but still present as benches along the present river bed sides. It shows the sub-actual river dynamics, in elevation perhaps due to the excessive puncture of alluvium in the Pulvar bed.

P-3856

Abandonment of River Chuya valley (South-Eastern Altai) and age constraints for the Altai megafloods

Andrei Panin^{1,2}, Grzegorz Adamiec³, Gennady Baryshnikov⁴, Piotr Moska³

¹Institute of Geography RAS, Moscow, Russian Federation, ²Lomonosov Moscow State University, Moscow, Russian Federation, ³GADAM Centre, Silesian University of Technology, Gliwice, Poland, ⁴Altai State University, Barnaul, Russian Federation

Abstract

Russian Altai is known for the traces of the Pleistocene cataclysmic floods ranked within the top ten terrestrial floods in the Earth history (Baker et al., 1993, 2013; Herget, 2005; Carling, 2013; etc.). Floods were generated by the outbursts of large lakes accumulated in the intermountain basins in the upstream area of River Chuya due to the damming by valley glaciers. Flood waves spread through the Chuya and then the Katun' valleys to River Ob'. The main flood has usually been dated to MIS 2 according to few radiocarbon ages from the lacustrine sediments in Katun' tributary valleys (Butvilovskiy, 1993; Herget, 2005) and TCN dating of large clasts transported by the megaflood (Reuter et al., 2006). Direct OSL ages from megaflood and cover deposits point at older times (Baryshnikov et al., 2015; Zol'nikov et al., 2016), however optical dates provide interpretation problems due to the possibility of incomplete bleaching. In this study we make the attempt to constraint the age of the megaflood(s) from the geomorphic features of the Chuya valley.

In the middle course, upstream from the Chibit village, River Chuya leaves its old mature valley and cuts a 20-km-long young canyon through the rocks of the Northern Chuya Ridge. In the abandoned valley reach, numerous evidence exist of its occupation by valley glacier that entered from the Chibitka tributary valley and moved upstream the old Chuya valley. This glacier plugged the Chuya valley and forced the river to cut through the rocks aside. A set of OSL ages from glacio-fluvial deposits allow to date this glacial advance and the valley abandonment at 80-90 ka BP. Another glacial phase was dated at 50-60 ka BP. During this phase, River Chuya was dammed at the confluence of old and young valley reaches, and valley lake was formed, which left lacustrine silts within the young canyon. No traces of this lake were found in the abandoned valley, which was probably filled by ice.

The above events provide constraints for the age of the Chuya megaflood. The megaflood(s) must have occurred before 50-60 ka BP, otherwise the lacustrine silts would not survive in the canyon. Moreover, the abandoned valley and clear glacio-fluvial landforms within it do not bear any traces of the cataclysmic flow, which must have swept away all the sedimentary fill of the old valley. It means that the Chuya megaflood must have occurred before 80-90 ka BP. It could have been associated with the first Late Pleistocene glacial advance in the late MIS 5, or with the Pleistocene maximal glaciation of Altai during MIS 6.

Optically stimulated luminescence dating of lowland floodplain sediments in Ireland towards a floodplain evolution model

Jonathan Turner¹, Ciara Fleming¹, Sebastien Huot², Mary Bourke³

¹University College Dublin, Dublin, Ireland, ²Illinois State Geological Survey, Illinois, USA, ³Trinity College Dublin, Dublin, Ireland

Abstract

Reconstruction of Late Quaternary floodplain evolution and flood histories requires reliable and robust geochronologies, which in Ireland been hampered by problems presented by radiocarbon dating, including contamination by old carbon sources from eroded peatland, or the lack of suitable dating materials *per se*. Here we present a preliminary evolutionary model for the middle River Nore, Co. Kilkenny, applying integrated morphological, sedimentary and micro-XRF chemostratigraphic methodologies, together the first attempt to employ optically stimulated luminescence (OSL) dating in an Irish fluvial setting.

OSL dating on quartz mineral (150 – 250 microns) was carried out on samples retrieved from recently excavated trenches and exposed bank sections, and analysed using the Single Aliquot Regenerative dose protocol (SAR). Samples were characterised by a dim to very dim luminescence response, typical of sediment in recently glaciated landscapes. As the sedimentary units were rather thin, judicious sampling was performed in order to properly assess the dose rate. Manganese oxide concretions found in the sections and in greater abundance above clay-rich layers, presented a highly elevated activity in radium 226, compared to its parent, uranium 238. This was in contrast to the bulk sediment matrix, which implies that these oxides formed post-sedimentation and are actively absorbing radium. This finding presented further challenges towards devising an OSL chronology, which will be discussed.

The first phase of dating in one reach suggests that only the uppermost 1.5 metres of alluvium are of Holocene age with basal ages dating to the early Holocene (c. 9 ka). Given the sedimentological context and overlying geochronological evidence, an underlying clay is likely to be from a Late Glacial lake system. Geochemical data suggests a dominant detrital rather than biological origin for these sediments, inferring low productivity consistent with a cooler period such as the Younger Dryas. Relatively shallow depths of Holocene sediment may infer low sedimentation rates, but evidence for a non-conformity at the site, together with the cluster of early-Holocene dates towards the base of the Holocene sequence may indicate floodplain stripping and/or an absence of sedimentation during the evolution of the floodplain. Preservation of deposits associated with extreme floods in the Nore was inconclusive.

Errors on the dates reflect the systematic and random uncertainties (e.g. calibration, water content, partial bleaching). Further analysis will provide additional age constraints on the floodplain evolution in the middle Nore. The preliminary results indicate that in minerogenic, sand-rich floodplain sites such as those constituting much of the middle Nore valley, where organic matter for radiocarbon dating is limited, OSL dating presents a viable alternative dating method for reconstructing Holocene alluviation. Moreover, limitations inherent in the properties of sediment from paraglacial landscapes can be overcome using a careful sampling strategy.

Late Holocene channel pattern change from laterally stable to meandering

Jasper Candel¹, Maarten Kleinhans², Bart Makaske¹, Wim Hoek², Cindy Quik¹, Jakob Wallinga¹

¹Wageningen University & Research, Wageningen, Netherlands, ²Utrecht University, Utrecht, Netherlands

Abstract

River channel patterns may alter due to changes in hydrological regime related to changes in climate and/or land cover. Such changes are well documented for transitions between meandering and braiding rivers, whereas channel pattern changes between laterally stable and meandering rivers are poorly documented and understood. We hypothesize that many low-energy meandering rivers had relatively low peak discharges and were laterally stable during most of the Holocene, when climate was relatively stable and human impact was limited. Our objectives in this work are to identify a Late Holocene channel pattern change for the low-energy Overijsselse Vecht river, to develop and apply a novel methodology to reconstruct discharge as a function of time following a stochastic approach, and to relate this channel pattern change to reconstructed hydrological changes. We established that the Overijsselse Vecht was laterally virtually stable throughout the Holocene until the Late Middle Ages, after which large meanders formed at lateral migration rates of about 2 m yr⁻¹. The lateral stability before the Late Middle Ages was constrained using a combination of coring information, ground-penetrating radar (GPR), radiocarbon (¹⁴C) dating, and optically stimulated luminescence (OSL) dating. We quantified bankfull palaeodischarge as a function of time based on channel dimensions that were reconstructed from the scroll bar sequence and channel cut-offs using coring information and GPR data, combined with chronological constraints from historical maps and OSL dating. We found that the bankfull discharge was significantly greater during the meandering phase compared to the laterally stable phase. Empirical channel and bar pattern models showed that this increase can explain the channel pattern change. The bankfull discharge increase likely reflects climate changes related to the Little Ice Age and/or land use changes in the catchment, in particular as a result of peat reclamation and exploitation.

Integrating geophysical surveys and drill cores for establishing the subsurface stratigraphic framework of the paleo-Yamuna river, northwest India

Imran Khan, Rajiv Sinha

Department of Earth Sciences, Indian Institute of Technology Kanpur, Kanpur, India

Abstract

The fluvial landscapes of northwest (NW) India prominently built by a large network of perennial river systems were home to the well-known Bronze Age Indus Civilization. A pronounced change in the distribution pattern (in both time and space) of urban settlements of mature and late Indus Civilization in NW India has been linked to a large river flowing through this region which in turn was influenced by the intensity of the Indian summer monsoon. The role of the paleo-Yamuna river that once flowed through northwest India on the sustenance of the so-called large river and the Indus civilization has been postulated but not established due to the lack of subsurface stratigraphic data. This study focuses on an integrated study using resistivity surveys and drill cores to provide the subsurface stratigraphic framework of the paleo-Yamuna river deposits followed by optically stimulated luminescence based chronology for constraining the chronology of the deposits. We present new data based on vertical electrical resistivity soundings (1D-VES), multi-electrode electrical resistivity tomography (2D-ERT), multi-probe well log surveys and drilling in one of the paleochannels of the Yamuna to map the large-scale geometry and architecture of the valley fills of the paleochannel system in the subsurface. The geophysical signatures recorded as VES on two transects trending NW-SE in Karnal and Kaithal districts of Haryana at 9 and 13 locations respectively, along with continuous ERT reveal the presence of subsurface sand bodies (>20m thick) interbedded with silty clay layers that are laterally stacked. The occurrence of thick and wide sand bodies in the subsurface implies that these are the deposits of a large river system and suggests that the Yamuna was connected to the paleo-Ghaggar River as hypothesized by earlier workers based on remote sensing techniques. Further, these fluvial sand deposits show longitudinal and lateral chronological variation suggesting that the stratigraphic record of the Haryana plain was built by avulsing river systems.

P-3860

First approach to review Badlands landscape evolution in Quaternary

Juan F. Martínez-Murillo¹, Estela Nadal-Romero²

¹Departamento de Geografía, Universidad de Málaga, Málaga, Spain, ²Instituto Pirenaico de Ecología, CSIC, Zaragoza, Spain

Abstract

Badlands are defined with different criteria: lithological conditions, weathering processes, landform features, agriculture potentiality, and even the difficulty of being crossed by humans (Martínez-Murillo and Nadal-Romero, 2018). The term “badlands” refers to regions that have soft and poorly consolidated material outcrops, limited vegetation, reduced or no human activity, and a wide range of geomorphic processes, such as weathering, erosion, landslides, and piping. These features interact at different spatial and temporal scales to shape these distinct landforms. According to Moreno-De las Heras and Gallart (2018), three general badland initiation patterns can be distinguished: i) first two patterns correspond to the expansion of hillslope gullies initiated at mid-slope sections, caused by within-slope conditions, or at the slope bottom, through a combination of within-slope and basal conditions; ii) the third one to the disruption of a non-channelized hillslope by mass movements that open a bare soil or rock scar to weathering and water erosion. The analysis of these phenomena is particularly relevant in subhumid and humid badlands, where these landforms are relatively small and young, which means that their initiation can be physically examined. Conversely, in semi-arid and arid areas, badlands are usually very extensive and relatively old, so that their initiation factors are frequently obscured by the action of other drivers that control the long-term evolution of these systems.

This study makes a first approach to review already published studies focussed on the Quaternary and landscape evolution in regions with Badlands, giving special attention to the geomorphic process leading to their origin and evolution. A list of publications in these topics was compiled using Scopus, ScienceDirect, and Google Scholar. At this first stage, the searches were conducted using the following codes: “Badlands” AND “Quaternary”, “Badlands” AND “Landscape evolution”, “Badlands” AND “Holocene”, “Badlands” AND “Pleistocene”, “Badlands” AND “Quaternary”, and “Badlands” AND “Anthropocene”. In total, the results showed 67, 52, 79, 99, and 0. The database is analysed with the purpose of shedding light to the question ‘how and why badlands appear and evolve?’ in order to better understand how the current Global Change can influence their future evolution, and their on and off-site effects in the eco-geomorphological system and human activities.

Wizards, tephrochronology and the evolution of a jökulhlaup sandur in Iceland

Andrew Dugmore¹, Anthony Newton¹, Emily Lethbridge²

¹University of Edinburgh, Edinburgh, United Kingdom, ²Árni Magnússon Institute for Icelandic Research, Reykjavik, Iceland

Abstract

We use tephrochronology tied to the Greenland ice core record to explore the development of a 10th-century jökulhlaup in front of Sólheimajökull in southern Iceland. We establish precise links between the geomorphological records and passages in the 12th-century Icelandic historical work 'The Book of Settlements' in which wizards are said to be responsible for the flood. In the early 10th century the snout of Sólheimajökull stood at the southern limit of its bedrock channel (some 4km beyond current limits). The consequences of this included the absence of an incised floodplain in front of the glacier and the potential for volcanogenic floods to sweep to the east and west. The first elements of the 10th century flood spread over the eastern margins of Sólheimasandur and also flowed west. The initial route west can be traced through a coll and onto Skogasandur. On the sandur the flood first flowed further west along the foot of the bedrock escarpment. Where it lapped against the edge of the escarpment pumice gravels from the edge of the flood grade into the airfall deposits of a tenth-century Katla tephra, proving precise dating evidence. As the meltwater flowed west the flood routes evolved. The channel on the sandur at the foot of the escarpment was beheaded, and as the bedrock channel along the western side of the glacier deepened, the water flow through the coll was also cut off. This resulted in a switch of the western floods from an almost due westerly flow towards Skogar to a southerly and easterly flow back towards the present course of the Jökulsá (and the most direct route from the glacier to the sea). As the routes changed so did the geomorphological impacts and sediments laid down by the flood. The westerly flow began rich in pumice, and the flood would have acquired more pumice as it incised the old pumice fan lying over the NE part of Skogasandur. As later stages of the flood incised the bedrock channels to the west, large volumes of palagonite boulders were incorporated into the flow. Thus, the later stages of the flood that swept back towards the east created the terrace units covered in palagonite boulders to both the east and west of the present river course. To the east, this palagonite terrace borders an extensive pumice terrace formed during the initial phase of the flood. This detailed case study illustrates the potential importance of flood routing and timing in determining the sedimentological characteristics of Quaternary flood deposits, as well as examining how such events were preserved in cultural memory in medieval Iceland.

P-3862

Variable Late Glacial to Holocene seismicity in the Eastern Alps, Austria? First results from a lacustrine paleoseismic study

Christoph Daxer, Ariana Molenaar, Michael Strasser, Jasper Moernaut
Institute of Geology, University of Innsbruck, Innsbruck, Austria

Abstract

Comparison of earthquake frequency in Fennoscandia and Northern Central Europe since the Last Glacial Maximum (LGM) suggests a general seismicity pattern for deglaciated areas, with high seismic activity in the Late Glacial, a rather calm period in the early Holocene and another increase in seismicity during the middle to late Holocene. In these tectonically relatively stable regions, postglacial rebound is believed to be the main contributor to changes in the stress field. However, in formerly glaciated, tectonically active mountain ranges, the role of tectonic stress vs. postglacial rebound on earthquake recurrence is still unclear and further strategically-located paleoseismological studies are needed.

Here, we present preliminary results of a lacustrine paleo-earthquake project in Carinthia, situated at the southeastern rim of the Eastern Alps, Austria. This region, although located in an intraplate setting, has experienced several historically and instrumentally recorded earthquakes of an M_w up to 7. Eight lakes, all of them remnants of Pleistocene glaciations, were investigated using high-resolution reflection seismics and sediment cores. Our findings show that at least three lakes contain a datable archive of simultaneously-triggered slope failures, for which past seismic activity constitutes the most likely mechanism. By mapping the subaquatic landslides and combining them with analyses on long (~12 - 14 m) sediment cores and bathymetric data, we aim at reconstructing the paleoseismicity and its spatio-temporal distribution in the Carinthian/Friuli area during the last ~14 ky. One of our studied lakes, Klopeiner See, located at the very eastern margin of LGM ice extent, represents an extraordinary archive of deglaciation history. Due to a condensed Holocene section, we can resolve 12 m of Late Glacial history in a sediment core. By geophysical core logging, XRF- & medical CT-scanning as well as detailed core description, we are able to distinguish numerous event deposits from cm- to m-scale and date them accurately using radiocarbon dating, while also gaining insight into landscape evolution during deglaciation.

Our data hints at pulses of enhanced seismicity during the Late Glacial, peaking at the Pleisto- to Holocene transition, with several voluminous landslides covering large parts of all lake basins. Interestingly, the Carinthian lacustrine records show relatively little evidence of seismically triggered landslides in early to mid-Holocene times – a similarity to other paleo-earthquake studies in both the Fennoscandian Peninsula and the Alps. However, other than in the Swiss or French Alps, the tectonic contribution to recent uplift rates in our study area is relatively large. This suggests that seismicity in the Alps was – and maybe still is – rather governed by postglacial rebound than tectonically induced stress.

Lateglacial reactivation of the Harz Boundary Fault (northern Germany) caused by glacial isostatic adjustment

¹Leibniz Universität Hannover, Hannover, Germany, ²Leibniz Institut für Angewandte Geophysik, Hannover, Germany, ³Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover, Germany, ⁴Lantmäteriet, Geodetic Infrastructure Referenssystem, Gävle, Sweden

Abstract

Seismic activity in northern Germany is rare, but recent earthquakes were recorded e.g., east of Hamburg and in the Halle/Leipzig area. Many of these earthquakes occur at major Cretaceous reverse faults. A possible trigger mechanism is the release of lithospheric stress changes due to glacial isostatic adjustment in response to the decay of the Weichselian ice sheet in the Late Pleistocene (Brandes et al., 2015). The occurrence of recent seismicity and the long record of historic earthquakes require a re-evaluation of the seismicity in northern Germany.

One of these Cretaceous reverse faults, is the NW-SE trending Harz Boundary Fault, which is approximately 100 km long. At this fault, young tectonic activity was observed. A recent sinkhole close to the Harz Boundary Fault exposes a NNE-ward dipping planar fault plane that cuts through unconsolidated debris-flow deposits. To analyse the subsurface structure along the Harz Boundary Fault, high resolution shear-wave seismic and geoelectric (ERT) profiles were acquired, which image the steeply dipping Harz Boundary Fault and give evidence for a splay fault system with back thrusts, directly north of the main fault. Most likely, the NNE-ward dipping fault that is exposed in the sinkhole corresponds to the back thrust imaged with the geophysical methods.

Luminescence dating of feldspar and quartz minerals (IRSL and OSL) of the faulted debris-flow deposits indicates fault movements post dating ~15 ka. The timing of fault movements is supported with numerical simulations of GIA related changes in Coulomb failure stress. Modeling results for a compressional regime, as is assumed for this area, show that the Harz Boundary Fault became unstable between 14.2 to 7.8 ka. This matches with the estimated luminescence ages and supports the assumption of tectonic movements at the Harz Boundary Fault in the Lateglacial. The time window of these fault movements also matches data from the Osning Thrust, where a stress change related to GIA induced fault movements is also documented (Brandes et al., 2012).

Traces of seismic waves in Pleistocene, glaciolacustrine sediments. Case study from Usedom Island (NE Germany)

Malgorzata Bronikowska, Malgorzata Pisarska-Jamroży
Geological Institute, Adam Mickiewicz University in Poznan, Poznan, Poland

Abstract

The 3D view of soft-sediment deformation structures in glaciolacustrine fluidized succession from a coastal cliff on Usedom Island (Germany) induced by liquefaction were analyzed in aim to track records left in unconsolidated, laminated sediments by the seismic waves. Based on sediments textural and structural features of sediments, the layers engaged in soft-sediment deformation structures were interpreted by Hoffmann and Reicherter (2012) as seismites caused by liquefaction process induced by seismic waves during Pleistocene glacio-isostatic adjustment. Detailed research on the description of 3D soft-sediment deformation structures was carried out in laboratory where the sediment sample of cuboid sized 40x40x60 cm was cut horizontally slice by slice in every 1.5 cm in aim to take a photo of each of them. Deformation structures visible on every thin-section were contoured to calculate them and determine their size and shift. Next, three types of sediments occurring in each thin-section were distinguished: silt, sand and silty-sand. It was assumed that all observed features were formed in silty background. The adages of the structures were determined in places with clear changes in the color of sediments. Obtained data allowed for probable recognition the places in the sample, where the energy of wave was maximum (the smallest structures, the biggest mixing) or minimum (the biggest structures, minimum mixing). Although, the sample was too small to determine the whole wave period, several most likely scenarios for the wave propagation process were determined based on many possibilities recorded in studied case.

The study has been financially supported by a grant for the GREBAL project (No. 2015/19/B/ST10/00661) from the National Science Center Poland.

Complex structure of intraplate Mariánské Lázně fault zone that ruptured in Holocene (Bohemian Massif, central Europe)

Petra Štěpančíková¹, Thomas Rockwell^{1,2}, Jakub Stemberk^{1,3}, Petr Tábořík^{1,3}, Filip Hartvich¹, Hamid Sana¹, Tomáš Fischer³, Marlena Yaneva⁴, Alexander Radulov⁴, Yordanka Donkova⁴, Lucie Nováková¹, Annika Szameitat¹

Abstract

We studied the NNW-SSE trending Mariánské Lázně Fault (MLF) situated in the western part of the Bohemian Massif (Czech Republic, Central Europe). The MLF is morphologically pronounced and controls the eastern limit of the Cheb-Domažlice Graben for a length of about 100 km. In its northern part it borders the Cenozoic Cheb basin towards the Krušné Hory mountain front and intersects with the NE-trending Cenozoic Eger rift. The Cheb basin is famous for abundant occurrences of mantle-derived carbon-dioxide emanations, present-day earthquake swarms with maximum magnitude not exceeding Mw 4.0, and Mid-Pleistocene volcanism. The present-day earthquake swarms are strikingly aligned along a NNW-trending fault known only from the foci at depth with no geological or morphological expression on the surface. This seismogenic fault intersects the NW-trending border fault of the Cheb basin, the northern segment of the MLF, with no present-day associated seismicity. However, our paleoseismic trenching revealed larger prehistorical earthquakes that have resulted in the present-day morphology along the MLF. Because prevailing kinematics of younger events, revealed from the very first trench, appeared to be showing a strike-slip mechanism, we carried out 3D trenching at the Kopanina site to explore horizontal displacements and the structure of the fault zone. We excavated six additional backhoe trenches and six hand-dug trenches, which revealed a complex structural set-up with oblique faults and deformation probably as a result of right-lateral transpression during the Late Quaternary. Also, Holocene colluvia is faulted, which is in agreement with the results from the first trench, and which indicates Holocene surface-rupturing earthquakes on the MLF with possible minimum magnitude of Mw=6.3-6.5. Radiocarbon dating of charcoal sampled from the faulted Holocene layers, followed by OxCal modelling, show that the latest earthquake occurred during the 790 – 1020 AD period. Several candidates for a historical earthquake within that period have been analysed from the historic earthquakes catalogues. The most likely earthquake that would match that period and the related magnitude may be the one reported to have occurred in 998 AD. Further investigation on this correlation is under process. This historical earthquake revealed from trenching appears to be the youngest surface-rupturing earthquake in central Europe and the largest one identified in the Bohemian Massif so far, and has a major implication for seismic hazard for areas with slow-moving faults.

P-3866

Holocene behavior of the Wasatch Fault Zone, USA, affected by pluvial lake loading/unloading cycles on the hanging wall

James McCalpin

GEO-HAZ Consulting, Inc., Crestone, USA

The Wasatch Fault Zone (WFZ) in Utah, USA, is an active normal fault zone separating the Wasatch Range (upthrown block) from the Bonneville Basin (a closed depression on the downthrown block). Throughout the Quaternary large pluvial lakes alternately formed and then desiccated on the hanging wall (HW) of the WFZ. The latest pluvial lake (MIS2, Lake Bonneville) reached a highstand elevation of 1555 m (from 16.8-18.0 ka), and covered an area of 51,200 km² with a maximum depth of 300 m (volume 10,300 km³). The lake desiccated rapidly between 12-14 ka to approximately the extent of today's Great Salt Lake (volume 19 km³). Removal of the 10,281 km³ of water load caused post-pluvial isostatic rebound of the HW, as reflected in the domal upwarping of highstand shoreline by as much as 70 m in the centroid of Lake Bonneville. Even before the modern era of paleoseismology on the WFZ (1970s-present), geologists speculated about the effect of the HW depression/rebound cycle on the activity of the WFZ. They pointed out that the thick eastern shoreline deposits of Lake Bonneville had buried the pre-MIS2 trace of the WFZ, and that the highstand shoreline lay on the footwall (FW) of the fault. Post-MIS2 fault traces then had to rupture up through the shoreline deposits to reach the ground surface. Over most of the central segments of the WFZ post-MIS2 fault scarps have now grown to 20-25 m high in Bonneville shoreline deposits.

In the past 2 decades technological advances have permitted a more sophisticated analysis of fault-lake interactions. Deep 'megatrenches' have exposed a continuous record of WFZ slip events from the Bonneville highstand (16.8 ka) to the present, a record composing 9 successive paleoearthquakes in the northern Salt Lake City segment but only 7 in the southern SLC segment. Lidar DEMs (0.5 m resolution) now cover the eastern Bonneville shoreline and WFZ, permitting precise deformation surveys. A major elevation discontinuity in shoreline elevations exists in the center of the SLC segment, between the two megatrench sites. This discontinuity coincides with a 2.5 km-stepover in the WFZ and a buried gravity ridge that separates the deep part of Lake Bonneville from a shallow shelf. It now appears that differences in crustal depression/rebound across this discontinuity created a non-persistent segment boundary in the center of the SLC segment, causing the northern subsegment to rupture with the Weber segment to the north, while the southern subsegment ruptures with the Provo segment to the south. However, that behavior ceased about 9.5 ka as rebound waned. Since then the two subsegments have a very similar paleoseismic record.

High-head dams' construction – replication of the natural "Disturbance regime" of mountainous river valleys' evolution: illustrated by the Kokomeran River valley

Alexander Strom

JSC "Hydroproject Institute", Geodynamics Research Center, Moscow, Russian Federation

Abstract

Construction of high-head dams in mountain river valleys raises debates on their environmental acceptability. Indeed, it causes significant changes of the landscape and ecosystem. However, analysis of the evolution of river valleys in various mountainous regions all over the world shows that their blocking by large-scale rockslides – the so-called "Disturbance regime" proposed by Kenneth Hewitt (2006) is a common and rather frequent natural phenomenon. Such blocking can influence river valleys more than interplay of the tectonic and exogenous processes that forms a typical shape of river valleys with narrow gorges and steeper thalwegs where they cross actively growing mountain ranges, and widened valleys filled by fluvial deposits when passing through neotectonic depressions. It can be exemplified by the Kokomeran River in Central Tien Shan that had been blocked by rockslides repeatedly. Its thalweg profile (Fig. 1) can be divided into several sections. In the upper part of the valley, up to the confluence with the Djungal River, profile is steep where river crosses neotectonic uplifts, and flattens within intermontane depressions reflecting the prevailing role of neotectonic deformations in River valley shaping. Three large river-damming rockslides identified in this part of the valley had blocked it in the past, but later they had been incised by the stream completely. In contrast, downstream from the Djungal River mouth, where Kokomeran passes through the V-shape gorge between the Sarykamysh and Kavaktau neotectonic anticlines, stream remains tranquil. Such a profile extends for about 30 km, up to the Late Pleistocene Karachauli breached rockslide dam. It is likely that its base has not been reached by bottom erosion yet so that the Kokomeran River is still incising in the deposits accumulated upstream. One more nick point about 5 km downstream from the breached Karachauli blockage coincides with the breached Lower Kokomeran rockslide dam, most likely of the Holocene age. Recurrent formation of rockslide-dammed lakes and their subsequent breaching are the natural elements of mountain river valleys' evolution. Thus, constructing high-head dams and creating deep reservoirs we just reproduce natural phenomena.

Fig. 1. Thalweg profile of the Kokomeran River based on the 3" SRTM DEM. Red arrows mark river-damming rockslides: 1 – Kokomeran, 2 – Displaced Peneplain, 3 – Mini-Köfels, 4 – Lower Aral, 5 – Karachauli, 6 – Lower Kokomeran; blue arrows – main tributaries: WK – Western Karakol, Oi – Oikaing, Dj – Djungal, Mi – Minkush; brown indices – neotectonic depressions: Sus – Suusamy, Kyz – Kyzyl-Oi, Djum – Djungal, M-K – Minkush-Kokomeran; black indices – neotectonic uplifts crossed by the river: SUU-DJU – connection of the Suusamy Range and of the northern part of Djungal Range; DJU – southern part of the Djungal Range; SAR-KA – connection of the, Sarykamysh and Kavaktau Ranges; black arrows mark conventional boundaries between neotectonic uplifts and depressions.

Sedimentological features on hyperconcentrated flow deposit formed by the 300 years ago slope failure due to Nankai-Trough earthquake, central Japan

Masaaki Shirai¹, Takako Utsugawa², Kiyokazu Kawajiri³

¹Tokyo Metropolitan University, Tokyo, Japan, ²Rissho University, Saitama, Japan, ³Sagamihara City Museum, Kanagawa, Japan

Abstract

The “Oya-Kuzure” slope failure is located in the source area of Abe River, Shizuoka Prefecture, central Japan. It has been estimated that many failure events had occurred repetitively around the area and that a large-scale failure occurred early 18th century caused by the Hoei Earthquake (M: 8–9), one of the Nankai Trough earthquakes. The landslide slope is 700 m high and 1800 m wide with an estimation of 120 million m³ in volume and the 18th century slope failure deposits filled the upper reaches of Oya–Abe rivers at least 7km long.

The 40m high and 400m wide cliff is distributed along the river stream ca. 5km downstream from the “Oya-Kuzure” slope failure. Gravelly deposit on the outcrop is characterized by alternation of cobble and pebble layers of 0.5–5 m thick and topographically continued from debris flow deposit caused by the Hoei earthquake. Absence of internal sedimentary structure within each layer and occasional presence of oversized clasts (0.5–5 m long axis) in the cobble layer show that these gravel layers are hyperconcentrated flow deposit. Because of unconsolidated occurrence due to very young (ca. 300 years ago) deposition, gravels are taken easily from the cliff surface and fabric (imbrication and orientation) of them are measured easily.

Imbrication of gravels and distribution of hyperconcentrated flow deposit show southward flow direction. On the other hand, long axis (a-axis) orientation varies parallel–perpendicular to flow direction. In pebble layers, gravels of a-axis parallel (0 to $\pm 30^\circ$) to flow direction are popular (56/122); gravels of a-axis perpendicular (± 60 to 90°) to flow direction are 40/122. In cobble layers, whereas, gravels of a-axis parallel and perpendicular to flow direction show similar abundance (64/172 and 69/172, respectively). Detailed investigation on cobble layers revealed that gravel abundance of a-axis perpendicular to flow direction increase from lower part (11/40) to upper part (23/40). The upward increasing tendency of a-axis perpendicular gravels means upward increase of rolling gravels under the influence of tractional flow. It is expected that comparison of our results with existing models of hyperconcentrated flow will add several knowledges on hyperconcentrated flow and its deposit.

The role of large-scale rockslides in developing of the top part of Mzymta River (Caucasus, Russia).

Oleg Vladimirovich Zerkal¹, Andrey Alexandrovich Ponomarev¹, Alexander Andreevich Ponomarev²

¹Moscow State University, Moscow, Russian Federation, ²"Engprotection" Ltd, Sochi, Russian Federation

Abstract

The main objective of these studies was to study large-scale rockslides and rock avalanches in the high (elevation up to 1.5 km) Northern slope of the Aibga Ridge, at the base of which the valley of the Mzymta River is developed.

The geological structure of the slope involves Lower Jurassic terrigenous argillaceous rock strata, overlapping in the upper part of the slope by a series of porphyritic massif formations of Middle Jurassic, and complicated by a series of sub-regional faulting. The studied region is characterized by high seismicity.

The modern valley of the Mzymta River on the considered site has a complex character. The morphology of the valley represents the alternation of narrow linear sections where the channel has sharp differences and V-shaped appearance with a height of more than 20 m sides, and relatively wide areas, with the presence of several terraces above the floodplain. Studies have shown that the modern morphology of the valley of the Mzymta River is associated with wide development on the Northern slope of the Aibga Ridge large-scale rockslides and rock avalanches, the frontal parts of which reached the river.

One of the largest rock avalanche (which called «**Frontier**») had developed at the top of the northern slope of Aibga Ridge with capturing porphyritic series (J₂pr). As a result of a series of slope collapses, a circus with an escarpment up to 180 meters high and up to 640 meters wide was formed. In the Central part of the circus deposit low-depth glacial which apparently formed as a result of the development (late Pleistocene or Holocene) corrie.

The formation of large-scale slope deformations is probably associated due to the destruction of tuff sandstones and mudstones in the middle part of the slope, which led to the appearance of flaws and caused the subsidence of large blocks of massive porphyrites in the upper part of the slope, their displacement and collapse. The disintegration of landslide blocks in the process of destruction contributed to the formation of an extended rock avalanche in the structure of which the sequence of the primary structure was preserved. In the rear and in the middle parts of the rock avalanche lie large blocks of porphyrites and in the front part mainly blocks of sandstones and tuff sandstones.

Directly in the valley of the Mzymta river, the formations of a stone avalanche overlaps the deposits of the II floodplain terrace of late Pleistocene age. Given that in the landslide circus lie late Neopleistocene and Holocene glacial formations, the age of the studied avalanche can be determined as late Neopleistocene.

Krasnogorsky large-scale rockslide and its role in the development of Kuban river valley middle part (North Caucasus, Russia)

Oleg Zerkal¹, Igor Fomenko², Alexander Strom³, Lyudmila Mousaeva⁴

¹Moscow State University, Moscow, Russian Federation, ²Russian State Geological Prospecting University, Moscow, Russian Federation, ³Geodymanics Research Center - branch of JSC "Hydroproject Institute", Moscow, Russian Federation, ⁴MosoblHydroProject - branch of JSC "Hydroproject Institute", Moscow, Russian Federation

Abstract

The river Kuban is the main watercourse collecting surface runoff from the northeast macro-slope of the Caucasus Mountains. Its valley has a width of up to 400-500 m (at the level of the 1st terrace) when reaching the foothill plains. The valley is characterized by significant asymmetry. The left landslide border of the valley is steeper and represented by a cliff up to 50 m high, developed in Jurassic sediments.

Krasnogorsk landslide develops in the left side of the Kuban river valley. The landslide length in the direction of displacement reaches 400 m. The width of the landslide body in the head part is up to 200 m, tapering in the middle part to 120 m. In the lower part the landslide body is divided by a ridge formed by undisplaced rocks up to 30 m wide into two tongues 90 m and 70 m wide. Landslide tongues egress the erosional ledge of the r. Kuban which is up to 45-50 m high. According to drilling data the thickness of the landslide massif is about 15-18 m. The total volume of rocks involved in the displacements is estimated at 1 million cbm.

A detailed study of the general structure of the slope in the Krasnogorsk area showed that the modern landslide body was formed within the ancient landslide massif, involving a fragment of the ancient landslide massif in displacement. An ancient landslide has a length up to 1 km in the direction of displacement with a width of up to 450 m. According to drilling data and geophysical results the ancient landslide body thickness exceeds 30 m. The total volume of rocks involved in the displacement is estimated at 12 million cbm.

The landslide displacements include sediments of the Plinsbach, Aalen and Bayesian stages represented by sandstones and dolomitized sandstones, siltstones with intercalations of limestone.

Activation of landslide displacement will be accompanied by the flow into the river Kuban significant volume of material (approximately up to 0.3 million cbm). With the involvement of ancient landslide body additional parts in the displacement the volume of detrital material will significantly increase. The consequences of the rapid landslide material flow into the river bed will be:

- partial overlap of the river bed with its reformation (formation of additional branches), as the landslide develops on the high erosive side of the valley along which the main water flow goes;
- movement of the main flow of the river to the opposite bank of the valley, which will cause the sudden activation of erosion processes and the retreat of the bank;
- partial flooding of the territories located upstream along the river valley for a time until the river forms a new equilibrium valley.

Scale and formative age of Gunsakot landslide located in central Nepal Himalayas

Hiroshi YAGI¹, Yuki MATSUSHI², Hiroyuki MATSUZAKI³

¹Yamagata University, Yamagata, Japan, ²DPRI, Kyoto University, Uji, Japan, ³MALT, the University of Tokyo, Tokyo, Japan

Abstract

Dormant landslides of deep-seated type are densely distributed in the topographic transitional zone from the Midland to the Great Himalaya. Dormant landslides of the deep-seated type are distributed in an area below 3,500m a.s.l., because the mountain slope higher than that was presumably eroded away by valley glacier in the former Ice Age. As to geology, they are predominantly distributed in geological areas of phyllite & augen gneiss areas, considering both landslide area ratio and the number of the landslide site. Most of large landslides are sliding down to northwest, reflecting the geological structure that declines to northwest due to activity of MCT. Consequently, landslides of deep-seated type are also prone to develop on dip-slopes in this area. And landslides usually occur easier on dip slope than on anti-dip slope under same geological condition.

Area per site becomes larger in the area of augen gneiss which is distributed in the hanging wall side along MCT where relief abruptly increases. Aerial-photo interpretation detected a gigantic dormant landslide at Gunsakot locating in the upper course of Indrawati River, Sun Koi watershed, central Nepal Himalayas. Planar scale of the landslide is almost 10km² including source and depositional areas. Depositional area of detritus with the thickness of 300m more is 4 km² remained on the left bank of Indrawati river. Its volume is estimated to be 0.9 km³ in the source area and 1.2 km³ in the depositional area, respectively. The net volume is thought to be 1 km³ at least. Equivalent coefficient of friction, H/L, is 0.25, that is equal to 14 degree.

Detritus-flow mounds are distributed in the depositional area. Rock masses with long axis of 5 - 10m are scattered on the mounds. The authors got samples from the top part of the rock masses for ¹⁰Be dating to clarify the formative age of the gigantic landslide. The result of the dating varies 2000 and 8000 yrs. B.P. There are some minor scarps below the main scarp in the main source area facing to north-west, consequently a series of large scale landslides occurred several times after 8000 yrs. B.P. However, the rock masses of younger age might come from other scarp facing to south.

Gravitational deformation also has proceeded in the augen gneiss area, forming multiple ridges widely along the top ridge and uphill facing scarplets and linear depressions on its surrounding slope in southern part of Gunsakot. This implies more mega-scale landslide will occur in future.

Acknowledgement: ¹⁰Be dating in this study was carried out at Micro Analysis Laboratory, Tandem Accelerator, the University of Tokyo.

Impact of bedrock landsliding in the Quebrada Arcas alluvial fan system, Atacama Desert, Northern Chile

Anne Mather¹, Laura Evenstar², Adrian Hartley³

¹University of Plymouth, Plymouth, United Kingdom, ²University of Brighton, Brighton, United Kingdom, ³University of Aberdeen, Aberdeen, United Kingdom

Abstract

The large alluvial fan systems of the Central Depression in the hyper-arid core of the Atacama Desert of Northern Chile provide unique opportunity (through exceptional preservation) to examine landscape evolution processes over geologic time-scales (last 8Ma). We will specifically examine the role that bedrock landsliding plays within the catchment and fan evolution in terms of sediment flux and routing. Today the catchment area (1.7–4.3 km above SL) receives rainfall of ~50 mm pa whilst modern rainfall in the lower elevation (1-1.7km above SL) alluvial fan area is <1mm pa. Evidence from packrat middens suggests that even the wettest periods of the Quaternary were no more than 2 times wetter, thus maintaining a likely arid – hyperarid climate for the deposits and landforms examined in this study.

Quebrada Arcas catchment has an area of 760km² which incorporates 2.6km of vertical relief. Within the catchment are a series of deep-seated (100-200m) large bedrock landslides ranging in size from <1km² to >22km² in area. These can be broadly grouped into older landslides that pre-date a significant inset ignimbrite dated at 5.8 Ma and younger landslides that cross-cut and postdate this surface. The older landslides mostly populate an active NNE-SSW compressional fault structure (W of catchment), and the younger landslides are either associated with steeply tilted (38°) ignimbrite/sedimentary unit discontinuity surfaces (E of catchment) or over-steepened slopes associated with the main ephemeral river gorges. The younger and smaller (0.13km²) of these latter landslides is associated upstream with a 40m thick sequence of laminated lacustrine deposits (Salar de Carmen, 0.5km² in area) which contains large (m-scale) soft-sediment deformation units indicative of discrete and repeated seismic activity over the life-time of the salar.

Quebrada Arcas alluvial fan covers some 688km² and comprises 3 main depositional areas based on relative age and sedimentology. 1) An older depositional lobe to the south which covers 281km², has a probable age of 2-5 Ma and is dominated by clast-rich debris flows ; 2) A relatively younger lobe to the north which covers 244 km² and is dominated by clast-rich debris flows. Cosmogenic dating using ²¹He suggests surface flows were deposited ~1Ma, and 3) An active clast-poor mudflow dominated lobe which covers 155 km² below a fan head trench which extends 10 km from the fan apex. Lobes 1 and 2 demonstrate evidence for repeated large bi-modal debris-flow events. At the surface these are represented by linear chutes (some 1-2km long, 40m wide) lined with oversized (5m) granodiorite boulders, and associated downflow with large boulder-field splay lobes (some 0.3km² each). Individual splay lobes represent debris flows of some 3000m³/sec. These are thought to represent landslide (flood) related deposits based on geomorphology, sedimentology and provenance.

Abstract

In Central Europe (CE), the Odra Valley, including the Moravian Gate is regarded as one of the most significant corridors allowing people and fauna to migrate during the Upper Pleistocene. This area should be considered as a key region in CE for studies of human subsistence strategies as well as the disappearance of the Middle Palaeolithic and the emergence of transitional industries (Early Upper Palaeolithic, i.e. EUP). Until the beginning of this millennium, only a few chronological and paleoenvironmental records from individual sites have been known.

The aim of this paper is to present the latest results of the chronometric, geomorphological and paleozoological research carried out in archaeological sites located within Odra basin. In terms of taxonomy, the assemblages represent Central European Micoquian and Szeletian.

Age determination of archaeological remains was made with the use of optical dating of feldspar and quartz and accelerator mass spectrometry ¹⁴C. As a result, it was found that the sediments below the archaeological layers of the studied sites are composed of fluvioglacial sediments associated with the Odra glaciation (MIS 6). Based on the chronological records, it is clear that layers with archaeological material lying directly on middle Pleistocene sediments are much younger, corresponding to the time-span between MIS 5a and MIS 3. Middle Palaeolithic sites are associated with MIS 5a-MIS 5d to the beginning of MIS 3, while EUP sites with MIS 3 (48 to 40 kyr BP). It is worth mentioning, that until now, there are no traces of age overlapping of late Middle Palaeolithic and Early Upper Palaeolithic remains.

In the light of geomorphological and sedimentological studies, it seems that human activity covered various parts of the river valley. Sites are known from the elevations surrounding the valleys or from the valley slopes (Lubotyń 11, Pietraszyn 11) as well as from bank and channel zones (Pietraszyn 49a, Haller Av., Wrocław).

The majority of sites yielded Pleistocene faunal remains. The most interesting assemblage is known from site Pietraszyn 11 comprising the remains of small fauna, birds, predators as well as reindeers, horses, and mammoths.

The next site with a large number of remains dominated by Bovidae is Haller Av. in Wrocław, containing also remains of mammoths, rhinoceroses, horses, reindeer, wolf, birds (?) and fish.

Finally, in Pietraszyn 49a, the remains of mammoth, horse and rhinoceros have been recognised.

Recent data contribute an idea that Odra River valley was a theatre of intense and varied activity of archaic humans and anatomically modern human. Most of the data points to the very mobile nature of the occupations. This work was financially supported by the Polish National Centre of Science (grant number 2017/25/B/HS3/00925).

Luminescence chronology of the key-Middle Paleolithic site Khotylevo (Western Russia) – Implications for the timing of occupation and landscape development

Michael Hein¹, Marcel Weiß¹, Tobias Lauer¹, Alexander Otcherednoy²

¹Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany, ²Palaeolithic Department of Institute for the History of Material Culture of the Russian Academy of Sciences, Saint-Petersburg, Russian Federation

Abstract

Rich in Paleolithic sites, the Khotylevo region in Western Russia is a crucial data point for deciphering migration patterns to the northernmost latitudes (~53°N) of the Eastern European Plain. Currently there is still a lack of information on geochronology and site formation at the key sites, which impedes our understanding of the driving factors behind occupational phases as well as their regionalization. This ongoing project therefore focusses on the >10m section of the Khotylevo 1.6.2 site at the valley-slope of the river Desna. After extensive geomorphological logging, representative samples have been taken for luminescence dating and grain size analysis. With the quartz already in saturation, dating was conducted on 17 feldspar samples using a pIRIR290 protocol. The results yield information on both (1) the timing of middle Paleolithic occupation and (2) on the entire region's fluvial and landscape development of the Early to Mid-Weichselian.

(1) All the archeological remains are embedded within several sediment layers rich in organic matter, indicative of an interstadial (i.e., a warmer phase). Our dating suggests that these cultural layers cannot be distinguished chronologically and fall within the MIS 5a (82-71ka) period. This contradicts previous ¹⁴C data on charcoals and humic acids which placed these cultural layers between 30 and 55ka calBP. Since these dates were already nearing or even beyond the range of the method, we are confident that our robust and highly defined luminescence chronology is more reliable in this particular case. In accordance with other findings of the area (multiple Khotylevo sites, Betovo), it can be surmised that Neanderthals depopulated the entire region during MIS4 to return in mid-MIS3, thus avoiding the coldest periods.

(2) As implicated by our chronological and geomorphological data, there was a pronounced period of fluvial incision at the beginning of the Weichselian, eradicating Eemian sediments on site. The time of occupation (MIS 5a) mainly saw the deposition of slope sediments, interrupted by brief spells of half-bog formation. With the establishment of permafrost in MIS4, slope sediments dominated again in the form of big solifluction lobes. This caused the uppermost cultural layer to be sheared off, dislocated laterally and being redeposited with a deformation and a 45° tip some distance further downslope. The remainder of MIS4 was characterized by fluvial aggradation on site, with the sediments partly displaying a prominent coarse silt content on account of the simultaneous deposition of the "Khotylevo Loess" in the region. Topping the sequence is an MIS3 flood loam containing an interstadial soil (presumably "Bryansk soil") as evidence for landscape stability at that time.

Evidence of a short Upper Palaeolithic occupation of northern France at Amiens-Renancourt 1 (France) during Greenland Interstadial 3

Olivier Moine¹, Pierre Antoine¹, Sylvie Coutard^{1,2}, Gilles Guérin³, Christine Hatté³, Clément Paris^{4,5}, Ségolène Saulnier-Copard¹

¹Laboratoire de Géographie Physique : Environnements Quaternaires et Actuels, CNRS/Université Paris 1/UPEC, Meudon, France, ²Institut National de Recherches Archéologiques Préventives, Glisy, France, ³Laboratoire des Sciences du Climat et de l'Environnement, LSCE/IPSL, CEA-CNRS-UVSQ, Université Paris-Saclay, Gif-sur-Yvette, France, ⁴Institut National de Recherches Archéologiques Préventives, Passel, France, ⁵Archéologies et Sciences de l'Antiquité, CNRS/Université Paris Nanterre/Université Paris 1/Ministère de la Culture/Université Vincennes-Saint-Denis/INRAP, Nanterre, France

Abstract

Following the discovery in 2013 of a new concentration of the archaeological site of Renancourt (Somme, France), new investigations have been performed to document with great details the stratigraphical, chronological and palaeoenvironmental contexts of this important early Upper Palaeolithic site of northern France and that yielded thousands of Gravettian artefacts, large mammal bone remains and a unique set of ornamental items and several Venus figurines carved in Cretaceous chalk.

The stratigraphic sequence is composed of about 2 m of homogeneous loess including a brown-greyish horizon and, 30 cm above, the tundra gley that yielded the archaeological level. Continuous columns of 5-cm-thick sedimentological and malacological samples have been taken throughout the profile. Both pedogenic horizons yielded molluscan species successions that allow to distinguish (1) a transition phase marked by increasing temperatures and humidity and an increasingly diversified vegetation, (2) a maximum of humidity associated with an impoverished vegetation and (3) an opposite transition to colder temperatures that appears quicker and marked by drier conditions for the brownish horizon than for the tundra gley. Moreover, both successions are accompanied by a decrease in grain size, and thus in eolian dynamics.

These two horizons are bracketed by optically stimulated luminescence ages of about 31 and 27,5 ka. The archaeological layer yielded consistent radiocarbon ages on charcoal, burnt bones and earthworm calcite granules around 27,6 ka cal. BP and the brownish horizon yielded radiocarbon ages on earthworm calcite granules around 28,9 ka cal. BP. These ages allow to validate the attribution of the lithic industry to the Recent-Final Gravettian techno-complex and to correlate these two horizons with Greenland Interstadials 4 and 3. Molluscan successions thus depict intra-interstadial environmental changes and show that the human occupation takes place at the end of the stadial-interstadial transition recorded within the tundra gley. Contrary to expectations, the occupation thus precedes the interstadial optimum characterised by potentially less favorable conditions owing to a water-logged environment resulting from the increased intensity of the annual thaw of the permafrost active layer.

In northern France, recent discoveries demonstrate the discontinuous presence of Human populations in space and time during the Upper Palaeolithic and the rare and short nature of their occupations. Combined with the seasonal character of Human activities at Renancourt, our results demonstrate that this short occupation occurred during a milder climatic phase in an optimal environmental context. Imported shell ornaments and exogenous silex highlight a strong relationship with the center of the Parisian Basin, a possible refuge area during unfavourable climatic phases and seasons. This neighbouring southern area is indeed characterised by a slightly more diversified

vegetation and the absence of cyclical ice-rich permafrost installation. Conversely, only brief incursions would have occurred in northern France during the most favorable periods.

Life in the North -OIS3 adaptations at the northern edge of the habitable world. Case studies from northern Central Europe

Tim Matthies, Olaf Jöris

MONREPOS Archaeological Research Centre & Museum for Human Behavioural Evolution, Neuwied, Germany

Abstract

The Early-Upper Palaeolithic open-air sites Lommersum and Breitenbach, both located at the northern foothills of the German *Mittelgebirge*, shed detailed light on the behavioral strategies of anatomically modern humans that enabled them to colonize the northernmost periphery of the Aurignacian oikumene.

Lommersum, which dates into the early, colder part of the Aurignacian is dominated by reindeer and is regarded as a processing camp in the immediate proximity of a kill site. Breitenbach, on the other hand, dates into the final stage of the Aurignacian and has yielded a much wider faunal spectrum. However, its economy, too, is largely based on reindeer hunting. Both sites document the repeated human presence in the tundra-like environments of northern Central Europe during OIS 3.

In contrast to Lommersum, the enormous spatial extent and the richness of the Breitenbach site with various settlement features and a diverse find spectrum indicates repeated and also longer-term occupation(s). It thereby documents that the northern periphery of the Aurignacian oikumene was not merely sporadically exploited, but rather represented an integral part of the regional Aurignacian economic system. It is this intensity of occupation, which appears to foreshadow a type of settlement and site organization which – to some degree – characterizes the succeeding Mid-Upper Palaeolithic, i.e. the 'Gravettian', of eastern Central and Eastern Europe.

The diachronic comparison with the reindeer-dominated Late Middle Palaeolithic faunal assemblage from Salzgitter-Lebenstedt and the Late Palaeolithic Ahrensburgian site of Stellmoor – both located in comparable environments in the northern German lowlands – provides a better understanding of the adaptive advantages underlying reindeer-based economies at the edges of the habitable world.

Red palaeosols in Yunnan Plateau, southwestern China as an evidence of Quaternary landscape evolution and palaeoenvironmental change

Shenggao Lu

College of Environmental and Resource Sciences, Zhejiang University, Hangzhou, China

Abstract

Red palaeosols are widely found in the Yunnan Plateau, southwestern China, of more than 2000 m elevation, which could be used as an evidence of Quaternary landscape evolution and important archive of palaeoenvironmental change. Red palaeosol profiles on the plateau planation surface with elevation of 2200–2400 m were collected from different location of Plateau. Pedological, geochemical, magnetic, and mineralogical techniques were used to characterize the palaeopedogenesis of red palaeosols. The morphological features suggest that these red palaeosols were highly weathered soils commonly found in tropical-subtropical climates. The current pedoenvironmental conditions in the plateau are not favorable to the formation of red earth. The red palaeosols contain a larger amount of hematite and exhibit a higher degree of magnetic enhancement. The presence of hematite in red palaeosols is related to stronger weathering intensity under warm and dry soil condition. Therefore, it is deduced that under the present climate, the highly magnetic red palaeosols could not be developed in the areas with such high elevation of over 2000 m. Pedologically, the red palaeosols are characterized by stronger desilicification and allitization, kaolinite-rich clay minerals and strong sesquioxide illuviation in Bs horizon. These pedogenic characteristics are associated with the laterization process and the development of a deeply kaolinized palaeosurface evolved under humid tropical and subtropical climates. The Sa and Saf ratios of the red palaeosols range from 1.4 to 2.3, and from 0.8 to 1.4, respectively. These values are similar to those found in the highly weathered Oxisols and Ultisols, which are in a range of 1.31–2.19 for Sa. Therefore, only possibility is that these red palaeosols were uplifted by the neotectonics after formation. The presence of highly weathered soils at an altitude of 2200–2400 m indicated the influence of tectonic uplift on the soil vertical distribution of plateau. It is deduced that the red palaeosols formed at high temperature and under abundant rainfall conditions in the Early Pleistocene were uplifted to current height by the tectonic uplift of plateau. According to the difference in elevation between the red palaeosols and modern red soil base, it was estimated that the red palaeosols had been uplifted about 1600–2000 m since its formation.

Abstract

The direct interaction between soils and climatic conditions makes paleosols a potentially powerful resource for quantitative paleoclimatic reconstruction. On the Chinese Loess Plateau, the loess/paleosol sequences contain hundreds of paleosol horizons, which are regarded as one of the most important archives of past warm periods. Over the past two decades, reference has increasingly been made to the aspects of linking magnetic minerals within soils quantitatively to paleoclimatic reconstructions. Earlier studies have long focused on ferrimagnetic minerals. Recently, increasing studies have shifted their attention to quantitative relationships between hematite-related proxies and modern climatic factors. However, the linkage between the hematite formation and climatic variables remains controversial. Here we present the results of a comprehensive investigation of the magnetic properties and statistical analysis of a suite of clay and silt fractions of modern soil samples from 179 sites across the Chinese Loess Plateau (CLP) and adjacent regions. Our objective was to clarify the relationships between modern climatic variables and pedogenic hematite, as well as pedogenic ferrimagnetic minerals. Our results show that pipette extraction separates the fine-grained superparamagnetic (SP) and most of the single-domain (SD) magnetic grains into the clay fraction, and that the remaining silt fraction displays the magnetic properties of coarse pseudo-single domain (PSD) or a mixture of multidomain (MD)/PSD and a few SD particles. Only the pedogenic clay fraction shows a strong correlation with climatic variables. The application of redundancy analysis helps to distinguish the climate variables controlling the formation of ferrimagnetic minerals and hematite during pedogenesis. On the CLP, pedogenic ferrimagnetic minerals are sensitive to mean annual precipitation, while pedogenic hematite formation is preferentially dependent on mean annual temperature. The confirmation of the temperature-dependent nature of hematite on the CLP provides a new possibility for quantitatively reconstructing the paleotemperature history of Chinese loess/paleosol sequences.

Lithium isotopes in lake sediments as a proxy for past soil development at the catchment scale

Anthony Dosseto¹, Leo Rothacker¹, Alexander Francke¹, Frank Sirocko²

¹University of Wollongong, Wollongong, Australia, ²Johannes Gutenberg-University, Mainz, Germany

Abstract

Soil development regulates landscape evolution, as well as the delivery of sediments and nutrients to rivers. One key question is how this process responds to climate variability, tectonic and human activity. To tackle this issue, one approach is to investigate how soil development has varied during the Quaternary.

Lithium (Li) isotopes (⁷Li and ⁶Li) fractionate during clay formation and thus can be used as a proxy for the extent of soil formation. For instance, in river sediments, it has been shown that their Li isotopic composition directly correlates with weathering regimes at the catchment scale [1]. Applied to sedimentary deposits, this tool can be used to assess how soil development has varied over the Quaternary.

The Li isotope composition of Lake Dojran sediments (FYROM/Greece) shows that soil development continuously increased during the early and mid Holocene, in response to the end of the Younger Dryas (Fig.1; [2]). Unlike erosion, soil development was insensitive to short-lived (less than 1,000 yr) climatic fluctuations at 8.2 and 4.2 ka. At 3.5 ka, Li isotopes suggest that sediments deposited were poorly weathered, evidencing a deep erosion event associated with the emergence of agriculture in the region.

In Germany, Li isotope results from maar lakes show that for most of the late Pleistocene there was little soil development, as a consequence of an overall cold climate, and contrasting with extensive soil development during the Holocene. Although less intense than during the Holocene, some soil development occurred at about 50-55 ka, associated with the only period when *Picea* and *Carpinus* coexisted. These observations illustrate the role of ecosystems on soil development, and allow us to identify which vegetation taxa have a more important role compared to others.

[1] M. Dellinger, J. Bouchez, J. Gaillardet, L. Faure, and J. Moureau, "Tracing weathering regimes using the lithium isotope composition of detrital sediments," *Geology*, vol. 45, no. 5, pp. 411-414, 2017.

[2] L. Rothacker, A. Dosseto, A. Francke, A. R. Chivas, N. Vigier, A. M. Kotarba-Morley, and D. Menozzi, "Impact of climate change and human activity on soil landscapes over the past 12,300 years," *Scientific Reports*, vol. 8, no. 1, p. 247, 2018.

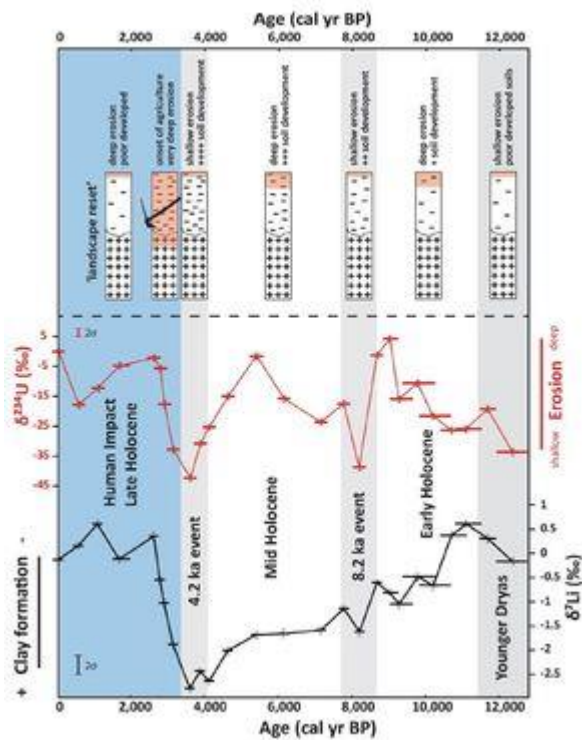

Figure 1. Lithium and uranium isotope compositions of Lake Dojran sediments, proxies of soil development and erosion, respectively [2]. Between 12,000 and 4,000 cal yr BP, soil development continuously increases while erosion responds to short-lived climatic events at 8,200 and 4,200 cal yr BP. At 3,500 cal yr BP, both proxies suggest a deep erosion event associated with the development of agriculture in the region.

Modelling of interglacial paleosol development in the Chinese Loess Plateau

Keerthika Nirmani Ranathunga Arachchige^{1,2}, Peter Finke¹, Qiuzhen Yin²¹Ghent University, Ghent, Belgium,
²University Catholique de Louvain, Louvain la Neuve, Belgium

Abstract

Modelling of interglacial paleosol development in the Chinese Loess Plateau

Introduction and Rationale of Research

The loess deposits in the Chinese Loess Plateau (CLP) are a huge continuous record of paleoclimates. Paleosoils and intercalated loess layers have long been studied and correlated with modelled paleoclimates.

Interglacials are the major periods of soil formation and greatly differ from other interglacials by duration and strength. It has been identified that paleosol formation does not strongly concur with globally established paleoclimate signals especially for interglacial Marine Isotope Stages MIS 5e, MIS9 and MIS13. Analysis of just soil data would not be straightforward to identify relations between modelled past climate intensity and soil development. Not only the past climate (precipitation, temperature) has an effect on soil formation but also vegetation and interglacial duration plays a vital role. Additionally, pedogenetic overwriting during later periods of soil formation may affect the observed soils. The intention of this research study is to identify the relative importance, magnitude of favorable conditions of soil forming factors on soil formation during six interglacials in the past 500 000 years in the CLP in China.

Research methodology

Combination of the soil formation model SoilGen and the earth system model LOVECLIM is a promising tool to compare simulated paleosol properties to paleoclimate.

Figure1. Graphical illustration of ongoing research work

Results

Figure 2. Example results of LOVECLIM-SoilGen climate-soil evolution model: distinct Bt horizon is visible in the MIS13 soil (right) than MIS5e

Table 1. Example result of paired t-test on difference of means representing an aridity gradient: H_0 : no difference between mean values of soil properties in the simulated soil. Clay content difference calculated by (MIS13-MIS5e).

Sites of CLP	Aridity percentile over CLP	Clay content
mean difference (kg clay m ⁻²)	P(H_0)	t
	Wet	
	to	
Wugong	0.127	-2.139 0.002
	Dry	
Chang'an	0.185	-1.249 0.080
Weinan	0.241	-1.417 0.013
Luochuan	0.349	-1.226 <0.001
Changwu	0.430	-0.691 0.001
Xifeng	0.676	-1.132 0.001
Pengyang	0.761	-0.035 0.039
Jingyuan	0.869	-0.413 0.000

Conclusion

Clay content was significantly higher in MIS 5e than MIS13 paleosols for all plots, indicating strong weathering and leaching in MIS13.

The clay differences between MIS 5e and MIS 13 soils become less with increasing aridity.

Precipitation surplus is the leading soil forming factor for soil horizonation during MIS13 than MIS5e.

Soil erosion process and human activities recorded by check dam deposit in the gully region of Chinese Loess Plateau

Yongui Song, Weiwei Lin

Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China

Check dams are important engineering measures to prevent soil erosion and to settle sediments and pollutants. The dam sediments are also good archive for past climatic change and human activities of small watershed. We choose a check dam (HSC) section from the Chinese Loess Plateau as a case to discuss their relationships. Firstly, based on AMS 14C and 137Cs dating, we established the chronological frame of this section. Secondly, we employed magnetic susceptibility, particle size, mineralogy to reconstruct the soil erosion process. Finally, we compared these records with the local rainfall and historical archives, and explore the relationship between the process of soil erosion and human activities since 1950s. The results show that the check dam deposition has recorded the process of soil erosion, which can be subdivided into 5 phases. The erosion process is not only related to precipitation changes, but also closely related to human activities. The reform and opening up, croplands creation and afforestation activities have great influence on soil erosion. This work can provide important clues to the study of regional man-land relationship.

Soils and environmental conditions in the Bronze and Early Iron Ages in the dry-steppe area of Russia

Fatima Kurbanova¹, Olga Khohlova², Alexander Makeev¹, Alena Papkina¹, Tatiana Puzanova¹

¹Lomonosov Moscow State University, Moscow, Russian Federation, ²Institute of Physical, Chemical and Biological Problems in Soil Science, Russian Academy of Science, Pushchino, Russian Federation

Abstract

Modern soils in the steppe area perfectly reflect climatic fluctuations in the Holocene. The main goal of our research is to reveal the landscape parameters of various time slices based on the features of paleosols buried under kurgans, which are widely spread in the study region. The relevance of the study is based on a complex set of methods, including morphogenetic studies of soils at various hierarchical levels and physical and chemical properties. The age of buried soils was determined by radiocarbon dating of various carbonaceous substances.

The kurgan cemeteries named *Krasikovo 1* (Pit-grave archaeological culture, The Bronze Age) and *Vysokaya Mogila* (Sarmatian culture, The Early Iron Age) are located in the dry-steppe area of Orenburg region, Russia. Set of burials belonging to the same archaeological cultures allows providing a short-term paleoclimate reconstruction for a long period of the time: The Bronze Age (~4600 BP) – The Early Iron Age (~2000 BP) – nowadays. Based on the study of buried and surface soils it can be concluded, that the Bronze Age environment conditions were similar to modern and characterized by a dry climate. In the Early Iron Age soils were formed in more humid period, which is evidenced by a relatively high content of organic carbon, less carbonate accumulation and lower carbonate table.

In the *Krasikovo 1* cemetery five kurgans were constructed with time intervals in 50-100 years and were divided into early and later constructed groups based on radiocarbon data. Paleosols buried under earlier constructed group of kurgans showed more humid soil properties: thick humus horizon and deep carbonate table; the soils buried under the second group are characterized by more arid properties: shallow humus horizon with a lower TOC content, high carbonate table, the presence of gypsum and lower values of magnetic susceptibility. These data allow us to assume that during the construction of kurgans the mean annual of precipitation decreased.

The radiocarbon data showed that the time interval between the constructions of two kurgans in the *Vysokaya Mogila* site is ~ 200 years (2191±35 and 2022±25 BP). The soil buried under the older kurgan has thicker humus horizon and higher humus content; the pedogenic carbonates are absent, and the gypsum formations located deeper than those in the younger paleosol. This comparison showed, that the environment within a short time interval became more arid.

The study of buried soils confirms rhythmic climatic fluctuations within the time span from the Bronze Age till nowadays. In the wide scale, environment conditions in the Bronze Age was similar to modern, while in the Early Iron Age the era of humidization occurred. Soil properties prove to be very reflective to quick environmental changes.

Understanding geomorphic and pedogenic forcing on the organic matter distribution from vegetation to soil and its use in paleovegetation reconstruction

Biswajit Roy, Kanva Goyal, Prasanta Sanyal
IISER Kolkata, Kalyani, India

Abstract

The $d^{13}\text{C}$ values of organic matter (OM) have been used to reconstruct abundance of C_3 and C_4 plants. However, the intimate connection of distribution of vegetation with geomorphic processes and landforms may impart variation in $d^{13}\text{C}$ of C_3 and C_4 plants. Such variation can impart change in $d^{13}\text{C}_{\text{SOM}}$ value without change in abundance of C_3 and C_4 plants. Therefore, it is important to understand the effect of lateral variation in riverine geomorphic architecture and its impact on the $d^{13}\text{C}$ value of vegetation and soil. In this study, a lateral transect (~6 km) of an undulatory geomorphic surface of north-south trending lateritic alluvium of South Bengal (India) was considered to unveil the effect of topography, and active channel distance on the contemporaneous vegetation and soil. A variation of ca. 50‰ is observed in the n-alkane H-isotopic composition ($d\text{D}_{\text{C}_{31}}$) of the dominating tropical deciduous species (*Sal-Shorearo busta*). The $d^{18}\text{O}$ value of the groundwater and the river water was analysed to understand the source of water for the trees. The D/H ratio suggests that the vegetation near the active channel was mostly influenced by the river water (enriched) and in distal areas by the groundwater (depleted). Preliminary study on the $d^{13}\text{C}_{\text{Bulk}}$ values of the deciduous species suggests an enrichment of 7‰ away from the active river channel. The difference can be attributed to the change in water-availability, canopy, topography, and vegetation density that varied along transect. The variation in the efficiency of water use was also observed in the average chain length (ACL) and carbon preference index (CPI) distribution. The higher ACL (>29) and CPI (>2) values are mostly associated with the badlands or upland soil environment with very low moisture availability. Preservation of the contemporaneous vegetation signals in the litter layer was regulated by the geomorphology, vegetation density, and soil texture. The upland, and the distal area, with sparse vegetation, tend to preserve more positive $^{13}\text{C}/^{12}\text{C}$ ratio (-24‰) compared to the lowland with well-developed soils (-28‰). The upland and distal soils, with coarser texture, suggests faster decomposition of OM (TOC% <0.2) due to higher percolation and soil aeration; whereas in fine-textured lowland soils depleted (-4‰) and high TOC % (>0.5) is observed. Further, due to continuous abrasion by the riverine process, the TOC is also low in the soils adjacent to the active river. The nitrogen isotopic composition ($d^{15}\text{N}_{\text{Bulk}}$) of OM increases as alteration/decay or leaching of organic matter proceeds. The faster decomposition and microbial processing of OM in upland and distal area soils registered higher $d^{15}\text{N}_{\text{Bulk}}$ (+4‰) value. This variation in the vegetation and soil will result in ambiguous interpretation about the past vegetation and thus requires detail vegetation, geomorphic and physical or chemical characterisation before employing it as paleo-record archives.

Fig. 1. Variation in the soil $\delta^{13}\text{C}_{\text{Bulk}}$, $\delta^{15}\text{N}_{\text{Bulk}}$, C/N and $\delta^{15}\text{N}_{\text{Bulk}}$ value, and Groundwater $\delta^{15}\text{N}_{\text{Bulk}}$ value along the lateral transect of the river.

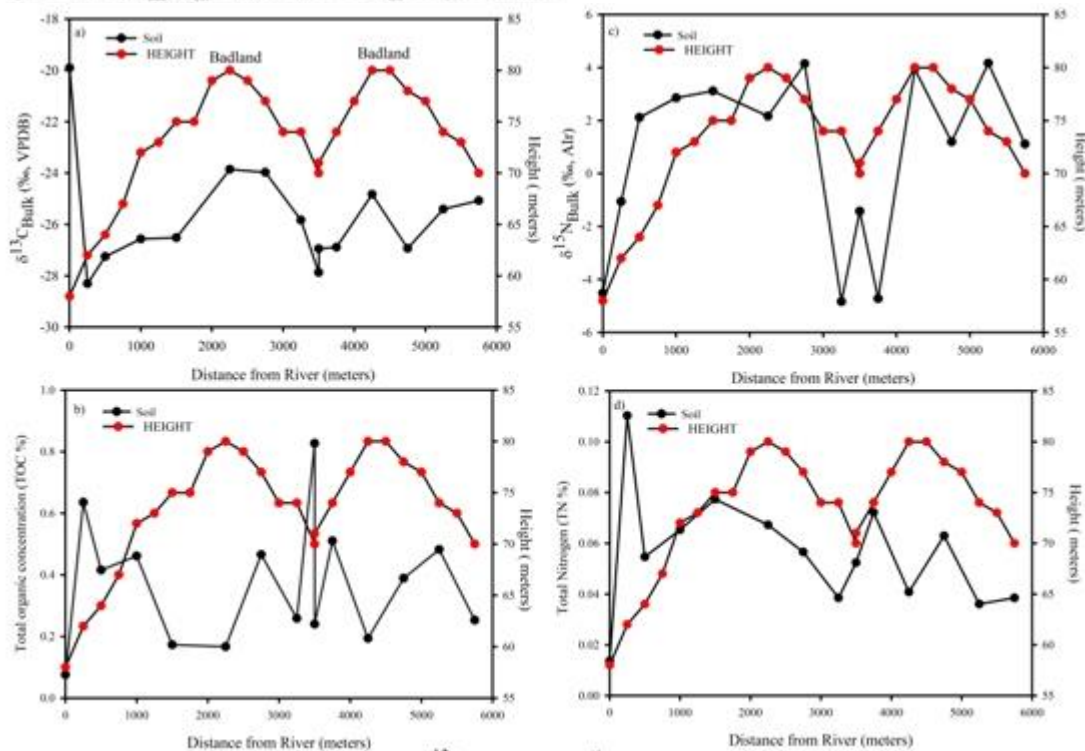

Fig. 2. Variation in the: Soil a) $\delta^{13}\text{C}_{\text{Bulk}}$, b) TOC, c) $\delta^{15}\text{N}$ value; and TN % along the lateral transect of the river.

Abstract

Previous studies of Pleistocene archives at the Mosel River focused mainly on the evolution and characterization of terrace levels (e.g. Rixhon et al. 2016; Cordier et al. 2006, Negendank 1978), on fluvial dynamics and soil development in general (Weidenfeller, 1990), and on the youngest terrace stage in more detail concerning dating purposes and fluvial erosion (Cordier et al. 2014). Cover sediments with intercalated paleosols on the Mosel terraces are valuable paleoenvironmental archives but were not studied in detail until now.

We present pedological data from two sediment-paleosol sequences (SPS) on Pleistocene fluvial terraces in the lower Mosel valley, including soil physical, micromorphological, geochemical and biochemical data. The chronology is based on 13 optically stimulated luminescence (OSL) model ages (Bandemer SPS: 7, Hetzerath SPS: 6) to support the proposed pedostratigraphy and yield the first minimum ages for fluvial terraces of the Mosel River older than Würmian. According to the terrace-grouping of Müller (1976) the Bandemer SPS is located on a high terrace (145 m above the present Mosel) and the Hetzerath SPS is located on an upper middle terrace (70 m above the present Mosel).

The surface soil at both SPSs is a Stagnic Luvisol supposed to have developed during the Holocene. The buried paleosols are generally Btg horizons of Stagnic Luvisols with different redoximorphic features formed in loess derivatives. Both archives cover the last three glacial-interglacial cycles as indicated by distinct paleosols and OSL based chronology. The Bandemer SPS comprises a fourth glacial-interglacial cycle indicated by soil formation in fluvial sands and gravels, however, within the saturation limit of OSL dating techniques.

Loess-palaeosol sections along the Rhône Graben: records of Late Quaternary changes of a climatic gradient from central to southern Europe

Nora Pfaffner¹, Daniela Sauer¹, Annette Kadereit², Sophie Cornu³, Barbara von der Lühe¹, Pascal Bertran⁴, Mathieu Bosq⁴, Sebastian Kreuzer⁵

¹Department of Physical Geography, University of Göttingen, Göttingen, Germany, ²Heidelberg Luminescence Laboratory, University of Heidelberg, Heidelberg, Germany, ³Aix-Marseille Université, CNRS, Collège de France, IRD, INRA, CEREGE, Aix-en-Provence, France, ⁴Institut National de Recherches Archéologiques Préventives (INRAP), PACAE, Université de Bordeaux, Pessac, France, ⁵IRAMAT-CRP2A, UMR 5060 CNRS-Université Bordeaux Montaigne, Pessac, France

Abstract

The Rhône Graben in south-eastern France stretches from 45°5'N at the confluence of the Saône River southward to 43°2'N at the Rhône delta on the Mediterranean coast. At present, the climatic conditions along this north-to-south transect represent a gradient from a humid-temperate to a Mediterranean climate. The aims of our study are (i) to reconstruct, how this climatic and environmental gradient changed over the Late Quaternary, based on a series of loess-palaeosol sections along that transect, and (ii) to correlate these sections with loess-palaeosol sections in central Europe.

At the current stage of the work, we have studied several loess-palaeosol sections along the Rhône Graben and developed a preliminary stratigraphy, based on three sampled key sections. The chronological framework will be established by optically stimulated luminescence (OSL) dating (in progress). Samples are currently analysed for colour, particle-size distribution, carbonate content, total contents of C, N, Fe, Al, Ca, Mg, K, Na, and contents of dithionite-extractable Fe and Al. Besides, plant biomarker analyses and thin section analyses will be carried out. The results will be used for reconstructing the changing palaeoenvironmental conditions through time at each site. Along the Rhône-Graben transect, mean annual temperature (MAT) increases from 12.2°C to 13.7°C, and the ratio of mean monthly maximum to mean monthly minimum precipitation MMP_{max}/MMP_{min} increases from 1.89 to 4.04, thus reflecting a progressive shift towards a typical Mediterranean precipitation pattern. The northernmost key section is located at 45°5'N: (1) Profile Les Chaux, NE of Tournon-sur-Rhône (MAT = 12.2°C, MAP = 810 mm, MMP_{max}/MMP_{min} = 1.89). The second key section is at 44°4'N: (2) Profile Garenne, NNW of Montélimar (MAT = 12.9°C, MAP = 840 mm, MMP_{max}/MMP_{min} = 2.81), representing the present-day transition zone between temperate and Mediterranean climate. The southernmost key section is located near Collias, West of Avignon (MAP = 698 mm, MAT = 13.7°C, MMP_{max}/MMP_{min} = 4.04), including (3a) Profile Collias-North (43°6'N), (3b) Profile Collias D112-South (43°6'N), and (3c) Profile Collias-Wood (43°6'N). The transect will be extended northwards over the next years to link central European sections.

Comparing the profiles studied so far, the most conspicuous stratigraphic unit is a brown palaeosol horizon, marked by vertically oriented calcium carbonate rhizoliths in most of the sections. Based on the position of this horizon, we assume that it formed during MIS 3. It appears to be a suitable marker horizon for correlating the loess-palaeosol sections along the Rhône-Graben transect. Furthermore, a red palaeosol horizon above a thick petrocalcic horizon in profiles (3b) Collias D112-South and (3c) Collias-Wood suggest Last Interglacial soil formation. However, the exact chronostratigraphic positions still need to be determined by OSL dating.

Late Holocene environmental dynamics in Zackenberg area (NE Greenland) through the study of earth hummocks

Jesús Ruiz Fernández¹, Marc Oliva²

¹University of Oviedo, Oviedo, Spain, ²University of Barcelona, Barcelona, Spain

Abstract

Although the most commonly used records to study past environmental and climatic conditions are marine and lake sediments and ice cores, there are many other records can provide valuable information for this purpose. This is the case of earth hummocks (*thúfur* or *pounus*), which have been scarcely used until now as paleoenvironmental record. Earth hummocks are dome-shaped periglacial features typical of poorly-drained permafrost environments. Their internal composition is made mostly of organic-rich layers that can be used to trace past environmental and climatic conditions.

In August 2018, three fields with hundreds of earth hummocks were studied in Zackenberg, an ice-free area located in the Northeast Greenland National Park (74°28' N, 20°34' W). We examined the morphometric, geochronological and sedimentological characteristics of these periglacial features. The three sites were located at altitudes ranging between 50 and 75 m asl distributed between different moraine systems from different glacial stages. Several sedimentological analyses of the internal structure of earth hummock were conducted (textural characterization through the quantification of sand, silt and clay fractions, organic matter content as the sum of both % labile and % refractory fractions, Rp index, and percentage of total organic carbon and total nitrogen), as well as six ¹⁴C datings in the Radiochronology Lab of the Laval University (Canada).

Results show that the average length of earth hummocks ranges between 67 and 85 cm, the width between 51 and 62 cm, the maximum height between 38 and 39 cm, the minimum height between 23 and 30 cm, and the depth of permafrost varies between 20 and 24 cm inside and between 1 to 13 cm outside of these features. These parameters are related to topography, as well as to water and sediment availability. Geochronological data show that earth hummocks have ages between 1.8 and 0.4 ka BP, while sedimentological analyses show a general increase in organic matter content from the bottom to the top. Therefore, geomorphological processes (transport and sedimentation of particles) predominate in the initial stages of earth hummocks formation, whereas in the stages of greater evolution of these features soil formation prevails. However, in detail there is a succession of mineral and organic layers. This succession reveals the occurrence of at least five contrasted stages in the environmental evolution of this area of NE Greenland during the last two millennia. Sedimentation rates vary between 0.15 to 0.26 mm/year in organic layers, while in mineral layers generated in dynamic geomorphological environments, sedimentation rates of 0.69 mm/year can be achieved.

Assessing loess proportions in Pleistocene periglacial slope deposits (PPSD) and their spatial variation

Fei Yang, Volker Karius, [Daniela Sauer](#)
University of Goettingen, Goettingen, Germany

Abstract

Admixture of loess plays an important role in the formation of Pleistocene periglacial slope deposits (PPSD) in the central European subdued mountains, and it is also a key criterion in their classification. Typical patterns of loess admixture in different types of PPSD have been extensively reported for numerous regions of central Europe. However, the quantification of loess proportions in PPSD still remains a challenge. The lack of quantification methods hampers (1) the establishment of relationships between the loess proportion and its effect on ecologically relevant soil properties (e.g., water-holding capacity, base saturation, etc.), and (2) the assessment of variations in the loess proportion of an individual PPSD in different relief positions across a landscape.

In this study, we tested the potential of laser-diffraction particle size analysis for quantifying loess proportions in PPSD, and used color determination by spectrophotometry for independent cross-check.

We examined the particle size distribution of twenty pedons developed in PPSD and Holocene colluvial deposits in different topographic positions along a little valley carved into Lower Triassic sandstone (Buntsandstein) near Göttingen, central Germany. The particle size distribution of the Holocene colluvial deposits, upper layers (ULs) and intermediate layers (ILs) mostly showed a bimodal pattern. It included (1) a silty mode, corresponding perfectly to that of nearby primary loess that served as a reference, and (2) a sandy mode, matching with that of the basal layers (BLs), which consist entirely of local weathering materials. The consistency of the silty mode between the UP and the IL, irrespective small variations among different sites reflected that the loess component in the ULs was incorporated from underlying loess that previously existed. Very similar loess contents at different depths within individual ULs (and colluvial deposits) indicated a rather complete homogenization due to a variety of processes, including solifluction, bioturbation and anthropogenic influence. Further, the only slightly overlapping particle size distribution curves of loess and sandstone allowed for the calculation of loess proportions in loess-containing layers. Proportions of loess in loess-containing layers varied from less than 10% to more than 90%, and showed maximum loess proportions in the ILs. The loess proportions calculated based on laser-diffraction data showed a high correlation ($r^2=0.88$, $n=79$; A horizons excluded) with the b^* value (yellowness) obtained by spectrophotometry. This close relationship suggests that (1) a detailed assesment of grain size distributions may provide reliable estimates of loess proportions in the studied soils and (2) the b^* value may serve as another sensitive proxy that can be used to calculate loess proportions in soils. This new approach enabled us to assess spatial variations of loess admixture in PPSD at a landscape scale and thus to obtain a deeper understanding of the erosional-depositional history of each site.

Buried late Pleistocene paleosols in the context of the Quaternary landscape evolution of North-Western Siberia

Sergey Sedov^{1,2}, Vladimir Sheinkman^{2,3}, Alexey Rusakov⁴, Tatiana Kulikova^{2,3}, Roman Bobkov^{2,3}, Andrey Yurtaev⁵

¹Instituto de Geología, UNAM, Mexico City, Mexico, ²Tyumen Industrial University, Tyumen, Russian Federation, ³Earth Cryosphere Institute, RAS, Siberian Branch, Tyumen, Russian Federation, ⁴ St Petersburg State University, St Petersburg, Russian Federation, ⁵ Tyumen State University, Tyumen, Russian Federation

Abstract

Recent development of non-glacial scenario for the Quaternary landscape evolution of North-Western Siberia (Sheinkman 2016, 2017) stimulated search for the paleopedological archives in this region. During the 2013-2018 field surveys we identified and studied 3 major Late Pleistocene pedostratigraphic levels in the sedimentary sequences of the high terraces of the rivers, which run to the north and south from the Siberian Uval. The lowest level identified in the Middle Ob' terrace sections Kiryas and Belaya Gora yielded U/Th dates 100-120 kyr BP and thus is attributed to the MIS5 – Kazantsevo thermochrone. It is represented by a pedocomplex in which the lower paleosol unit has micromorphological signs of clay illuviation (indicative of taiga pedogenesis) whereas the upper one consists of the peat and gleyic horizons. We correlate this level with Mezin pedocomplex of the East European loess sequences and suppose that the differences of pedogenesis between the lower and upper unit mark the paleoclimate deterioration after MIS5e. MIS3(Karginsky interstadial) paleosols (with C14 dates from the soil organic materials in the range 25-35 ka BP) lie above the MIS5 level being separated by the alluvial sediments containing dropstones. These paleosols show macro- and micromorphological features redoximorphic processes (ferruginous mottles, nodules and coatings) and frost action (cryogenic aggregation, mixing of organic and mineral materials, grain size sorting). Pedogenetic properties of these paleosols are indicative of soil development under tundra or tundra-steppe ecosystems. The paleosol level corresponding to Late Glacial – end of MIS2 (C14 dates 10-12 ka BP) was identified in the uppermost parts of the high terrace sections of the basins of the rivers Taz and Nadym. This strongly gleyed paleosol is associated with a cryogenic horizon and partly is presented by pedosediments filling large ice wedge casts. We suppose that this paleosol level is associated with the warming events at the end of the last cryochrone. Paleoenvironmental interpretation of the paleosols agrees with the palinological and paleontological records.

Quaternary ice sheet limits on the continental shelf west of Ireland.

Stephen McCarron¹, Mudasar Saqab², Kieran Craven³, Daniel Praeg⁴, Benjamin Thebaudeau⁵, Xavier Monteys³
¹Maynooth University, Maynooth, Ireland, ²iCrag, UCD, Dublin, Ireland, ³Geological Survey of Ireland, Dublin, Ireland, ⁴Géoazur UMR7329 CNRS, Valbonne, France, ⁵Joyce Country and Western Lakes geopark, Westport, Ireland

Abstract

Recent investigations have shown that the continental shelf west of Ireland contains sedimentary landforms recording occupation by grounded, lobate ice sheet margins that extended from Ireland during at least the last glacial cycle. This paper reviews some of the offshore evidence of past glacial events available from high-resolution bathymetry, 2D/3D seismic datasets (Fig. 1), and shallow sediment cores providing information on the sedimentology, rheology and age of glacial stratigraphic units. The available data suggest that the continental shelf has been repeatedly occupied by tidewater ice margins characterised by ice streaming, possibly since the mid-Pleistocene transition. The offshore record provides as yet incomplete information on the extent and timing of glaciation from multiple centres of dispersal in Ireland. The dynamics of former ice sheets in Ireland, downwind of the climatically important central North Atlantic region, makes them of wider interest in the study of partially marine based ice sheet-ocean interactions in rapidly changing environments.

Fig 1. The first appearance of ice berg plough marks within a Plio-Pleistocene sediment wedge on the inner shelf west of Ireland.

Submarine evidence of ice-streaming and ice-sheet re-advance of the British Ice Sheet, offshore eastern Scotland and north-eastern England

Heather Stewart^{1,2}, Tom Bradwell², Margaret Stewart¹, Colm Ó Cofaigh³

¹British Geological Survey, Edinburgh, United Kingdom, ²University of Stirling, Stirling, United Kingdom, ³Durham University, Durham, United Kingdom

Abstract

An improved understanding past cycles of glaciation, timing and extent, has far-reaching implications for better understanding global climate change and ice-sheet behaviour. The study of palaeo-ice sheets and their drainage systems, both within the ice dome and their outlet glaciers and ice streams, are recognised as crucial for improved understanding of contemporary ice sheets such as the West Antarctic, East Antarctic and Greenland ice sheets (e.g. Stokes *et al.*, 2015). The 1000+ metre-thick Quaternary sediment sequence of the North Sea Basin provides an excellent opportunity to investigate evidence for numerous glaciations, including geomorphological features as discussed here.

The Quaternary strata of the North Sea basin are also important in terms of their role as overburden for hydrocarbon systems and CO₂ storage potential; multiple cycles of glaciation affect subsidence rates and migration pathways. Quaternary strata also form the foundations for offshore renewable installations and infrastructure for hydrocarbon exploration and extraction. The impact on geotechnical properties of glacial loading and unloading and lateral variation in these deposits is an important consideration for offshore development. Cycles of loading and unloading of ice also impact fluid release from the sub-surface and therefore geohazard assessment. Glacial geomorphology shapes the current seabed topography and glacial deposits determine seabed composition, which influences the benthic community composition and distribution as well as forming commercially valuable aggregate resources.

A number of major ice streams have been identified within the Pleistocene British–Irish Ice Sheet (BIIS), primarily based on onshore mapping and single beam bathymetric datasets offshore (e.g. Bradwell *et al.*, 2008). The identification of these ice streams is crucial to better understand the flow pattern and demise of the last BIIS.

This work combines multibeam echosounder datasets with high-resolution topographic digital surface models (NEXTMap), 2D seismic reflection profiles, and shallow borehole data, to reveal strong evidence for onshore-offshore palaeo-ice streaming in eastern Scotland and northeastern England, UK, which extends out into the western North Sea Basin. The study area includes the catchments of the North Sea Lobe, Strathmore, Forth–Tay, and Tweed palaeo-ice streams. Long suspected to terminate offshore, the full flow path and dimensions of these palaeo-ice stream systems are reconstructed with some certainty using these new data. Drumlin fields, large arcuate moraine ridges, smaller-scale moraine ridges, grounding zone wedges and incised channels are mapped in detail to provide new information about the offshore behaviour of the last BIIS.

Submarine geomorphology of the Celtic Sea continental shelf and the southern extent of glaciation on the Atlantic margin of Europe

Daniel Praeg^{1,2}, Stephen McCarron³, Dayton Dove⁴, Daniela Accettella¹, Andrea Cova¹, Lorenzo Facchin¹, Xavier Monteys⁵

¹OGS (Istituto Nazionale di Oceanografia e di Geofisica Sperimentale), Trieste, Italy, ²Géoazur, Nice, France,

³Maynooth University, Maynooth, Ireland, ⁴British Geological Survey, Edinburgh, United Kingdom, ⁵Geological Survey of Ireland, Dublin, Ireland

Abstract

Ice sheets have occupied the Atlantic continental margin of Europe as far south as the Celtic Sea, where the maximum extent of glaciation remains in question. The Celtic Sea contains no obvious glacial landforms, but is dominated by a system of shelf-crossing seafloor megaridges, up to 60 m high and 10 km wide, that extend seaward up to 300 km in water depths of 100-200 m. The last British-Irish Ice Sheet (BIIS) was thought to have reached a limit on the mid-shelf, based on glacial sediments sampled on and between megaridges in the Irish-UK sectors, but recent work in this area has shown that the BIIS extended at least 150 km farther, at minimum to the UK shelf edge at 48°20'N. Stratigraphic analysis of newly acquired core and seismic data has indicated the megaridges to be eroded sand bodies, which can be interpreted as a) glaciofluvial ridges modified by post-glacial megatides, or b) tidal banks truncated by wave energy. Here we examine megaridge morphology using a regional bathymetric grid and multibeam data across a 25x100 km area of the mid-shelf. At regional scale, the megaridges fan seaward to meet the shelf edge near-transversely along 600 km of its length, their axes rotating by 80° from W-E (Irish shelf) to almost N-S (French shelf). The fan-shaped network points to an apex in the north Celtic Sea, yet axial convergences are more common to seaward than landward. Individual megaridges consist of segments tens of kms long, of differing orientation, that form bathymetric highs. On the Irish-UK mid-shelf, multibeam imagery show that *en echelon* megaridge segments (up to 40 km long, 7 km wide, 55 m high) give way both axially and laterally to transverse 'ribs' (up to 10 km long, 10 m high). The ribs vary in form and spacing, distinct from asymmetric regularly-spaced sand waves within the multibeam data. Glacial sediments have been reported near seabed on and between both the megaridges and ribs, but subglacial lineations are not observed at seafloor. We hypothesise that the rectilinear network of megaridges and ribs are the eroded remnants of giant eskerine ridges flanked by glaciofluvial De Geer moraines, formed time-transgressively along an ice sheet margin during its retreat from the shelf edge. If correct, this interpretation would have broad implications for the dynamics of the last BIIS, and for the supply of meltwater and sediment across the shelf and slope to the North Atlantic at the LGM. Glaciofluvial vs tidal models for the formation of Celtic Sea bedforms invite testing through the targeted acquisition of core data, notably from areas of existing multibeam data in both the Irish-UK and French sectors.

Late Holocene increases in the rate of sea-level fall across the Antarctic Peninsula point to a weak Earth rheology

Alexander Simms¹, Pippa Whitehouse², Julie Zurbuchen¹, Lauren Simkins³, Grace Nield², Regina DeWitt⁴, Michael Bentley²

¹University of California Santa Barbara, Santa Barbara, USA, ²Durham University, Durham, United Kingdom,

³University of Virginia, Charlottesville, USA, ⁴East Carolina University, Greenville, USA

Abstract

Most Holocene relative sea-level reconstructions from across Antarctica are thought to reflect a steady, exponential fall in response to the decay of the last glacial maximum ice sheets. However, many of these reconstructions are obscured by large scatter in the sea-level index points and difficulties associated with dating geomorphic and sedimentary materials in Antarctica. We present new relative sea-level data from locations across the Antarctic Peninsula based on the dating of raised beaches. Our new data record episodic periods of increased rates of relative sea-level fall (isostatic uplift) as high as 5.3 mm/yr on both sides of the Antarctic Peninsula during the late Holocene. These periods of increased rates of relative sea-level fall support recent notions that the Earth beneath parts of Antarctica is much weaker than initially thought with upper mantle viscosities as low as 10^{18} Pa s, more than three orders of magnitude less than the Earth model (VM2) commonly used with ICE-5G. Furthermore, these periods of increased uplift are likely in response to late Holocene oscillations of the Antarctic Peninsula Ice Sheet and/or the ice caps of the surrounding islands. These relative sea-level histories also provide support for recent assertions that the retreat of the Antarctic Ice Sheet from the Last Glacial Maximum was not a steady decline but punctuated by both ice retreat and readvance.

P-4006

Deglaciation of Spitsbergenbanken, W-Barents Sea: improved reconstruction based on new acoustic data

Lilja Rún Bjarnadóttir, Frank W. Jakobsen
Geological Survey of Norway, Trondheim, Norway

Abstract

Spitsbergenbanken is a large bank (about 77000 km²) in W-Barents Sea. The bank is bordered by the northern Norwegian Sea to the west and by two large troughs; Storfjordrenna to the north and Bjørnøyrenna to the south and east. The bank consists of sedimentary bedrock and is locally influenced by fault zones/complexes. Although a large part of the bank is less than 50 m deep, the islands of Bjørnøya and Hopen are the only subaerially exposed parts of the bank. The glacial dynamics and retreat pattern of the Barents Sea Ice Sheet are fairly well known for the parts filling Storfjordrenna and Bjørnøyrenna as glacial landforms and stratigraphy in these troughs have been extensively documented in a number of studies. Spitsbergenbanken, has received comparatively little attention and despite many assumptions having been made on the general ice flow pattern and glacial dynamics of this bank, the general lack of field observations and empirical datasets from the area have so far made it hard to confirm or reject these ideas.

Increased acquisition of both crowd-sourced data such as Olex, as well as more high resolution multibeam data acquired by MAREANO from the area in the past years has added much to our understanding of the glacial history of Spitsbergenbanken. This includes new results from geomorphic mapping based on these bathymetry datasets and acoustic stratigraphy based on new sub-bottom profiler data from Spitsbergenbanken. Combined with findings from existing studies, these new results are used to reconstruct the main elements of the glacial history of Spitsbergenbanken, as well as comparing them with existing ice sheet modelling results from the area. Here we present the main conclusions of the new mapping and reconstruction, and their fit with modelling results, as well as a brief discussion on the most important controls on glacial dynamics and the wider importance of these new results.

P-4007

Late Holocene subtropical mangrove dynamics in response to the climate change

Marlon França^{1,2}, Allana Azevedo², Vanessa Pinheiro², Érika Rodrigues², Neuza Fontes², Marcelo Cohen², Luiz Pessenda³

¹Federal Institute of Pará, Belém, Brazil, ²Graduate Program of Geology and Geochemistry, Federal University of Pará, Belém, Brazil, ³University of São Paulo, Piracicaba, Brazil

Abstract

This work aims to study the impacts of climate change in the subtropical mangroves during the late Holocene on a southern Brazilian coastal plain and discuss the environmental conditions to the mangrove establishment near the austral limit of South America mangroves. Three sediment cores were collected to study palynological groups, sedimentary features, and geochemical data, synchronized by radiocarbon ages. The main result of this research was the mangrove genus succession, divided in three palynological zones composing two facies association: 1) herbaceous tidal flat and 2) mangrove tidal flat. The first zone between at least ~1815 and ~1629 cal yr BP was marked by the mangrove absence with marine particulate organic carbon, C3 terrestrial plants and macrophytes influence with $\delta^{13}\text{C}$ values between -26.7 and -20‰, $\delta^{15}\text{N}$ values $\bar{x} = 3.5$ and C:N around 21.8, while the second zone between ~1629 and ~853 cal yr BP is marked by the mangrove establishment represented only by *Laguncularia* pollen under influence of estuarine organic matter ($\delta^{13}\text{C} \bar{x} = -26.5$; $\delta^{15}\text{N} \bar{x} = 3.2\text{‰}$ and C:N around 16.4). The third zone reveals an increase of *Laguncularia* and presence of *Avicennia* pollen since ~853 cal yr BP. Near the surface (< 10 cm) occurs *Rhizophora* pollen, indicating the establishment of this genus during the last decades, under the modern environmental condition ($\delta^{13}\text{C} \bar{x} = -27.02$; $\delta^{15}\text{N} \bar{x} = 3.12\text{‰}$ and C:N around 17.42). This mangrove vertical succession may be associated with the low-temperature tolerance of mangrove, where the sequence *Rhizophora*, *Avicennia*, and *Laguncularia* mangrove occurs from northern to the southern limit of Santa Catarina coast, respectively, reflecting the temperature gradient. Then, probably, the establishment of the mangrove assemblage identified along the studied pollen profiles was influenced by a temperature increase of air and water during the late Holocene and, mainly last decades.

Basement Fault Propagation Through Quaternary Sediments Along The Indian East Coast: A Remote Sensing And GPR Based Study

Pitambar Pati¹, Chinmay Dash¹, Manok K. Jaishwal²

¹DEPARTMENT OF EARTH SCIENCES, INDIAN INSTITUTE OF TECHNOLOGY, ROORKEE, India, ²DEPARTMENT OF EARTH SCIENCES, INDIAN INSTITUTE OF SCIENCE EDUCATION AND RESEARCH , KOLKATA, India

Abstract

Two surface faults (Jajpur fault and Gop fault) have been identified along the coastal plains of Odisha in the Indian east coast; using tectono-geomorphological signatures and Ground Penetrating Radar (GPR). As direct expression of fault scarps is not available due to geomorphic and anthropogenic modifications, negligible relief and sedimentation; these faults are marked as wide zones showing various fluvial anomalies. Tectonic geomorphological parameters such as sinuosity index of channels, longitudinal river profiles, channel offset, drainage convergence, new streams generation etc.; validate the surface position and continuation of the Jajpur fault and the Gop fault about 48 km and 21 km, respectively. Though valley width to height ratio is an important parameter for fault identification across the stream path, but it is not implemented in plain area for alluvial rivers; as in the present study. Because in alluvial plains; valley width is more as compared to its depth due to loose sediments. The Jajpur fault offsets the Bramhani, Kharsuan and Baitarani rivers about 4 km, 2.7 km and 3 km, respectively. Anomalous sinuosity of Reb, Kapali and Salandi rivers, and linear arrangement of stream converging points marks this fault zone. The Gop fault is marked by offset of the Kushabhadra, Kadua and Prachi rivers about 3.6, 0.5 and 1.2 km, respectively. Abandonment of the paleo-course of the Kushabhadra River is marked by this fault. Optical stimulated luminescence (OSL) chronology of these paleochannels suggests 6 Ka of channel abandonment, which in turn suggests the last major activity along this fault. Both of these faults could be well detected from the longitudinal river profiles. GPR study across these fault zones shows a series of faults with more than a meter vertical displacement in subsurface strata. Geographical position and alignment of these coast-parallel faults fairly coincide with the underlying basement faults. Therefore, these surface faults are believed to have been developed due to surface ward propagation of the basement faults or nucleation of new faults at surface level by reactivation of those basement faults. These faults are responsible for recent infrastructure damage, coastal subsidence and loss of land to sea in the area.

Palaeoenvironmental Evolution at Lake Belevi, Surroundings of ancient Ephesus, Turkey

Hannes Laermanns¹, Anna Pint¹, Andreas Heiss², Maria Knipping³, Helmut Schwaiger², Friederike Stock⁴, Sabine Wulf⁵, Sabine Ladstätter², Helmut Brückner¹

¹University of Cologne, Cologne, Germany, ²Austrian Archaeological Institute, Austrian Academy of Sciences, Vienna, Austria, ³University of Hohenheim, Hohenheim, Germany, ⁴Federal Office for Hydrology, Koblenz, Germany, ⁵Ruprecht-Karls-Universität Heidelberg, Heidelberg, Germany

Abstract

Since the deceleration of the Holocene sea-level rise, delta progradation and siltation of marine embayments are accounted as some of the most significant landscape changes in coastal areas. This holds especially true for many sites in western Turkey where within the linear graben structures dramatic progradations of the coastline have occurred. In case of the Küçük Menderes, the direct environs of the ancient Ephesus have been subject to several studies while the areas further land inwards have been neglected so far. This study deals with the lake of Belevi that is located in the Küçük Menderes graben ca. 15 km east of ancient Ephesus and forms an excellent geo-bio-archive. On the basis of two sediment cores with a max. length of 15.60 m geochemical, sedimentological, microfaunal, palynological and tephrochronological analyses were performed in order to decipher the palaeoenvironmental change. The pollen and microfaunal assemblages reveal the development of a freshwater lake at about 8.3-8.1 ka. Due to the rising sea level and the transgression into the graben valley the lake was connected to the sea from late 6th millennium BC. The delta progradation of the Küçük Menderes provoked a westward shift of the shoreline which resulted in the development of a lagoon at the site of Belevi and a gradual shift from marine-brackish to lagoonal conditions. This is further reflected by peat growth with intercalated greyish lake layers from mid-5th millennium BC on. For the first time, the tephra of the Santorini eruption has been detected in the environs of Ephesus. An in-situ ash layer of 3 cm is overlain by several decimetres of allochthonous material. The palynological investigations clearly show that the vegetation was covered by an ash layer and low-growing plants were strongly affected. In the further course the occurrence of the *cerealia*-type pollen may hint agricultural activity within the closer surroundings at least since the 7th century BC. The human influence is further reflected in the speed of the delta progradation, respectively in the increased sedimentation rates since that time, that are mainly governed by the riverine sediment load, which, in turn, are very much dependent on the human impact on the vegetation cover of the drainage basins.

High-resolution geochemical record of three marshes from the San Francisco Bay area

Elizabeth Fard¹, Lauren Brown¹, Glen MacDonald^{1,2}

¹UCLA Department of Geography, Los Angeles, USA, ²UCLA Institute of the Environment and Sustainability, Los Angeles, USA

Abstract

The San Francisco Bay has the largest concentration of salt marshes in the state of California, representing a diversity of marsh habit. Protecting these environments is critical, as salt marshes provide refuge to endangered species, absorb carbon from the atmosphere, and preserve detailed evidence of past climatic, hydrologic, geomorphic, and ecologic conditions. In the last 170 years, 95% of the historic tidal wetlands in the bay have been destroyed due to diking and filling. Additionally, many of the remaining marshes have been impacted by pollutants such as heavy metals over this period, making ecological trajectories and resilience to disturbance uncertain. In this study, we collected data from three different marshes in the Bay Area to document the geochemical changes including heavy metal concentrations, and shifts in productivity as a response to climatic and anthropogenic changes since the mid-Holocene. Preliminary results confirm anthropogenic impacts on the geochemistry of marshes in the San Francisco Bay over the last 150-200 years following European arrival. However, based on statistical time-series analysis of long-core elemental concentrations, results show that modern conditions are not so far removed compared to prehistoric conditions, as often suggested by century-scale analyses. Modern levels of Pb and Mn are unprecedented throughout the cores, likely due to increased erosion due to European land clearance, logging, and increased production and emissions of Pb (lead). Our results show the effects of anthropogenic changes on these ancient and ecologically important marshes in the San Francisco Bay area that can help better inform restoration ecologists and policy makers, specifically with regards to heavy-metal pollutants.

Holocene coastal dune evolution in Western France: reconstruction from archaeological data

Aneta Gorczynska¹, Pierre Stéphan^{2,3}, Yvan Pailler^{4,5,6}, Bernard Le Gall¹

¹Laboratoire Géosciences Océan, Université de Bretagne Occidentale, BREST, France, ²CNRS, Brest, France,

³Université de Bretagne Occidentale, Brest, France, ⁴Institut National de Recherches Archéologiques Préventives, Rennes, France, ⁵Laboratoire Trajectoires, CNRS, Paris, France, ⁶Université de Paris 1, Paris, France

Abstract

The long-term evolution of coastal dune barriers is controlled by variations in sediment supply, relative sea-level (RSL), wind energy, vegetation cover, anthropogenic forcing. Based on stratigraphical, geomorphological and chronological investigation of sand drift, numerous works highlighted the link between episodic sand invasion and changes in climate conditions (enhanced storminess) along the Atlantic coasts of Europe. While well-constrained chronologies of Holocene dune accretion were reconstructed in Portugal, Spain and Ireland, the data available for the French Atlantic coast are limited to the Aquitaine dune complex (SW France). This lack of data is mainly due to the absence of well-developed palaeosoils interbedded into the aeolian sand deposits, especially in Brittany where only thin humic layers are preserved into the coastal dune sediment records.

In this paper, we propose an alternative approach based on the use of archaeological information available in the coastal dunes of Brittany. Located in the most western part of the Atlantic coast of France, the Brittany peninsula is characterized by a limited sand supply from rivers and from soft cliff retreat. Consequently, the offshore sedimentary cover is thin and the shallow waters are dominated by rock outcrops. The coastal sediment accumulations usually form single-ridge sandy barriers, topped with a thin dune, isolating brackish lagoons, salt-marshes or small-size infilled valleys. However, some coastal dune complexes extend more than 2 km inland, consisting of foredunes and artificially stabilized dune fields where a high density of well-conserved archaeological sites were excavated from the end of the 19th century. These widely available archaeological data were used as chronological indicators to reconstruct the coastal dunes evolution during the last 7000 years at a regional scale (figure).

Figure. Examples of archaeological sites discovered in dune contexts. A. Excavations of the necropolis of Saint-Urnel (Plomeur, Finistère) in 1923-1924; B. and C. Megaliths discovered in the dune field of the Bay of Audierne (Kerharo, Plomeur, Finistère) 1978-1978.

From a re-evaluation of the archaeological documentation, 236 archaeological sites distributed along the Brittany coastline were selected to provide accurate information in terms of dune stratigraphy and chronology. Three main phases of aeolian activity were identified at a regional scale: Phase 1 dated from 1600 to 500 cal. BC, Phase 2 dated

from 800 to 1400 cal. AD, Phase 3 dated from 1650 to 1850 cal. AD. A synchronicity is found between the North, West and South coasts of the Brittany peninsula and suggests that periods of sand dune invasion were triggered by a series of regional forcings, involving a decreasing RSL rise, significant changes in the coastal sediment budget and palaeogeography.

Morphological diversity of *Quercus* fossil pollen indicates evergreen forest in the northern South China Sea during the last glacial maximum

Lu Dai¹, Qinghe Hao¹, Limi Mao², Jibin Xue³

¹Ningbo University, Ningbo, China, ²Nanjing Institute of Geology and Palaeontology, Nanjing, China, ³South China Normal University, Guangzhou, China

Abstract

We aimed to obtain high resolution vegetation data and climate information about the LGM in the inland of the northern SCS based on key pollen types. Dominant *Quercus* fossil pollen grains in the terrestrial (core LX02) and marine sediments (core MD05-2906) of the northern SCS have been identified at the infrageneric level by using scanning electron microscopy. Based on tectum ornamentation, we recognized five sculpture types of *Quercus* pollen, namely, rodlike, rodlike masked, rodlike vertical, verrucate and micro-verrucate. According to comparison with pollen sculptures of modern *Quercus* species collected by us, such a high diversity of *Quercus* fossil pollen types indicated that broadleaved forests were widely distributed in the inland along the northern SCS and included the sect. *Ilex* and sect. *Cyclobalanopsis* in subg. *Cerris* and sect. *Quercus* of subg. *Quercus*, of which evergreen sect. *Cyclobalanopsis* populations were highly dominant. Low abundance of deciduous *Quercus* pollen probably derived from temperate-subtropical forests, while abundant evergreen pollen types of *Quercus* and sect. *Cyclobalanopsis*, as well as other pollen of broadleaved taxa in the pollen assemblages, strongly suggest that the inland has been covered by dense subtropical forests. Consequently, the warm and humid subtropical climate prevailed during the LGM in the inland along the northern SCS. Our results shed new light on regional climatic conditions during the LGM in eastern Asia based on high diversity of *Quercus* fossil pollen in terrestrial and marine deposits from northern SCS.

A multiproxy approach in the study of the Holocene evolution of a densely inhabited coastal area: the Apuo-Versilian plain.

Monica Bini, Giovanni Zanchetta, Roberto Giannecchini, Caterina Morigi, Luca Lorenzini, Fabio Fabiani
Pisa University, Pisa, Italy

Abstract

The Apuo-Versilian plain, a key area for the study of Quaternary (Blanc, 1936), is nowadays densely inhabited, and the geomorphological features related to fluvial and marine processes that contributed to its formation have been destroyed by human activities.

Our approach based on the analyses of historical cartography, geomorphological, remote sensing, stratigraphic, and archaeological data together with the study of new cores, have allowed us to reconstruct the main steps of the evolution of the Apuo-Versilian plain. This study was complemented by analyses of speleothems data from nearby caves for reconstruction of the general frame of the hydrological and climatic changes occurred during the Holocene. Our study suggests that over the last 7000 years the plain has undergone an important progradation. However, this general progradation has not been continuous, showing phases of stability and even phases of retrogradation.

A new core, performed near the Porta Lake in the central part of the plain, intensively radiocarbon-dated, shows an increase in the alluvial plain aggradation at ca. 6600 cal yr BP and ca. 2700 cal yr BP.

The first event (6600 yrs BP) is likely to be related to the general trend documented in several Mediterranean coastal plains after the deceleration of sea-level rise and increase in fluvial sediment supply (Anthony et al. 2014). The second event (2700 yrs BP) might be related to a paleoclimatic deterioration documented between 2800 yrs BP and 2600 yrs BP in a speleothem in the Apuan Alps (Isola et al. 2018).

Since ca. 1200 AD the Apuo-Versilia plain has experienced a progressive shift seaward of the coastline. The settlements and the coastal towers have followed this shift, adapting to the environmental changes. An increase in the rate of progradation up to 2.5 m/yr is documented between 1600 AD and 1850 AD. This change could be related to the effects of the climate condition during the Little Ice Age, which seems to correspond locally to an increase in flood events documented after 1500 AD (Giannecchini & D'Amato, 2012). Despite the frequent occurrence of flooding events also in present times, a general phase of coastal erosion has replaced the long phase of progradation.

The environs of Elaia's ancient harbour – a reconstruction based on microfaunal evidence

Anna Pint¹, Martin Seeliger², Peter Frenzel³, Stefan Feuser⁴, Felix Pirson⁵, Helmut Brückner⁶

¹Institute of Geography, University of Cologne, Cologne, Germany, ²Faculty of Geosciences, Goethe University Frankfurt, Frankfurt, Germany, ³Institute of Earth Sciences, Friedrich Schiller University Jena, Jena, Germany,

⁴Institute of Classical Studies, Kiel University, Kiel, Germany, ⁵German Archaeological Institute (DAI) Istanbul, Istanbul, Turkey, ⁶Institute of Geography, University of Cologne, Cologne, Germany

Abstract

During Hellenistic and Roman times Elaia, the maritime satellite city of ancient Pergamum, was an important place of trading and traffic in the eastern Mediterranean. Intense mercantile and military activities are documented by literary sources and archaeological evidence. Our study aims at reconstructing the history of Elaia's harbour within the context of migrating shorelines. For that purpose, a sediment core was drilled in the centre of the basin of the ancient closed harbour, one of Elaia's three harbours. As indicated by a diverse marine microfauna (ostracods, foraminifers), the site's evolution starts after a short transgression phase in fully-marine conditions and with many phytal taxa, followed by a lagoonal soft bottom assemblage mirroring the construction of the breakwaters in early Hellenistic times. Ongoing siltation caused the abandonment of the harbour in late Roman times.

While foraminifers are more abundant during the marine period and can be used together with ostracods, the latter are more valuable proxies recording the siltation of ancient coastal harbours. Furthermore, our study demonstrates that Elaia holds a unique position as a harbour city during ancient times in the eastern Aegean region, because it was not completely influenced by the high sediment load associated with river deltas. Consequently, no dredging of the harbour basins is documented – neither by sedimentological means nor by literary accounts or archaeological evidence. In addition, due to the short settlement period of Elaia (maximum 1000 years) – bracketed by natural conditions – the closed harbour basin constitutes a valuable geo-bio-archive.

Recognizing sedimentary environments on Amazon by mult-sensors data

Suzan Rodrigues¹, Simmon Souza²

¹Universidade de Brasília, Brasília, Brazil, ²Unicamp, Campinas, Brazil

Abstract

The use of Synthetic Aperture Radar (SAR) images operating in the microwave range, as well as optical images that operate on Visible-Near Infrared (VNIR) to recognize and map the different fluvial environments of the Lower Amazon has facilitated the recognition of difficult areas especially in cloud-covered regions throughout the year. The area of interest (central sector of the Lower Amazon River) was chosen because it is the closest region of the city of Santarém, whose validation and verification of the technique, in order to increase the accuracy and quality of control points, more accessible. The recognition and mapping of the sedimentary features was based on automatic classifications and visual interpretation of the optical images, SAR and the SPC-SAR image, product of the synergism between the optical multi-sensors and SAR. The results allowed the identification of guiding classes: tree vegetation, aquatic grass, water, sand, mud, exposed soil and urban area, resulting in the association of environments: lakes, river dikes, fluvial channels, river deltas, riverbanks, fluvial ", river beach and river. The indexes generated for the general and kappa accuracy of the guide classes were: 89% and 0.90 for the optical sensor image; 88% and 0.67 for the SAR image; and 84% and 0.77 for the SPC-SAR product. These data corroborate works such as de Souza & Rodrigues (2017) in which they obtained good results with the technique in an island called "Ilha Grande do Tapará", in the Amazon river, whose optical and fused product offered a better product in relation to the SAR image. In this way, it is concluded that the use of remote sensor images provides important results for the recognition of sedimentary and geomorphological environments in a short time, making these products material for environmental management programs, as it will facilitate the decision making of difficult to access areas.

Stratigraphic hiatus of coastal deposits from 6-3 ka BP along the macrotidal west coast of Korea

Tae Soo Chang¹, Jin Cheul Kim², Chang Soo Son³, Seung Soo Chun³

¹Korea Maritime and Ocean University, Busan, Korea, Republic of, ²Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of, ³Chonnam National University, Gwangju, Korea, Republic of

Abstract

Extensive tidal flats is a typical coastal landform found both in embayments and along the open macrotidal west coast of Korea (eastern Yellow Sea). Typically, beach-dune systems along the shore overlie the tidal flats from places to places. An about 20-50 km-wide and approximately 50 m-thick coastal deposit thus extends from the shore across the broad continental shelf, the region receiving abundant sediment supply from large rivers. Here, a variety of transgressive sedimentary facies formed in the course of the Holocene in association with the postglacial rise in sea level. An interesting feature is the general lack of sedimentary deposits in the period from roughly 6–3 ka BP, not only on the shelf itself, but also along the tidal shore. Geochemical and sedimentary facies analyses of numerous long cores, supplemented by ¹⁴C-AMS and OSL age dates, reveal that, stratigraphically, the beach-dune deposits along the shore are underlain by muddy tidal flat deposits, which results in a clear upward coarsening grain-size trend and thus intimates transgressive deposition associated with sea-level rise over the past 7–8 ka. However, within the sequence, a time gap of about 3 ka has been documented to exist between about 6–7 ka BP, marking the age of the uppermost underlying tidal flat deposits, and about 3 ka BP, marking the age of the basal beach-dune sands. Non-deposition commencing around 6-7 ka BP may have been caused either by a sudden decrease in sediment supply or by local sea-level fall. After about 3 ka BP, high sediment supply may once again have resumed, amongst others forming the sandy beach deposits along the coast. This means that the regime shift occurs from tide-domination to wave-domination in that period of time. Further study requires to validate this fact particularly along the Chinese part of the Yellow Sea.

Abstract

The GNL Quintero 1 (GNLQ1) site is a paleontological deposit characterized by a wide dispersion of faunal assemblages of terrestrial origin. This site of Late Pleistocene age (21-27,000 cal BP) is currently submerged at a depth of 13 m and 650 m offshore from the present-day coastline of Quintero bay (~32°S), coast of central Chile. One of the most outstanding features of this site is the high concentration of extinct megafauna bone remains, characterized by a large number of individuals of diverse taxa in high resolution and high integrity contexts. GNLQ1 site also present no conclusive evidence of early human occupations, represented by two bone cut-marks. However, further research is required. For all these reasons, the GNLQ1 site represents the only documented Late Pleistocene drowned terrestrial site along the Pacific Coast of South America, offering primary information about submerged paleolandscapes. Considering the geological context of the study area, there are numerous natural variables that have influenced the formation and preservation of the GNLQ1 site, including eustatic variations, tectonic activity, climate changes, among others. In this work, we show the integration of results from geological analyses (geomorphology, sedimentology, stratigraphy, mineralogy, geochemistry and geochronology), together with geophysical studies through the application of remote sensing (side scan sonar, subbottom profiler), and archaeological methods (survey, excavations, documentation, photogrammetry and 3D modeling, and bone recovery) and taxonomic analyses, carried out on the surface as well as underwater. These results have allowed us to assess the variables that have conditioned the formation of this site, its depositional environment, and the physical-chemical processes that have affected it, helping to understand and contextualize this remarkable finding, contributing to establish the basis to systematize future searches for early - potentially submerged - sites in South America.

Getting to the core of climate change: using marine sediment cores to reconstruct past climatic conditions in the high Arctic

Amy Gray

Loughborough University, Loughborough, United Kingdom, UNIS, Longyearbyen, Svalbard and Jan Mayen

Abstract

Climate change is arguably one of humanity's greatest threats, with human activity widely recognised to be driving the current discrepancies between anticipated change and current planetary warming. As such, one of science's greatest challenges is trying to determine how climate change is going to impact upon Earth's biome and the ecological systems upon which we depend, with a view to ensuring that humanity doesn't irreparably damage our planet's biological functionality.

When looking at patterns of climate change globally, over the last century, the High Arctic has experienced rapid warming at a higher rate than the global average. This makes the Arctic a prime location to study in order to better understand the immediate environmental impacts of climate change. However, unlike more populated parts of the world, the Arctic is relatively sparsely monitored, and as such, documenting environmental changes and their impacts remains challenging. Consequently, more effort needs to be made to study this remote and challenging environment in order to refine our understanding of the science behind climate change and its planetary and humanitarian consequences.

This project aims to overcome the challenges associated with the lack of high-resolution, long-term environmental monitoring in the Arctic by developing a state-of-the-art multi-proxy approach to analysing ocean sediment cores. In particular, this project will focus on detailing records of sedimentological, chemical and ecological changes in marine sediment cores from the waters around Svalbard to decipher past and present environmental changes in response to climate fluctuations.

Suspended ocean sediments sequentially accumulate on the ocean floor to form chronological layers that encapsulate details of past environments. Once dated, environmental conditions can be deduced by analysing various properties of the core's sediments. In the case of this project, this will be achieved using advanced multivariate statistical approaches (e.g. structural equation modelling, generalised additive models), which will focus on factors such as grain consistency, chemical composition, presence/diversity of fossilised lifeforms (Diatoms) and the concentrations of pollutants.

By understanding past climate-driven environmental changes, it is then possible to develop more accurate impact-assessment models to anticipate future environmental responses to climate change. This improved understanding will help influence policies on global carbon reduction targets and encourage sustainability and innovation in carbon neutral industries.

Sediment core collection has already been undertaken at previously unstudied locations to the north and north-west of Svalbard (Figure 1). Analysis is underway.

Figure 1

This poster will detail the advantages and pitfalls of using sediment cores to infer past climate-induced environmental changes in data-poor areas, such as the Arctic, and the likelihood that this type of methodology can be reliably used to expand and improve the models that decision-makers use to gauge policy responses to the current climate crisis.

Dancing to the water table's beat! Multi-millennial dynamics of hidro-hygrophilous vegetation in Doñana (SW Iberia), the largest European wetland

José Antonio López-Sáez¹, Sebastián Pérez-Díaz¹, Antonio Rodríguez-Ramírez², Juan J.R. Villarías-Robles¹, Reyes Luélmo-Lautenschlaeger^{1,3}, José S. Carrión⁴

¹CCHS-CSIC, Madrid, Spain, ²Universidad de Huelva, Huelva, Spain, ³Universidad Autónoma de Madrid, Madrid, Spain, ⁴Universidad de Murcia, Murcia, Spain

Abstract

The Doñana wetlands, in the estuary of the Guadalquivir River, constitutes a vast seasonal freshwater area of enormous international ecological importance including a long dune ecosystem, salt and freshwater marshes, temporary ponds, peat bogs and lagoons, probably the largest wetland and one of the most emblematic protected areas in Europe for its rich biotic diversity. They were declared National Park in 1969, Biosphere Reserve in 1981, Important Wetland site under the Ramsar Convention in 1982 and UNESCO Natural World Heritage site in 1984, and they are also integrated into the Natura 2000 network. Furthermore, Doñana marshes constitute one of the largest and best preserved Mediterranean marsh areas in Western Europe, being considered today a hotspot of biodiversity.

As a result of man-made habitat changes, a complex mosaic of diverse aquatic habitat types of different size and water depth are found: from natural to artificial wetlands, from fresh to hypersaline and from ephemeral to permanent water. Although their aquatic ecosystems are well known in terms of their ecology and biodiversity, the most important knowledge gap is the lack of information on historical inundation patterns, and their relationships with natural climatic variability and/or anthropogenic disturbances. Understanding how marshland ecosystem has been influenced by both climate variability and human transformations for millennia, is crucial to anticipate short and long-term trends of annual flood patterns and hydroperiod, and to better understand the response of hygrophilous and hydrophilic vegetation to flood cycles of future climate scenarios. Despite some studies on the vegetation history of the Doñana wetlands, there is a shortage of detailed studies on the temporal and multi-millennial dynamics of aquatic and hygrophilous vegetation. In fact, none of them relates such dynamics to climate variability, human impact and the geomorphological changes that occurred in Doñana during the mid-late Holocene. Understanding the behavior of this complex marsh environment would require high-resolution palaeoenvironmental long-time series. Here, we present the first detailed high-resolution palynological analysis of the Doñana marshland. This is the first attempt to understand the complex relationships established between aquatic and hygrophilous vegetation, climatic variability and human activities in the Doñana marshes during the last five thousand years (mid to late-Holocene).

P-4020

Environmental change in a backbarrier wetland over the last millennium

Elizabeth Gardner^{1,2}, Helene Burningham¹

¹UCL, London, United Kingdom, ²Arup, London, United Kingdom

Abstract

Lowland, coastal wetlands often comprise a complex array of habitats that reflect the interface between marine and terrestrial forcing. They are often highly responsive to changes in climate and human impacts that typically alter sediment dynamics, water quality and hydrology, and the sedimentary archive they preserve is key to exploring changes in forcing and system response. Sheskinmore Lough, located on the west coast of Donegal, northwest Ireland comprises a shallow (<1.5m) freshwater sedimentary lake surrounded by a diverse array of coastal and freshwater wetland habitats within a backbarrier context. In particular the environmental history of the site and its complicated hydrogeology has resulted in a complex ecosystem structure that supports 23 nationally and internationally significant and protected (SAC and SPA) habitats, including lowland oligotrophic lake, orchid-rich calcareous grassland, machair, mire, and fen.

Stratigraphic evidence of a shift from estuarine to freshwater conditions constrains lake formation to c. 1000 years ago when it is thought that dune dynamics blocked a secondary valley of the neighbouring Loughros More estuary. Shallow and deep cores across the lake and wider wetland reveal a sedimentary drape of calcareous dune sand over acidic granitic bedrock, within which wetland peats have accumulated. A multiproxy evaluation of stratigraphies at the centre of the lake reveals distinct climatic and geomorphological shifts that define the three key phases in the recent (multi-century scale) environmental and ecohydrological history of the system. Supported by radiocarbon dating, evidence of shifts between drier and wetter conditions are linked to aeolian forcing (supply of wind blown sand) and transitions between open-water, vs. riverine and floodplain conditions are determined through sediment analyses, macrofossil and diatom analysis. Long-term historical variability in ecosystem structure and function is clearly driven by climate variability over the century time-scale, with the added driver of human intervention at the recent decadal scale. Contemporary management of the site is focused on maintaining a suite of habitats to support key species, but significant questions remain regarding the sustainability of this, and in particular how far removed the site is from its' historical envelope of variability. Here, we explore environmental change and forcing at the transition between late Holocene and the Anthropocene in the context of the contemporary conservation management.

P-4021

Grain-size and sedimentary records of the XYZ Core in the downstream of the Cao'e River, northern Zhejiang province, China

ZHU Lidong, ZHANG Xiao, HUANG Ying, YE Wei, LI Fengquan, CHEN Qu, WANG Tianyang
College of Geography and Environmental Sciences, Zhejiang Normal University, Jinhua, China

Abstract

Based on the analysis of grain-size constitution and distribution curves of the XYZ core in the downstream of the Cao'e River—the central section of the Ningshao plain, we arrived at the following conclusions: (1) According to the grain-size constitution, the sediments of the XYZ Core can be divided into four lithologies: silty sand, sandy silt, silt, and clayey silt. They distribute along the core alternately. The core is divided into 9 layers and they compose multiple grain-size combinations. The 9 layers are marked as layer 1 to layer 9 from the bottom to the top. Among them, layer 1 and layer 4 are silty sand, and the percentage of clay is 10%~15%, which is poorly sorted and the dynamics is complicated. Layer 3 and layer 5 are sandy silt, the percentage of silt is no more than 70%, and clay is more than 20%. The percentage of clay is low. Layer 2, layer 7, and layer 9 are silt, the percentage of silt is more than 70%, and clay and sand are less than 20%. Layer 6 and layer 8 are clayey silt, the percentage of silt is more than 70%, and clay is more than 20%. The percentage of sand is very low. (2) According to the C-M graph of the max and the mean values and the analysis of its variation, there were four types of deposits from the bottom to the top: fluvial, tidal flat, shallow marine, and lakes and marshes. For layer 1 and layer 2, the hydrology was high energy and unstable, which indicates a fluvial environment; for layer 3 to layer 7, the max hydrology weakened, but the mean hydrology was strong and the range was still wide, and the hydrology was similar to the SYTT tidal flat samples. It referred to a tidal flat environment; for layer 8 and layer 9, the hydrology was weak and stable, which indicates still water environment. Based on the grain-size and biology information, it can be concluded that the under part of layer 8 belonged to shallow marine environment, but the upper part and layer 9 belonged to lakes and marshes environment. (3) Vertical variation of grain-size indicates that clay increased from the bottom to the top with fluctuation, while sand declined. The average grain diameter is decreasing and the sorting coefficient is higher. The sediments change from the bottom to the top reveals that the XYZ Core and its adjacent area experienced sea level rise, and then water level decreased during 9690~5131 cal.a BP. The results of the study are helpful for identifying the paleoenvironmental evolution characteristics of the Qiantang River Basin.

Abstract

The Tagus estuary is one of the larger estuaries of Europe (area of c.325km²). Lisbon is located in the northern margin of the estuary and despite the long diachrony of its occupation since the Palaeolithic, the city was founded during the Iron Age and grown continuously since then. The riverine front, containing archaeological evidences of occupation since the Iron Age, and clearly modified during the Roman Period, was successively enlarged at the end of the Middle Age by the construction of landfills, conquering area to the river that was used since then for the development of maritime-related activities and others.

In 2014 a 7.5m-long core was collected from sediment below the landfill (-1m MSL) during the re-arrangement works of Ribeira das Naus (a Lisbon downtown riverine street built-up on a landfill constructed in the 1940's) in an area used as a dock - Doca da Caldeirinha - between the 18th and the 20th centuries. According to bibliography, the area was strongly affected by the 1755 earthquake and related tsunamis.

Several environmental proxies, combined with ¹⁴C dating, were analyzed at vertical high resolution. The sediment is essentially composed by mud (>90% of fine particles) with ca. 9% of organic matter and ca. 4% of CaCO₃. δ¹³C values are around -25‰, reflecting estuarine conditions. Sediments have accumulated between 2000 cal BP and 1362 cal BP, evidencing high sedimentation rates (SR) in this area during the Roman Period. SR were extrapolated using Clam 2.2 software and values of 0.9 cm yr⁻¹ (-8.5m to -5.7m MSL; 2000 cal BP to 1600 cal BP) and 1.9-2cm yr⁻¹ (-5.7m to -1m MSL; 1600 cal BP to 1362 cal BP) were determined. The high SR can result from both natural and anthropic causes; however, changes on the sedimentary pattern of the Tagus estuary over the last 2000 years are mainly due to human impact. The pollen record preserved in the core attests the existence of open landscape vegetation between 2000 cal BP and 1362 cal BP with the occurrence of heath and widespread of anthropogenic taxa. The inexistence of sediments younger than 1300 cal BP above -1m MSL could be related with anthropogenic activities (e.g. dredging of the area for maintenance of the maritime activities) or due to natural causes (e.g. lack of accommodation space in this low intertidal area, erosion by extreme events).

This work was done under the scope of the project Lisbon Stories and supported by Instituto Dom Luiz - IDL (UID/GEO/50019/2019). The authors also acknowledge the availability of Ana Filipa Fernandes for laboratory work.

Past environmental changes during the mid-Holocene sea-level rise (7-5.5 Ka) at the NE coastal plain of Buenos Aires, Argentina.

Mariel Samanta Luengo^{1,2}, Isabel Vilanova^{3,4}, Enrique Fucks¹

¹CEIDE-UNLP, La Plata, Argentina, ²CONICET, La Plata, Argentina, ³CONICET, Buenos Aires, Argentina, ⁴Museo Argentino de Ciencias Naturales BR, Buenos Aires, Argentina

Abstract

Coastal plains contain important archives of the environmental changes, in particular, salt marsh sediments has been an important tool for the understanding of sea level fluctuations during the Holocene. The NE coastal plains located adjacent to Río de la Plata estuary, specifically from Bahía Samborombón area, developed over several sea-level transgressive periods during the Quaternary. The sedimentary sequences along this plain have a stratigraphic continuity and abundant fossil record characterizing different depositional environments. In this regard, these sedimentary sequences are considered as key archives for reconstructing the geomorphological history as well as past environmental conditions related to the Holocene sea-level changes. This study integrates geomorphological and paleontological (pollen, non-pollen palynomorphs, shells) proxy data from the central zone of Bahía Samborombón (~35.6°S), to reconstruct the salt marsh vegetation history and environmental changes at millennial to centennial time scale, and to develop a geomorphological evolution model during the mid-Holocene sea-level transgressive phase corresponding to MIS 1. The dominance of Chenopodiaceae and Poaceae suggest that between ~7000-6670 cal yr BP halophytic salt marsh vegetation predominates over an extensive tidal flat environment under significant marine influence. It is consistent with geomorphological evidences like relict tidal channels. Pollen assemblages registered during this period present similarity with the middle-high salt marsh zone developed in the current coastal strip of Bahía Samborombón. This environment developed at ~10 km from the present shoreline. During this period relative sea-level rose, reaching ~+3 meters at 6800 cal yr BP. Between 6670-6535 cal yr BP the replacement of a middle-high salt marsh vegetation by another of low salt marsh zone occurred as a result of continuous sea level rise. The gradual increase of dinocysts *Operculodinium* spp. and *Spiniferites* spp. indicates the greatest tidal influence in response to sea-level rise that continues in this period. Between 6535-6453 cal yr BP continues the predominance of marsh vegetation under significant and increasing marine influence. This halophyte vegetation coexists with freshwater communities. After ~6450 cal yr BP, the palynological record is limited to dinocysts and scarce pollen content. However, the record of autochthonous mollusk assemblages of *Tagelus plebeius* with articulated valves and in life position could be indicating environmental stabilization. This is coherent with the maximum transgressive of the sea-level registered for the zone, which is followed by a period of stability of the relative sea-level at +4 m during ~6000-5500 cal yr BP. After 5500 cal yr BP the formation of sand bars and beach ridges towards the east (seaward) occurs, isolating the environments that developed behind, and protected from the action of the marine tidal influence. Eolian and pedogenetic processes took place on the ancient tidal plain at ~10 km from the current coast.

Abstract

Resilience has become an important theoretical context for interpreting the sustainability of socio-ecological systems because of its applicability to socioeconomic and environmental systems under changing conditions, regardless if changes are slow and less perceptible. Estuarine and coastal ecosystems around the world are constantly changing in response to combined effects of climate drivers and human activities, and many of them may be approaching critical thresholds threatening their healthy functioning and services they provide. However, shifts from one ecological stable state to another can last for long periods, making long-term studies necessary to understand the real nature of these transitions.

Estuaries contain sediments that preserve the signature of multiple processes acting upon the coastal system. These records can therefore provide valuable palaeoecological data covering decadal to millennial time-scales and overcome the lack of long-term monitoring data required to investigate these processes. We have collected sediment cores from shallow, near-coast sites in the Sado estuary that provides a natural archive of environmental change since the early Holocene. The Sado Estuary is the second largest estuary in Portugal, with an area of approximately 24,000 ha. It is a mesotidal system, well mixed and generally well oxygenated, with a salinity variation depending on the annual precipitation and river flow. Most of the estuary is classified as a natural reserve but it also plays an important role in the local and national economy. Tidal marsh habitats cover about 30% of the total area. The Sado estuary is a good example of a site where human pressures and natural values coexist each other.

Using a combined spatial and temporal approach, this work aims to study ecological resilience and regime shifts in this part of the SW Portuguese coast. Thus, we study the sedimentary infill of a number of tidal marshes located in the Sado estuary to assess variability in both sensitivity and exposure to sea level rise (SLR) at a local scale. Site-specific accretion and wetland elevation change are quantified, and temporal trends understood to produce reliable projections of the effect of SLR. Empirical time-series of tidal data and coeval sedimentological records obtained from the study sites regarding wetland response and sea level changes are used to assess past trends that can inform future scenarios of wetland changes and responses. Contemporary data and multiannual to millennial reconstructions provide insights on patterns and drivers of abrupt environmental change in response to SLR and yield important information on the average state and natural variability of the coastal system. We expect that our results will provide information on the long-term development and patterns of variability of the Sado estuary in relation to socio-cultural activities, which is vital to understand and mitigate the effects of global change on coastal ecosystems.

Enrichment of hazardous trace elements in Kochi Backwaters sediments, India

Busnur Manjunatha¹, Naveen Kumar¹, Jithin Jose¹, Karunakara Naregundi², Mohd Tarique³, Waliur Rahaman³
¹Department of Marine Geology, Mangalore University, Mangalagangothri-574 199, Mangalore, India, ²Centre for Advanced Research in Environmental Radioactivity (CARER), Mangalore University, Mangalagangothri-574 199, Mangalore, India, ³National Centre for Polar and Ocean Research, Ministry of Earth Sciences, Government of India, Headland Sada, Vasco 403804, Goa, India

Abstract

The most complex mixture of biogeochemical interactions on earth taking place at the land-ocean interaction in the coastal zone. This is due to the different types of inputs and processes taking place, including materials from atmosphere, terrestrial and marine environments including anthropogenic inputs as well as generation of new particles during the mixing of river with the seawater. About 90% of terrestrial material transported through rivers to the oceans are trapped in the coastal marine systems due to the rapid removal of both dissolved and particulate matter as a result of drastic changes in physico-chemical and biogeochemical processes. However, deposited sediments, their re-suspension and re-mobilization of red-ox sensitive toxic elements in sedimentary column make the narrow coastal zone as a sink and source for contaminants to the nearshore ocean water. India has long coastline (7517 km), dense population (250 million) with fisheries resource (3.5 - 4.7 million tons) that alone contributes to 10% of the GDP. The coastal systems in India includes brackish water, estuarine, deltaic and coastal waters, wetlands; coastal mudflats; tidal flats, rocky shores; mangrove forests; and nearshore marine areas and coral reefs that are under the threat from effluents, untreated sewage and solid waste discharge ($50 \times 10^6 \text{ m}^3\text{yr}^{-1}$, $0.41 \times 10^9 \text{ m}^3\text{yr}^{-1}$ and $34 \times 10^6 \text{ tonnes yr}^{-1}$ respectively). The south west coast of India, Kocki backwaters in particular, is under the impact of anthropogenic activities since little more than a century. In this study, a sediment core was collected from the vicinity of anthropocentric region. The nuclear fission product nuclide - Cs-137 was used as a stratigraphic marker to determine the pre- and post-bomb produced nuclides sections to determine the age of the sediment core. Sediment texture determined by conventional technique, whereas major and toxic trace elements - Cr, Pb, Ni, Cu, Zn and Cd, in the sedimentary sub-sections measured by ICP-MS. On an average, these elements are enriched by factors of 2.75 (Pb), 3.83 (Cr), 7.06 (Zn) and 39.41 (Cd) as compared to their background levels. Most of these elements tend to increase from the early part of the 20th century till recently, suggesting anthropogenic inputs. Since, these are non-degradable elements, they cycle in the coastal zone thereby not only cause hazards to the coastal living resource, but also to human health. The most red-ox sensitive element- Mn is strongly depleted in the sediment by an average of 70% as compared to background level suggesting the impact of deoxygenation in the estuarine/coastal waters. This has implication to the reduction of marine bio-diversity as well as the decrease of biotic resources.

P-4026

Impacts of the 2017-2018 winter freeze and sea-level rise on the boreal limit of an American mangrove

Marcelo Cohen¹, Adriana Souza¹, Kam-biu Liu², Erika Roudrigues¹, Qiang Yao², Junghyung Ryu², Luiz Pessenda³

¹Federal University of Pará, Belém, Brazil, ²Louisiana State University, Baton Rouge, USA, ³University of São Paulo, Piracicaba, Brazil

Abstract

The global mangrove distribution has been significantly influenced by the winter air temperature extremes and sea-level rise. The combined effects of these driving forces in the septentrional limits of the American mangroves still need to be investigated. We analyzed the black mangroves dynamics from Louisiana coast-United States of America in response to air temperature changes and Relative Sea-Level (RSL) rise based on a spatial temporal analysis of Quickbird (spatial resolution of 60 cm) and drone (3 cm) images between 2004 and 2018. These data were combined with digital elevation models based on topographical data obtained by photogrammetry and Global Navigation Satellite System. During this time, the black mangrove area from Port Fourchon increased from 30.4 ha to 124.3 ha as the monthly average of minimum temperatures during the winters in the study site have increased from 4.7°C to 6.6°C between 1970 and 2018. However, the 2017/2018 winter freeze, with 14 days of minimum temperature less than or equal 0°C and January with an average minimum temperature of 4.1°C, degraded ~90% (110.8 ha) of black mangroves, where the youngest *Avicennia* (<1 m tall) were most impacted. The 2017/2018 winter freeze caused significant impacts on the studied mangroves equivalent to 1980s winter freezes. In addition, losses of about 27 ha of mangrove and marsh areas, located behind the beach ridges, along 4.5 km of coastline, have been caused by landward sand migration on muddy tidal flats occupied by wetlands. This migration led to a coastal retrogradation of ~200 m during the last 17 years due to overwash events, contributing to a continuous degradation of these wetlands. The combined action of these climatic and oceanographic processes is leading to the loss of mangrove areas along the coastline, while mangroves are migrating to more continental and norther sectors as the RSL and monthly average of minimum temperatures rise. Therefore, the poleward expansion of mangroves caused by the global warming are not occurring linearly. The response of this ecosystem to the extreme winters (warmer and colder) should cause events of expansion and contraction of mangrove areas, but with a migration trend to more temperate latitudes. However, the expansion and degradation of mangrove areas caused by the global warming and winter freezes, respectively, probably are not directly proportional to increase and decrease in temperatures. Local coastal characteristics related mainly to the rates of RSL changes, sediment supplies to coastal system, longshore currents, and the interaction topographic gradients of muddy tidal flats and tidal ranges may accentuate or mitigate the effects of climatic extremes.

Holocene evolution of Kuttanad Kole (Ramsar) Wetland in SW India - A multi-proxy approach

Padmalal D

National Centre for Earth Science Studies, Trivandrum, India

Abstract

The Kuttanad Kole Wetland (KKW) in the Southern Vembanad basin, SW India is a unique wetland system, where paddy cultivation is being carried out 1-2 m below mean sea level. The fertile soil in KKW is formed essentially from deposition of fluvial sediments from the hinterland rivers. Although many studies have been carried out on different aspects this wetland system not much information exists on the geological evolution of the KKW, which is acting as the prime carbon sink in the region. Therefore, a study has been undertaken to unravel the Holocene evolution of this wetland system using multi-proxy data of 21 drilled borehole cores retrieved from the wetlands. Except the top 2-3m of riverine sediments, the rest of the core sediments are of lagoonal nature with occasional presence of marine and brackish water shells. The entire sequence is deposited over lateralized Neogene sediments. The top riverine sediments are yellowish brown with heavy minerals derived from charnockite provenance which is characteristic of the hinterland rivers. On the contrary, the heavy mineral suite in the lagoonal sediments of Early-Middle Holocene age is dominated by the mineral sillimanite derived from the Khondalite group of rocks that occur in areas south of Achankovil Shear Zone (ASZ). This points to the fact that, during Early-Middle Holocene, the KKW part of the Vemband basin was not influenced by the hinterland rivers that drain the Charnockite provenance, instead influenced by the longshore drift of sediments from the Khondalite terrain south of the ASZ. This together with the occurrence of subfossil shells of *Villoritta* sp. (and indicator species showing the fresh water end of an estuary) in the lagoonal sediments with radiocarbon dates of 3-4 k yrs of BP reiterate that the hinterland rivers that drain the Charnockite provenance joined the KKW only during Late Holocene. Based on the study, a 3-fold evolutionary model has been proposed and is discussed in the paper.

The paleolimnological approach in the environmental and sea-level reconstructions in the Eastern coast of the Baltic Sea.

Iurii Kublitsky¹, Angelina Shatalova¹, Liudmila Syrykh¹, Alar Rosentau², Dmitriy Subetto¹, Anna Ludikova³, Natalia Sokolova¹

¹Herzen State pedagogical University of Russia, Saint-Petersburg, Russian Federation, ²The University of Tartu, Tartu, Estonia, ³Institute of Limnology, Saint-Petersburg, Russian Federation

Abstract

In the conditions of modern climate change, special attention is paid to paleogeographic reconstructions, because the prediction of climate scenarios in the future is modeled on the basis of data from past eras. One of the most reliable methods for the reconstruction of natural conditions of the Late Pleistocene and Holocene is a complex study of bottom sediments of lakes. Climate changes cause the nature and intensity of sedimentation processes, which is reflected in the formed sedimentary sequence of bottom sediments of lakes. Of particular interest is the study of the relationship between changes in climatic conditions and the paleo level of the Baltic Sea. It is established that one of the reasons of Littoral transgressions is eustatic ocean level rise, associated with the degradation of glaciers and climate changes (Bjork et al., 2008). The study of the bottom sediments of the lakes flooded by the Baltic transgressions and isolated from them will allow reconstructing in detail the climatic conditions under which such an increase in sea level could occur. After the reconstruction of the dynamics of natural and climatic conditions, it will be possible to assess the relationship between the intensity of transgressions and the average temperatures of July.

With the aim of reconstruction, the dynamics of the transgression-regressive cycles of the Baltic Sea and comparing this changing with the natural conditions in the northern part of the Karelian Isthmus, the lakes were chosen at different hypsometric levels: Goluboye (11 m ASL), Mozhevelnoye (14 m ASL) and Trigoriskoye (16 m ASL).

The strong salinity influence was identified in the sediments of Goluboye lake by Br/Ti ratio. For this core sediment analysis of the loss on ignition, diatom, geochemical, palynological, Chironomidae and radiocarbon analysis will be applying. The obtained data will show the relation between organic and inorganic material, physicochemical features and bio-productivity of lakes, the duration of sediment formation, vegetation change, average temperatures in July.

The first results of lab analysis will be presented at the conference.

Acknowledgments: the study was supported by the President's grant № MK-5595.2018.5.

Abstract

Rhodolith beds (Rb) are priority marine benthic habitats because of their relevance as biodiversity hotspots and their role in the carbonate budget. Mediterranean Sea hosts rhodolith-dominated habitats, targeted over the years for ecological research and management actions, but also. an important fossil legacy of Rb, formed under contrasting climatic scenarios since Neogene. Most of Mediterranean Rb refer to relatively shallow-water situations (30-75 m), far less is known about deeper water occurrences.

An outstanding Rb has been recently identified between 70-100 m off Egadi Archipelago (Central Mediterranean Sea) in the frame of the Marine Strategy Framework Directive. The seabed has been mapped by remote sensing and ground-truthed with by Remote Operated Vehicle (ROV) visual observation and sampling with Van Veen grab (70 l).

The resulting cartographic outcome provides a precise information on the Rb distribution and its main features, including algal morphotypes, dominant algae species and associated biodiversity. The ecological study has been complemented by the radiocarbon dating of the inner structure of some rhodoliths to investigate the tempo of their origin and subsequent growth to unravel the evolution of this carbonate facies during the Holocene.

The Rb carpets an area > 7 km² between Marettimo and Favignana Islands (Egadi Archipelago), with a coverage of live rhodoliths up to 95%. The dominant morphotype is *pralines*, ellipsoidal to discoidal in shape, with an average size of 12 mm and maximum size of 31 mm. Old algal nodules, other bioclasts, or, less frequently, terrigenous particles serve as nucleus of individual rhodoliths. Living calcareous algae are *Lithothamnion valens*, *Lithothamnion* cf. *minervae*, *Phymatolithon lenormandii*, and *Lithothamnion* spp. *Lithothamnion* spp. characterize the algal association close to the nucleus, with scatter presence of *Lithophyllum* sp. The dominant sediment type is mostly biogenic gravelly-sand. Seafloor bedforms (megaripples and ripples) and frequent bioturbations by epifaunal and semi-infaunal sea-urchins have been observed on ROV videos. Benthic fauna (e.g., mollusks) corresponds to the circalittoral environment, with exclusive species of the Coastal Detritic biocoenosis or related to coarse sediments. Moreover, the textural aspects associated sediments is in line with moderate water energy at bottom. Radiocarbon ages reveal that the cores of rhodoliths date back to 2734±24, 2559±23 and 2397±23 yr cal BP, which correspond to the Roman Little Climate Optimum. Calculated growth rate provides a very low figure (0.004 mm/yr). The inception of such Rb occurred under warmer climate conditions, but its development is continuing at present because of the persistence of adequate light conditions and bottom hydrological regime, with a very slow growth-rate reflecting the demanding conditions for their development. Therefore, the Egadi case certifies a rare example of a deep-water resilient Rb, which should be taken into consideration for the potential recognition of fossil analogs in the Mediterranean Basin.

P-4201

A research program to understand human behavioural adaptations to the MPR

Ana Mateos, Jesús Rodríguez

National Research Center on Human Evolution (CENIEH), Burgos, Spain

Abstract

The Mid-Pleistocene Revolution (MPR) was a period of profound ecosystem reconfiguration. It is generally accepted that those environmental changes affected the survival opportunities and the distribution patterns of humans in Europe. The human responses to those environmental perturbations were likely complex and, in many respects, they are still not well understood. One way or the other, human adaptive responses imply changes in behaviour and Human Behavioural Ecology (HBE) provides a theoretical framework to approach the study of the behavioural responses of hominins. The basic premise of HBE is that human behaviour is shaped by natural selection, and its aim is to understand the patterns in behaviour by identifying the constraints that affect differences in reproductive success (O'Connell, 1995). HBE focuses on how a particular behaviour contributes to the fitness and reproductive success of the individual. The methodological approach consist in the definition of Formal Optimality Models, i.e. mathematical models which incorporate the cost and benefits of a particular behaviour in a certain environment and determine the net return of that behaviour. Although the framework of HBE may be applied to any aspect of human behaviour, in archaeology it has been mainly used to understand trophic behaviour by using Optimal Foraging Models (Winterhalder, 1981).

In this framework, Formal Optimality models may be developed to evaluate the responses of hominins to the changing environments during the MPR. These models should incorporate the availability of plant and animal resources, their characteristics, the cost of exploitation of those resources in the different environmental conditions and the requirements of hominins. Moreover, the models may also incorporate the availability of other resources (e.g. shelter or raw materials) the costs associated to their use, and the cognitive or technical capabilities of the hominin species. Resource availability may be reconstructed from the palaeontological record, but the requirements of hominins should be extrapolated from human physiology. Estimating the cost of harvesting different resources, however, requires combining information provided by the archaeological record with palaeophysiological data obtained from the extrapolation of experimental studies with *in vivo* subjects (Mateos et al. 2018; Prado-Nóvoa et al, 2017).

The METHOD IFG

Jesús Rodríguez¹, Ana Mateos¹, Christine Hertler², Maria Rita Palombo³

¹National Research Center on Human Evolution (CENIEH), Burgos, Spain, ²The Role of Culture in Early Expansions of Humans (ROCEEH), Senckenberg Forschungsinstitut, Frankfurt am Mein, Germany, ³Dipartimento di Scienze della Terra, Sapienza Università di Roma, Rome, Italy

Abstract

The Mid-Pleistocene Revolution (MPR), or Early-Middle Pleistocene Transition (EMPT) was a period of profound ecosystem reconfiguration, caused by climatic changes driven by variations in orbital forcing that took place at around 1 Ma. Changes in climate drastically affected vegetation in complex ways and led to a significant renewal of mammalian faunal complexes in Europe and elsewhere. In particular, it is generally accepted that those environmental changes affected the survival opportunities and the distribution patterns of humans in Europe. However, it is not well established how, where, when and at which extent the environment affected human population dynamics.

The study of complex phenomena, as the ones described above, requires the contribution and cooperation of researchers from several fields. During the last decades, palaeontologists, palaeoanthropologists and archaeologists have produced organized datasets describing hominin distribution and databases containing quantitative palaeoenvironmental and palaeoecological. In parallel, several conceptual models have been proposed to explain the dynamics of the human colonisation of Europe in this period, but too often they reflect the actual data only loosely or were based selectively on data provided from a specific research field. Complex questions like understanding the dynamics of the early dispersal and, at least, temporary settlement of the continent require multidisciplinary synergic approaches.

Mathematical modelling has revealed itself as an extremely helpful tool to describe complex systems dynamics in other disciplines, but it has been rarely used in terrestrial Quaternary palaeoecology or Palaeolithic archaeology. The METHOD International Focus Group (“Modelling EnvironmentAl Dynamics and Hominin Dispersals Around the Mid-Pleistocene Revolution”), funded by INQUA HabCom (1604F), promotes an active collaboration among researchers interested in understanding the dynamics of the first European humans, the specialists with knowledge on the ecological and environmental scenarios and the people with the skill to set up mathematical models, including mathematicians, physicists or engineers with experience in the study of complex systems through mathematical modelling and computer simulations.

Since the MPR was a planetary event, the IFG has a worldwide scope, though it is initially focused on Europe because the quality and quantity of available data are significantly higher for this than for other regions. Europe constitutes an excellent case study to explore the application of quantitative approaches and mathematical modelling in the study of the early human settlement and dispersals.

METHOD organised a number of activities during the 2016-2019 inter-congress period to promote collaboration among researchers and to provide training in specific topics. Main workshops were held in Burgos (2017, 2018), Mauer (2017) and Rome (2019), and Training Labs on the uses of databases and different modeling techniques were organised in Sassari (2016), Frankfurt (2017, 2018) and Burgos (2018). Up to 45 researchers from 10 different countries participated in the activities organised by METHOD during this period.

Early Pleistocene paleo-vegetation maps of the Guadix-Baza Basin (Spain) and plant resource availability for early humans

Yul Altolaguirre^{1,2}, Meike Schulz^{1,2}, Ericson Hölzschén^{1,2}, Christine Hertler¹, Angela A. Bruch¹

¹ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt am Main, Germany, ²Goethe University, Dept. of Geosciences/Geography, Geology, , Frankfurt am Main, Germany

Abstract

The Guadix-Baza Basin is situated in the province of Granada, in South-Eastern Spain. The Early Pleistocene deposits of the Basin contain some of the oldest (around 1.4 Ma) evidences of hominin presence in Western Europe. Taxonomic composition of the Early Pleistocene vegetation is known thanks to pollen analysis of the lacustrine deposits of the Baza sub-basin. The Coexistence Approach (CA) has provided paleoclimatic measurements for different precipitation parameters. The analysis reveals a cyclic climate with phases of different humidity which in turn create cyclical vegetation changes. A humid phase ('interglacial'), with precipitations higher than the modern ones and a dry phase ('glacial'), with precipitations more similar to the ones currently registered in the Basin. During the humid phase, the main vegetation unit of the Basin would be similar to the modern meso- and supra-Mediterranean *Quercus* forests. During the dry phase, the more widespread vegetation unit would be the *Artemisia* steppe. Paleo-vegetation maps for both humid and dry phases are created by extrapolating modern precipitation maps with paleo-precipitation measurements given by the CA method. In these maps the vegetation is divided in different vegetation units which are constrained by precipitation values, much like the modern vegetation units in the modern Guadix-Baza Basin. The potential plant resources for each vegetation unit are extracted from ethnobotanical data. Plant resources are measured as the quantity of edible plant parts from taxa found in the pollen record and the usual taxonomic composition of the modern vegetation units that are considered analogues of the Early Pleistocene ones. The forested vegetation units provide higher amount of plant resources and are more widespread during the humid phases. The steppic vegetation unit occupies the majority of the area during the dry phases. The access of early hominins to edible plant parts was heavily limited during dry phases, although the more productive vegetation units would still be present in areas next to freshwater environments (riparian vegetation unit) and higher altitudes. Early inhabitants of the Basin could have found enough edible plant parts in these units even during the dry phases. These map reconstructions have the potential to be used in simulation approaches, such as agent-based modelling.

P-4204

A Cognitive Agent Architecture for Simulating Early Human Decision-Making and Knowledge Transfer

Jan Ole Berndt, Ingo J. Timm
Trier University, Trier, Germany

Abstract

There is a variety of questions concerning human evolution and culture that are difficult to answer based on the archeological record alone, such as: How do energy consumption and energy gain, availability of stone tools and fire for food preparation and preservation, group size and composition impact early human mobility? Additionally, vice versa, how does mobility affect knowledge and cultural transfer between groups? Moreover, which individual and group decisions drive these processes and lead to an evolutionary advantage?

Agent-based modeling and simulation methods can complement classical archeological research by opening up experimentation as a research method to answer the aforementioned questions. However, existing agent-based approaches in archaeology and paleoanthropology fall short of representing the cognitive abilities needed by the modeled humans to use technology for gaining strategic evolutionary advantages. This necessitates agents that use knowledge for individual decision-making and to adopt particular roles for coordinated action in groups. Utilizing knowledge representation, reasoning, and learning techniques from artificial intelligence, it is possible to represent these sophisticated behaviors in simulation models. To this end, we present an extendable agent architecture based on artificial intelligence and cognitive science which allows for simulating knowledge-based processes like planned action for tool manufacturing and hunting as well as cultural exchange.

Our agent architecture is based on the Beliefs-Desires-Intentions (BDI) approach to practical reasoning. It uses mental states to implement goal-directed behavior for representing strategic usage of technology as well as preconditions and effects of activities. An agent has a local state, available actions, perception, and activity selection methods. In its local state, an agent maintains its situational state knowledge (Beliefs), abstract goals (Desires), intended courses of action (Intentions), capabilities (Plans), and goal relevance in the current situation. Such an agent's state knowledge covers the perceived situation of its environment (e.g., food resources, predators, shelter, group members), its goals represent its immediate or long-term needs (e.g., food acquisition, reproduction, protection, knowledge acquisition), and its capabilities model the available strategies to achieve these goals by means of intended activities given its state knowledge (e.g., manufacture a handaxe to increase utilization of food resources).

Moreover, technology usage requires complex interrelations between capabilities which only become available if specific technology or tools are present. Those tools in turn can be acquired using other capabilities. Additionally, activities like hunting are group capabilities which are based on cooperation of several group members fulfilling different roles. These capabilities can also be passed on within a group to enable agents to learn from each other. To achieve this in a simulation, we present strategic agent decision-making mechanisms which evaluate possible worlds in order to anticipate potential future gains from actions without an immediate physical benefit.

Paleoenvironment of the central north Anatolia during the MPT: A possible refuge for large & small mammals?

Ozan Erdal¹, Burçin Aşkım Gümüüş², Mehmet Korhan Erturaç³, Hilal Okur³

¹Istanbul Technical University, İstanbul, Turkey, ²Gazi University, Ankara, Turkey, ³Sakarya University, Sakarya, Turkey

Abstract

Basins formed on the Central North Anatolian Shear Zone (NASZ) preserve well exposed sedimentary successions of various depositional environments providing insights on the paleoenvironment of Anatolia since the late Pliocene throughout the Quaternary.

These records provide evidence for tectonic evolution of this distinct transform fault zone but also provide insights on the paleoenvironment of Anatolia. Bounded by the pontide mountain range to the North, each basin is connected with river network and also the corridor morphology of the NASZ.

Based on the fossil remains of small and large mammals as well as invertebrates collected from the Suluova Basin, the climatic and environmental changes can be inferred throughout the Pleistocene, especially including the formation of a vast paleolake during the MPT (1.7-0.8 Ma). For instance, the giant giraffid *Sivatherium* from the early Pleistocene indicates such palaeoenvironment with grasslands and well-watered humid landscape under control of warmer temperature which is more or less sustained up to late early Biharian (~MNQ20) following the habitat preferences of voles (*Mimomys* cf. *pliocaenicus*) and wood mouse (*Apodemus* cf. *dominans*), in addition to unidentified fish teeth, some freshwater invertebrates (e.g. *Unio* sp., *Pisidium* sp., *Valvata* sp.) as well as some terrestrial molluscs (e.g. *Vallonia* sp?, *Daudebardia* sp. and *Carpathica* sp.; Pupilloidea). Molar remains of *Mammuthus trogontherii* allow us to infer that Suluova has been on the route of the Pleistocene dispersion of mammoths where the paleolake might acted as refugia by providing favourable conditions during the increased aridity of MPT prior to MIS 22.

Following the MPT, the basin and the Suluova Lake was captured from SE part by the Yeşilirmak River. Remains of hamsters (*Mesocricetus brandti*) from the early Toringian, indicates again that Suluova, as the rest of Anatolia in general, plays an important role for the evolution of hamsters during Middle Pleistocene, which is favoured by alternating dry periods and spreading lakes causing steppe-corridors for hamster's dispersals and adaptations.

In conclusion, Suluova Basin can be considered as local, yet one of the most significant regions where faunal and climatic changes can be observed around the evolving paleolake of which shorelines may have played a refugial role during the MPT.

Corridor-barrier function of Palaeo-Dniester Valley facilitated the dispersal of steppe rodent species: the example of Early Pleistocene ground squirrels

Lilia Popova¹, Bogdan Ridush², Adam Nadachowski³, Yuiy Veklych⁴, Lutz Christian Maul⁵, Ericson Hoelzchen^{6,7,8}, Arlett Ulbricht⁹

Abstract

During the Early Pleistocene, two ground squirrel species, *Spermophilus nogaici* (Northern Black and Azov Sea areas) and *S. polonicus* (Central Europe) coexisted in geographically well separated ranges. Studied samples from Tiligul (Ukraine) and Kamyk (Poland) represent early evolutionary stages of these species and have approximately the same biostratigraphical age: early Odessa faunal complex (Tiligul) and Villanyian-Biharian transition (Kamyk).

S. nogaici and *S. polonicus* have been analysed and compared by means of occlusal morphology, modular wear facets and mesowear. A significant difference in trophic niches of these species and a high similarity of phylogenetically significant characters has been established. We suggest that *S. polonicus* branched off from *S. nogaici*; the speciation was fast and triggered by the expansion to the northwest.

Here we discuss a palaeogeographic scenario, which could have driven populations of early *S. nogaici* on the edge of the ground squirrel adaptive zone (which always implies open habitats) to give rise to *S. polonicus*. This expansion must have occurred between the FADs of *S. nogaici* and of *S. polonicus*, i.e. within the Tiglian (Beregove) time.

River valleys are broadly known as highways of long-distant expansion of species. Climatic changes amplify the corridor effect of valleys because wet epochs reduced the area of open habitats on watersheds and steppe species became more or less restricted to the valleys, with their floodplains and woodless slopes.

In this way the Middle and Upper Dniester area could provide a steppe corridor between ranges of *S. nogaici* and *S. polonicus*. The Pliocene-Quaternary history of the Dniester includes two stages. The first one is the period of the lateral wandering of the river under the condition of tectonic stability, with large yearly flooded areas, low broad terraces and relatively frequent catastrophic floods. Such conditions facilitated the dispersal of ground squirrels over the Dniester via cutting incised meanders, but were not conducive for an expansion along the valley. In the second stage, the Dniester valley underwent incisions and a transformation into a deep canyon-like valley with well-developed internally-canyon terraces on the inner banks of meanders. Within this stage, barrier functions of the river enhanced. Changes in the corridor function of the Dniester valley for open-habitat species included the appearance of new non-flooded surfaces (positive effect on the expansion of xerophilous species to the northwest) and development of numerous tributaries (negative effect).

The Beregove time, which, for the Middle and Upper Dniester, was a turning point between the meandering and canyon stage, might create a beneficial combination of the landscape characteristics to pave *S. nogaici* the way northwest. Starting uplift and revitalization of karst within Prae-Beregove terraces and the Prut-Dniester watershed created open habitats with necessary for this species xerophilous vegetation.

Spatio-temporal interpolation of paleoclimate data based on $\delta^{18}\text{O}$ climate variability observations

Christian Willmes¹, Ericson Hölzchen², Christian Sommer³, Jesús Rodríguez⁴

¹University of Cologne, Cologne, Germany, ²Senckenberg Research Institute, Frankfurt, Germany, ³University of Tübingen, Tübingen, Germany, ⁴Centro Nacional de Investigación sobre la Evolución Humana (CENIEH), Burgos, Spain

Abstract

In this study we present a method that allows to compute paleoclimate datasets for the last 1.2 mio. years in 1ky temporal resolution. The computational model is based on a spatio-temporal interpolation along $\delta^{18}\text{O}$ measures, to provide a high resolution record of paleoclimate variability, between modeled paleoclimate and current observed climate data. In particular we interpolate temperature and precipitation monthly values between time steps. The interpolated results are evaluated, using different techniques and approaches, against modeled and observed published paleoclimate data sets, based on qualitative and quantitative evaluation methods.

The interpolated climate data, that are 36 layers per interpolated time step of monthly precipitation, minimum temperature and maximum temperature, will be published as open data, to enable and foster reuse of the data for example in the context of paleoenvironmental modeling applications.

The presentation will detail mostly on the development of the interpolation technique and the evaluation of the datasets. It will also give advice for what kind of applications, in terms of scale and scope, this data is suitable and for what kind of applications this data is unsuitable.

Concepts and design of a Multi-Scale Agent-Based Model Simulation on Pleistocene Hominin Migration in Java

Mika Puspaningrum¹, Christine Hertler^{2,3}, Ericson Hölzchen^{2,3}

¹Institut Teknologi Bandung, Bandung, Indonesia, ²Senckenberg Research Institute, Frankfurt, Germany, ³Heidelberg Academy of Sciences, Heidelberg, Germany

Abstract

Considered as relatively isolated island, Java has yielded a remarkable record of early hominin fossils, extending back to the Early Pleistocene. Java holds an important role of *Homo erectus* migration as it records the furthest point of an early dispersal out of Africa. The question why and how hominins migrated further to Southeast Asia has been in the centre of the debate of early human expansions beyond the African continent. The migration and dispersal of early humans in Java have been long-studied. Despite of that, the interpretation of early hominin migration in stratigraphic context is not straightforward and has always been challenged by multiple factors. A number of relevant issues promoting the migration are still being questioned. For example: changes in paleogeography, paleoenvironment, vegetation types and their succession, climate parameters, and finally the interpretation of human and animal biology, ecology and behavior. Notably, due to the use of different proxies and divergent interpretation of the stratigraphic records, the reconstruction of migration varies. Thus, the situation cannot simply be resolved or improved by additional empirical data. Instead, an experimental approach is necessary, which allows studying the preconditions, circumstances and effects of the relationships between human behavior, environmental dynamics and glacial / interglacial shifts as well as climate change.

In this study, we use ABM (Agent-Based Modeling) as an approach to reconstruct mobility patterns, migration and dispersal of early hominins into and within Southeast Asia, including the island of Java, by analysing and testing the interaction among human groups and between humans and their respective environments. ABM offers a perfect opportunity to examine the advantages and disadvantages of a variety of scenarios of human migration into and in Java and compare their respective performance through simulation. This study deals with both *Homo erectus* and earliest *Homo sapiens* inhabiting Java during the Pleistocene. We try to formalize agents' attributes of both hominin species, environment patches of Java during the Pleistocene and rules controlling the migration. As a first step, we discuss concepts of migration and respective transfers into an agent-based modelling approach.

A first look at non-pollen palynomorphs from the Llanos de Moxos, Bolivia

Nicholas Loughlin, Bronwen Whitney
Northumbria University, Newcastle Upon Tyne, United Kingdom

Abstract

The application of non-pollen palynomorphs (NPPs) in enhancing pollen based landscape reconstructions in the Neotropics is still in its infancy. Here we present the first examination of fungal NPPs from the seasonally inundated forest-savanna of south-western Amazonia. A 1000-year NPP record from Laguna El Cerrito is integrated into an existing pollen and charcoal record providing new insights into past land-use, agriculture and vegetation change within the pre-Columbian raised-field region of the Llanos de Moxos (northern Bolivia). Palynological analysis has shown that fire was used as a common management practice until AD 1300 in a landscape dominated by herbaceous taxa, however, savanna trees and gallery forest did not recolonise the region until after AD 1500. Here we use additional modern NPP analysis of surface lake sediments from across the mosaic landscape of the Llanos de Moxos to refining the interpretation of vegetation structure and composition in the palaeoecological record. Autecological characteristics for NPP morphotypes are speculated upon for types identified from Bolivia. Integrating previously published work from Ecuador and Venezuela we suggest that despite regional differences in environmental and climatic conditions, key morphotypes are frequently encountered across ecological gradients.

P-4210

Pollen dispersal in traditional processing of buckwheat and its application in agricultural archaeology

Xue Shang

University of Chinese Academy of Sciences, Beijing, China

Abstract

Pollen, as an important index of the paleoenvironment and ancient human agricultural activities, is also one of the significant indicators for research on buckwheat agriculture. In order to test buckwheat pollen dispersal during each crop processing stage, we applied traditional processing simulation experiments of buckwheat crops in a modern village, to collect aerial pollen and perform statistical analysis. The result has shown that the distribution of buckwheat pollen in residential areas is closely related to human processing behaviour. Among all the processing procedures, pollen release rate is highest in the threshing and the sieving stages. The redistribution and burial of pollen during crop processing is an important reason for the prominent increase of crop pollen concentration in the cultural layer. Not only can it indicate the cultivation and processing behaviour of humans but also provide a basis for identifying the crop processing remains in archaeological sites and assessing the intensity of agricultural activities.

P-4211

Local vegetation patterns in a human-modified environment in the Tianluoshan site, indicated by coprolite analysis

Yunan Zhang

School of Archaeology and Museology, Peking University, Beijing, China

Abstract

The Tianluoshan site is located in the Lower Yangtze Region, China and dated back to 7000-5500 cal B.P. in the Late Neolithic Phase. 103 coprolites from the Tianluoshan site were analyzed to explore the palynological and biomarker information.

In biomarker analysis, n-alkanes are dominated by n-C16, n-C17 and n-C18 homologues from microbial input, indicating fecal bacteria existing in the scats of carnivorous or omnivorous animals. n-Alkanols display a strong even-over-odd predominance, with higher abundances of n-C24 and n-C26 alkanols, pointing to grass vegetation. The relatively high abundances of cholesterol, cholestanol and 5 α -stigmasterol in sterols provide strong evidence that most excrements originated from domestic dogs and possible pigs and humans. Higher proportions of plant-derived sterols over animal-derived sterols further imply that the diets of these domestic dogs highly depended on human-derived food.

Compared to traditional pollen analysis of natural sediments, dung pollen spectra have been demonstrated to be the best analogue of local vegetation in previous studies. Thus, pollen and non-pollen palynomorphs analysis of these coprolite samples may present an opportunity to examine the possible human subsistence and microenvironments modified by human activities in the Tianluoshan site.

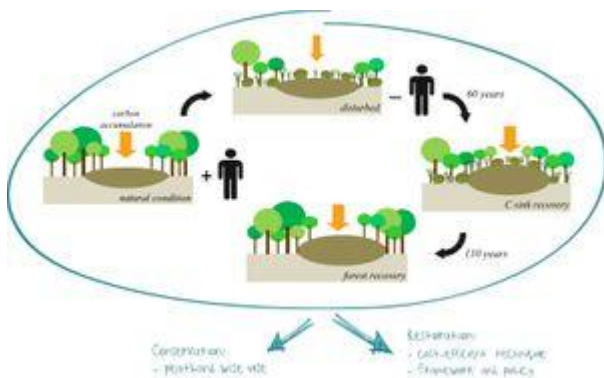

Two types of vegetation, represented by typical subtropical forest arboreal and herbaceous pollen, as well as shrub and liana pollen, can be distinguished from detrended correspondence analysis of pollen data. The first type of vegetation, together with cereal pollen in the DCA plot, may indicate the large areas of rice cultivation in a wooded zone. Large amounts of entomophilous shrub and liana pollen were first observed in ancient pollen record in the Lower Yangtze Region. This vegetation pattern may indicate either natural plant succession at forest edge after human disturbances or intentional cultivation and maintenance of useful plants in a house garden. Previous macrofossil researches also gave clues of bottle gourd and peach cultivation on the same site, suggesting the presence of garden areas. Under the term "human niche construction", our pollen data supports more diversified human-environment interactions besides rice cultivation, which has been widely discussed before.

In non-pollen palynomorphs analysis, 31 previously undescribed morphotypes were recorded and compared to possible existing types. An inverse relationship of *Cercophora*-type and *Sporormiella*-type in DCA, covarying with tree and shrub pollen respectively, consists with a preference of *Cercophora*-type fungi growing in forest environment in previous research. *Sporormiella*-type, as the most reliable dung indicator in previous studies, shows a correlation with shrub and liana pollen, which may further suggest possible human diets or compost system. Other taxa include aquatic fungi *Savoryella* sp., and pathogen species *Curvularia* sp., *Urocystis* sp., etc.

Resilience of a peatland in Central Sumatra, Indonesia to past anthropogenic disturbance

k. [anggi hapsari](#)¹, [siria biagioni](#)¹, [tim jenniferjahn](#)², [peter reimer](#)³, [asmadi saad](#)⁴, [supiandi sabiham](#)⁵, [hermann behling](#)¹
¹university of goettingen, goettingen, Germany, ²Leibniz Centre for Tropical Marine Research (ZMT), Bremen, Germany, ³goshen college, goshen, indiana, USA, ⁴university of jambi, jambi, Indonesia, ⁵bogor agriculture university, bogor, Indonesia

Tropical peatlands are important for biodiversity provisioning and carbon (C) storage that are currently threatened mainly by landuse conversions. Conservation and restoration efforts thus are needed to maintain their functions. Nowadays, conservation concepts aiming to segregate human from ecosystems are no longer conceivable. Therefore, understanding peatland response (resistance, recovery or transformation) to human disturbance, can help to integrate human needs in conservation strategies and improve the restoration design. Located close to the archaeological remains of Malayu Empire, Sungai Buluh peatland in Sumatra, Indonesia provides an opportunity to study the resilience of a tropical peatland to human disturbance in the past. We analyzed a 250 cm long peat core for pollen and spores, charcoal and carbon (C) content to delineate the anthropogenic impact to the peatland and the ecosystem's response. The results revealed that extensive human activities in Sungai Buluh that changed the vegetation composition and decreased the peatland's capacity to store carbon started soon after humans occupied the vicinity of the peatland ca. 1000 cal yr BP. Following the site abandonment after the demise of the empire in ca. 600 cal yr BP, the result suggests that the Sungai Buluh peatland recovered in terms of both floristic composition and C sink function with the latter recovered faster (ca. 60 years) than the former (ca. 170 years). The "resilience-friendly" human activities as identified in this study can be used as a blueprint for peatland sustainable use. Additionally, the recovery time of Sungai Buluh hints at the appropriate period allocation for tropical peatland restoration projects.

Sedimentary processes in lake nearshore areas and their interaction with human activity of Palaeolithic and Mesolithic communities in young-glacial landscape

Piotr Weckwerth, Michał Jankowski, Grzegorz Osipowicz, Agnieszka M. Noryśkiewicz
Nicolaus Copernicus University in Toruń, Toruń, Poland

Abstract

Geomorphological, pedological and ecological investigations are a necessary component of archaeological studies. These investigations enable the reconstruction of the local palaeoenvironmental conditions of ancient human populations. The analysed archaeological sites of late Palaeolithic and Mesolithic communities (Ludowice, Trzciano and Paliwodzizna) are located in an area of young-glacial landscape in northern-central Poland (Chełmno-Dobrzyń Lakeland and Drwęca River Valley), in the marginal part of large kettle holes, on the surface of sandurs and in tunnel valleys. These landscape features changed dynamically due to climate fluctuations and hydrological network transformations in the Late Glacial and early Holocene.

Geomorphological research made it possible to identify the glacial landforms favourable to late Palaeolithic and Mesolithic settlements. Recognition of the geological structure and reconstruction of sedimentary processes made it possible to identify the type and dynamics of landform transformation in the nearshore zone of former lakes where the archaeological sites of late Palaeolithic and Mesolithic communities were documented. The research involves grain-size distribution analysis of sediments and recognition of their sedimentary environments on the basis of lithofacial analysis. The Ludowice site lies in the marginal part of a large depression where the former lake developed. At this site, three cycles of sediment deposition were distinguished in the lake nearshore zone. Two cycles of sedimentation were associated with the domination of cross-shore littoral transport, and the third with the activation of shoreline erosion and slope denudation. The Trzciano site is located on a sandur surface and in the vicinity of the Wieczno Lake. The results of sedimentological research indicate redeposition of sand and gravel deposits as a result of human activity, and surface sediment wash-off processes. The Paliwodzizna site lies in the northern part of the Grodno Lake tunnel valley, in the littoral zone of a former lake. Investigations of grain-size distributions and the results of lithofacial analysis enabled the reconstruction of littoral zone morphology and lake-level fluctuations that affected the location of late Palaeolithic and Mesolithic settlements.

The geomorphological, pedological, archaeological and ecological analysis performed at the sites located in a young-glacial landscape have demonstrated that sediments layers are mixed as a result of denudation processes, sediment wash-off, wave action and human activity in the area where land, streams, mires and lake all meet. This transitional environment was influenced by the movement and processing of material flowing into the lake from terrestrial runoff and stream connections, which affected the physical and biological processes in the lake onshore zone. The local palaeoenvironment was characterized by changing hydrological conditions due to climate fluctuations during the Late-Glacial/early-Holocene transition, when geological processes developed intensively.

This study was carried out as part of a scientific project financed by the National Science Centre (NCN) in Cracow (Poland), project no. 2016/23/B/HS3/00689.

The dIANA baseline database for the Baltic Sea region

Heli Etu-Sihvola¹, Hervé Bocherens², Dorothee Drucker², Aripekka Junno³, Kristiina Mannermaa⁴, Markku Oinonen¹, Joonas Uusitalo¹, Laura Arppe¹

¹Laboratory of Chronology, Finnish Museum of Natural History, University of Helsinki, Helsinki, Finland, ²Department of Geosciences and Senckenberg Centre from Human Evolution and Palaeoenvironment (S-HEP), University of Tübingen, Tübingen, Germany, ³Arctic Centre, University of Groningen, Aweg 30, 9718 CW, Groningen, Groningen, Netherlands, ⁴Department of Philosophy, History, Culture and Art Studies, University of Helsinki, Helsinki, Finland

Abstract

The north European (paleo)dietary isotopic research has significantly expanded during the last twenty years. As a result, the data are scattered into dozens of publications written in multiple languages, making them laborious to find and use. Here we present the first publicly available compilation of this data, the open access dIANA database (Dietary Isotopic baseline for the Ancient North; <https://www.oasisnorth.org/diana.html>). The dIANA database contains currently mainly animal bone collagen $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and $\delta^{34}\text{S}$ analyses (>1300 samples) and radiocarbon dates but also has a growing number of other types of ancient and modern ecological data, such as fish and plant values. The data have been extracted from over 50 studies published between 2003 and 2019. Temporal range covers the last 57 ka.

Our data examples show existing spatiotemporal isotope patterns related to diet and differences in the environmental carbon sources, and the current status of baseline research and the need for further analyses in the circum-Baltic area. Likely due to demanding soil conditions and the required sample size, archaeological or paleoecological bird and freshwater fish analyses are still underrepresented in the data. In order to significantly improve the situation regarding wild faunal baseline for Fennoscandia and northwest Russia, we analysed a collagen dataset ($n=81$; $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and $\delta^{34}\text{S}$) from the Finnish modern zoological collections. These results significantly increase the number of data for North European birds and the amount of Finnish faunal analyses in general.

Our work adds to the body of knowledge of North European spatiotemporal isotopic patterns, which are visible especially in the Baltic seals but also reveals that the selection of animal species and sample numbers in the dIANA data are temporally and geographically skewed. Our results also reveal the areas that are still scarce in data and show the overall need for further scientific datings, invaluable for the understanding of the complexity of dietary patterns. Moreover, accompanied with dietary modellings, the data helps to understand the origin of carbon, relevant in estimating chronological reservoir offsets.

The dIANA database is aimed to support various types of (paleo)ecological, dietary and chronological research in northern Europe. Further development plans include listing the used pretreatment method and expanding the database to contain more isotope systems, and in the future also human data.

Etu-Sihvola, H., Bocherens, H., Drucker, D., Junno, A., Mannermaa, K., Oinonen, M., Uusitalo, J., Arppe, L. The dIANA database – resource for isotopic paleodietary research in the Baltic Sea area. *Journal of Archaeological Science:Reports* (under review)

P-4215

Investigating the impact of faunal biodiversity on late Neanderthal and early modern human behaviour in Britain

Fiona Skinner, Rhiannon Stevens, Louise Martin
UCL, London, United Kingdom

Palaeolithic Britain had a highly variable landscape into which Neanderthal and early modern human groups ventured. Climate during the late middle Palaeolithic was characterised by repeated warm and cold events while the upper Palaeolithic was dominated by the rise and fall of the last glacial maximum. As the north western peninsula of Europe, Britain was at the limit of the hunter-gatherer geographical range and the ultimate test for biological and cultural adaptations. Neanderthal and modern human groups came and went during this time, with long episodes of apparent absence. The archaeological record for this period in Britain is sparse and challenged further by the methods of early excavators and difficulties associated with cave stratigraphy.

Through combining biomolecular (ZooMs, stable isotope and radiocarbon) analyses with traditional zooarchaeological studies at Palaeolithic sites in south and west Britain we aim to provide further insight into the ecological plasticity of hominin groups ranging so far from the heartland of their home range. This approach will significantly increase the available data for faunal presence/absence and further understanding of how faunal ecology and migratory behaviour responded to changing environments. Integration of these various streams of archaeological and scientific evidence will test how changes or continuity of faunal biodiversity influenced hunter-gatherer settlement patterns, landscape use, versatility in the landscape and responses to a variable climate. This poster outlines the project rationale, sites under study, methodologies and initial results.

Dynamics of prehistoric settlement regional patterns governed by cultural and environmental factors in the south east Baltic territory (Lithuania)

Liudas Daumantas¹, Andrej Spiridonov^{1,2}, Lauras Balakauskas¹

¹Department of Geology and Mineralogy, Vilnius University, M. K. Čiurlionio 21/27, LT-03101, Vilnius, Lithuania,

²Institute of Geology and Geography, Nature Research Centre, Akademijos str. 2, LT-08412, Vilnius, Lithuania

Abstract

Predictive modeling is a very effective tool for disentangling human distributional attributes, whether it is used for cultural heritage management, prediction of new archeological sites or research of human-environment. Thus, we applied this approach to study regional distribution patterns of prehistoric settlements in Lithuania. The goal of the study was to estimate how environmental-confinement and regional niche of settlement locations changed throughout prehistory and correlate it with archeological and environmental data. For this purpose we used time-series study design that divided Lithuanian prehistory into 6 periods. Coordinates of prehistoric settlements were extracted from the digital archeological-site dataset PROLIGIS. A set of 21 GIS and PCA environmental variables was used as an input for the random forest and Generalized Additive Model (GAM) analyses. The problematic nature of archeological and spatial data was approached by using dummy variables (simulated as random fields on the basis of original variables) for null hypothesis tests of variables' importance, as well as by validating results with repeated stratified cross-validation and repeating analysis with only precisely dated settlements. Results revealed that there is a marked difference in settlement distribution patterns and "ecological niches" between Neolithic and Bronze Age, while Stone Age and Metal Age periods display intra-group similarity with some small scale trends. Stone Age settlements are environmentally well-confined and characterized by high spatial clusterization. Whereas, location of Metal Age settlements are hard to predict by variables used and their distribution is close to spatial randomness. Nevertheless, Metal Age models have more reliable null hypothesis test scores. Location of Stone Age settlements is mostly confined by amount of water in a region, distance to flint mines and to the sea, ruggedness of region's landscape, ratio of sand to moraine loam area and region's mean slope length and steepness factor. Whereas, location of Metal Age settlements is mostly confined by amount of water in a region, ruggedness of region's landscape, distance to the sea, average slope steepness and average elevation above channel network in a region. We suggest that the observed large-scale settlement reorganization event that happened in Lithuania between Neolithic and Bronze Age is related to the three major events that happened about that time: 1) massive immigration of steppe people into territory of Lithuania, 2) major spread of agriculture and Neolithic 'package', 3) long-lasting drought climatic event. This research was funded by a grant (No. S-LL-18-2) from the Research Council of Lithuania.

Effects of climate and land use on Holocene vegetation in the Italian Lepontine Alps

Lieveke van Vugt^{1,2}, Erika Gobet^{1,2}, Willy Tinner^{1,2}, Christoph Schwörer^{1,2}

¹Institute of Plant Sciences, University of Bern, Switzerland, ²Oeschger Centre for Climate Change Research, University of Bern, Switzerland

Abstract

Mountain ecosystems are extremely vulnerable to climate change, and specifically the tree line ecotone is very sensitive to temperature changes. However, besides climate change, land use is an important factor as well in shaping ecosystem properties, vegetation composition and species distribution. Sediment series from high-elevation lakes provide valuable records of the interactions among climate, humans and vegetation. We present a pollen, spore and macrofossil-inferred reconstruction of the Holocene vegetation from Lago Inferiore del Sangiatto (1990 m a.s.l.), a small lake located close to the treeline ecotone of the Ossola region in the Italian Alps (timberline at ca. 2050 m, treeline ca. 2250 m a.s.l. in the Sangiatto area). Archaeological evidence for human presence in the area surrounding Sangiatto goes back as far as the Mesolithic; the important nearby mountain pass Albrun, connecting the Ossola valley (Italy) with the Valais (Switzerland), was intensively used during Roman times.

The sediment record starts at the end of the Late Glacial and spans the entire Holocene. Analyses of pollen and plant macrofossils show that Swiss-stone pine forests (*Pinus cembra*) established at the onset of the Holocene. The composition of the forest slowly changed to a mixed conifer forest, including *Larix decidua* and *Picea abies*. Increasing human impact and land use (e.g. anthropogenic indicators *Plantago lanceolata* and *Cerealia* pollen) around the lake allowed the mass expansion of *Alnus viridis* during the Neolithic.

To reconstruct the natural fire regimes and the impact of anthropogenic fires we analysed micro- and macroscopic charcoal. Anthropogenic fires, used to create pastures for cattle grazing, may have played an important role in the mass expansion of *Alnus viridis* and the change in vegetation composition around the lake, which resulted in today's pure larch forests.

This study is the first to describe the afforestation processes at the start of the Holocene and the impact of land use on the vegetation of this region. Our results provide important information for nature conservation, for instance for the Alpe Devero Natural Park, in which our lake is located. In particular, the long-term ecological record of Sangiatto may help identifying threats to alpine biodiversity under future climate change.

Anthropogenic and natural drivers of vegetation and fire history along the forest-steppe border of the eastern Andes (38-50°S)

William Nanavati^{1,2}, Cathy Whitlock^{1,2}, Valeria Outes³, Gustavo Villarosa³, Virginia Iglesias⁴, María Eugenia de Porras⁵

¹Department of Earth Sciences, Montana State University, Bozeman, USA, ²Montana Institute on Ecosystems, Montana State University, Bozeman, USA, ³INIBIOMA (CONICET-Universidad Nacional del Comahue), San Carlos de Bariloche, Argentina, ⁴Earth Lab, University of Colorado, Boulder, USA, ⁵Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA), CONICET, Mendoza, Argentina

Abstract

Disentangling anthropogenic and natural drivers of vegetation and fire history at different spatiotemporal scales is a fundamental challenge in Earth Systems science. In the forest-steppe ecotone of southern South America, fire and climate have shaped the position of lower treeline, but the influence of pre-European peoples at the ecotone is less clear. A new 10,800-year history of climate, vegetation, fire, and land use from Laguna Portezuelo (38°S, 71°W, 1730 m elev.), east of the Andes, provides information on pre-European anthropogenic fires in *Araucaria* forest. *Araucaria* was an important resource for pre-Europeans and is ingrained into Mapuche-Pehuenche cultural identity. The pollen record shows that *Araucaria* expanded in the late Holocene with rising human populations and strengthened ENSO. Prior to that, the forest-steppe region supported scattered *Nothofagus* (mostly *N. dombeyi*-type pollen) and moderate-to-high fire activity. Beginning at 6800 cal yr BP, changes in ecotone composition and fire are attributed to increased climate variability and human presence. Increased *Nothofagus* and *Araucaria* pollen and null-to-low fire activity occurred at 1800, 1200, and 800 cal yr BP, in association with increased strength and frequency of wet El Niño events. After 500 cal yr BP, increased abundance of *Plantago*, *Rumex*, and other disturbance taxa (e.g., Apiaceae and Caryophyllaceae) and high fire activity mark Euro-American land use. Non-native *Pinus* pollen in the 20th century indicate the establishment of *Pinus* plantations near Laguna Portezuelo.

Although archaeological investigations suggest that people lived in southern South America east of the Andes since ca. 12,000 cal yr BP, the vegetation and fire history for most of the postglacial period was governed by the strength and position of the SWW storm tracks. From the late-glacial to early Holocene, region-wide increases in fire were associated with aridity while the SWW were weakened and south of their present position. Between 7000-4000 cal yr BP, increased arboreal taxa and decreased fire throughout Patagonia suggest effectively wet conditions, as the SWW moved northward to their present position. After 4000 cal yr BP, a combination of rising human population and greater climate variability, led to spatially heterogeneous but generally rising fire activity along the forest-steppe ecotone. Throughout Patagonia, wet El Niño and/or negative Southern Annual Mode (SAM) events increased biomass, but made the landscape less flammable and reduced anthropogenic burning. Transitions from wet El Niño and/or negative SAM to dry La Niña and/or positive SAM events increased burnable biomass, amplifying anthropogenic burning. During the last 100 years, increased Euro-American settlement and land clearance led to forest loss, more disturbance, and the spread of introduced taxa along the eastern flanks of the Andes. The ecological changes in recent decades far outweigh thousands of years of pre-European human influence on fire and vegetation history.

The change of $\delta^{13}\text{C}$ values in Belizean soil and its implications on Maya agriculture

Katarena Shiner, Julie Hoggarth, Steve Dworkin
Baylor University, Waco, USA

Abstract

The size and extent of the Classic Maya civilization was dependent on the ability to produce sustainable agriculture. The dependence on “rainfall-dependent maize agriculture” would make the Classic Maya people susceptible to drought and other climate variabilities (Hoggarth et al., 2016). In the semitropical Belize Valley, the Maya experienced wet and dry seasons and had to account for each season in their agricultural cultivation (Lucero, 2011). The Maya used diverse cultivation systems including house gardens, terraces, and wetland agriculture systems (raised fields/ditch fields) (Dunning et al. 1998; Fedick 1996). Most of the tropical plants native to the Maya lowlands in Belize use the C_3 photosynthetic pathway (Webb et al., 2004). Maize is the only known cultivated plant using the C_4 photosynthetic pathway in this area, indicating that unless the area was previously a grassland, high $\delta^{13}\text{C}$ values denote the presence of cultivated maize (Lentz, 1999; Tieszen et al., 1993; Webb et al., 2004). Therefore, an identifiable transition in carbon isotope ratios can be used to identify the transition from grassland/forest cover in a region, to agricultural practices focused on growing maize. A preliminary pilot project was undertaken between 2017 and 2018 in which excavations were conducted in the agricultural ditch field system southwest of Baking Pot, Belize. The goal of this project is to determine the climatic conditions and the agricultural use of the ditched field system during Maya occupation at Baking Pot, Belize. Preliminary results from samples collected in 2017 demonstrate an increase in $\delta^{13}\text{C}$ values between 40-60 cm in Ditch 1 suggesting the introduction of maize. Ditch 1 returns to more negative isotopic values below 60 cm indicating a return to native vegetation. Ditch 2 shows similar results with an increase in $\delta^{13}\text{C}$ values between 60-100 cm in and a return to native vegetation below 1 meter.

Testing the effectiveness of high-resolution palynological records for investigating human-environment interactions in the Irish Mesolithic.

James Perkins¹, Laura Basell¹, Gill Plunkett¹, Ingelise Stuijts², Meriel McClatchie³

¹Queen's University, Belfast, United Kingdom, ²The Discovery Programme Lake Settlement Project, Dublin, Ireland,

³University College, Dublin, Ireland

Abstract

Until recently, Mesolithic people were viewed as opportunistic hunter-gatherers who had little control over or impact on their environment whereas Neolithic people were sophisticated agriculturalists, capable of domesticating plants and modifying landscapes through large-scale forest clearance. However, recent interdisciplinary studies from Britain have challenged environmentally deterministic views of Mesolithic people by showing that they were managing and systematically exploiting economically important plants¹, and creating small-scale woodland clearances².

Ireland's Mesolithic settlers also exploited plants for food, fuel and timber but evidence for woodland management is limited. Also, palynological evidence for anthropogenic clearance is negligible because: (a) research into Mesolithic disturbances has been lacking since the 1980's, (b) clearances were potentially overlooked due to a dearth of high-resolution analyses, and (c) few multi-proxy investigations have targeted Mesolithic sites. Consequently, the human-environment interactions of Ireland's Mesolithic occupants are poorly understood.

This paper presents the results of two new, high-resolution palaeoenvironmental studies of key Irish Mesolithic occupation areas³. The first study examines whether the human-environment interactions of the Mesolithic occupants of three sites in County Antrim, Drumakeely, Drumnaglea and Lisnasoo⁴, could be detected in a stand-alone palynological sequence taken from Frosses Bog, within 1 km. of each site. The second study investigates the nature of anthropogenic disturbance at different spatial scales at Derragh Island, County Longford, using published anthracological and archaeobotanical evidence for woodland exploitation^{5,6}, and palynological data derived from two on-site sequences and one off-site sequence obtained from 30m away.

When compared, the results: (1) show that proximal multi-pollen and multi-proxy records provide greater insights into the complexities of Mesolithic human-environment relationships than distal, stand-alone pollen records, and (2) highlight the possibilities and limitations of these approaches. This paper emphasises the urgent need for further multi-proxy/interdisciplinary research into the palaeoenvironmental impacts of Mesolithic people on Ireland's post-glacial woodlands. Only when these impacts are understood can the dynamics of Late Quaternary environmental change in Ireland be fully acknowledged.

A millennium history of river connectivity and anthropogenic disturbances in central China

Lingyang Kong, Guangjie Chen
Yunnan Normal University, Kunming, China

Abstract

Anthropogenic pressure derived from heavy metal pollution, eutrophication and hydrological regulation are known to threaten ecosystem health in many lakes. In the context of millennium-scale climate fluctuation and catchment development, however, little is known about the long-term response of lake biota to the independent impact of multiple stressors. Daye Lake, located in the middle reaches of the Yangtze River, is selected for sediment analyses due to its longest documented history of smelting in central China, as well as its change in connectivity with Yantze River.

Multiple-proxy analyses (e.g. ^{137}Cs and AMS ^{14}C dating, lithogenic metals, heavy metals grain size, X_{if} and cladocerans) provided a millennium history of metal pollution, hydrological fluctuation and ecosystem changes from a 110-cm long sediment core. The grain size results also showed a gradual increase in water level up to ~60cm, and more recently displayed stronger hydrological fluctuation after ~20cm. Particularly, lithogenic metal and X_{if} records show that the catchment development and soil erosion was more intensive prior to ~60 cm and after ~20 cm. While heavy metal input was elevated prior to ~60 cm as observed in previous studies, their concentrations showed a rapid spike after ~20 cm which corresponded well to the severe pollution level of Daye Lake as shown in modern surveys. While TOC and TN results showed a gradual trend of nutrient enrichment before 1950, the process of lake eutrophication has accelerated after 1990s. Accordingly, the cladoceran flux showed a gradual decrease up to ~60 cm, and a clear increase after ~20 cm. Cladoceran assemblages showed a clear replacement of oligotrophic *Bosmina longispina* by *Bosmina longirostris*, prior to ~65cm. After ~1990, *Bosmina longirostris* decreased obviously with a concurrent increase in littoral cladocerans in the context of heavy metal pollution and eutrophication.

Human and environmental dynamics in the crater lakes region of western Uganda during the late Holocene

Julius Bunny Lejju

Mbarara University of Science and Technology, Mbarara, Uganda

Abstract

A sedimentary record obtained from the marginal sites of a crater lake within an archaeological site provides evidence of human and vegetation dynamics in the crater lakes region of western Uganda during the late Holocene, ca. 4,000 years BP. The last ca. 4,000 - 3000 yr. BP is characterized by a period of forest vegetation cover, indicating a phase of wet and moist environmental conditions in the region mainly dominated by swamp forest vegetation (Palmae) taxa. This phase is also characterized by high levels of diatom taxa, suggesting a period of moist conditions. This period was followed by a phase of reduced forest environment, ca. 3,000 - 2500 yr. BP, mainly contributed by less moist C₄ grasses (Poaceae morphotypes) at the expense of C₃ taxa. This period is also characterized by significant increase in proportions of charcoal records, suggesting a period of increased anthropogenic activities reflected by forest clearance and anthropogenic fires. Diatom records also declined to significantly low levels possibly reflecting a reduction in moist environmental conditions. The last ca. 2,000 yr. BP is characterized by episodes of forest and fire fluctuations indicating evidence of anthropogenic activities in the crater lakes region. Generally, this period is characterized by variable anthropogenic activities reported in archaeological records that suggest a period of increased anthropogenic activities in western Uganda, more specifically the last ca. 1000 yr. BP. Significant increase in charcoal records with reduced forest habitat is evident during this period from the last ca. 1000 yr. BP, suggesting increased anthropogenic fires and forest clearance. The last ca. 200 yr. BP is characterized by significant reduction in forest cover at the expense of grass cover (Poaceae morphotypes) mainly contributed by short C₄ Poaceae morphotypes that indicate less moist environmental condition. Charcoal records are relatively high during this period, indicating episodes of increased anthropogenic forest clearance and fire regimes. Generally the last ca. 1000 yr. BP is a period of transition in western Uganda that began approximately around the 10th century AD with significant social, political and economic changes in the region. This period included the emergence of large sedentary settlements with increased population density and the rise of strong political hierarchies centered at major archaeological sites such as Bigo, Ntusi and Munsa.

¹Key Laboratory of Vertebrate Evolution and Human Origins, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China, ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ³University of Chinese Academy of Sciences, Beijing, China, ⁴Liaoning Provincial Institute of Cultural Relics and Archaeology, Shenyang, China

Abstract

Chahai-1 Section, which contains multiple culture layers, provides us the information of human activities and vegetation history from late Pleistocene to middle Holocene in Chahai region, Liaoning Province, northeastern China. Culture layers and AMS14C dating results show that Chahai region had been occupied by humans at 12700~12570 cal BP, 10200~9300 cal a BP and 7200~6300 cal a BP. Fossil pollen results of Chahai-1 Section show a process of increased humidity and the vegetation was converted from shrub grassland to forest grassland before 12700 cal a BP. Then an arid steppe landscape was presented at about 12700~12570 cal a BP, and forest disappeared in this region. The vegetation was dominated by meadow grassland with few trees between 10200 and 6300 cal a BP. A dramatic increase in tree revealed the temperate deciduous broad-leaved forest recovered in this region and then which was converted into sparse-wood grassland or shrub grassland after 6300 cal a BP.

The relation between vegetation and human could be divided into three stages: (1) Rational utilization period: the period between 12600 and 9300 cal a BP, lifestyle was dominated by hunting and gathering, local vegetation was little influenced by human activities. (2) Excessive utilization period: population expansion intensify conflict between resource and human during 7200~6300 cal a BP, lots of trees were felled, which caused an abnormal phenomenon that grassland landscape exhibited in Holocene optimum. (3) Ecological recovery period: accompanied with weakened human activity intensity after 6300 cal a BP, forest recovered in Chahai region rapidly.

Environmental conditions of Neolithic settlement development on the northern edge of Sandomierz Upland (Poland)

Przemysław Mroczek¹, Marcin Szeliga², Radosław Dobrowolski¹, Irena A. Pidek¹, Jacek Chodorowski³, Andrzej Plak³, Mirosław Furmanek⁴, Maksym Mackiewicz⁴, Piotr Bartmiński³, Marcin Siłuch⁵

¹Department of Geomorphology and Palaeogeography, Maria Curie-Skłodowska University, Lublin, Poland, ²Institute of Archaeology, Maria Curie-Skłodowska University, Lublin, Poland, ³Department of Geology and Soil Science, Maria Curie-Skłodowska University, Lublin, Poland, ⁴Institute of Archaeology, University of Wrocław, Wrocław, Poland, ⁵Geoinformation Laboratory, Maria Curie-Skłodowska University, Lublin, Poland

Abstract

The area of geoarchaeological studies is located on the border between the loess Sandomierz Upland and the sandy-loamy areas of the Iłża Foothills (central Poland). Numerous traces of human activity from the Middle Palaeolithic to modern times have been documented in this area. Detailed research was carried out in the mouth of the Przepaść River to the Kamienna River near Ćmielów. The main objective of the research was to comprehensively reconstruct human settlement and economic activity in the study area in the last ~10,000 years, along with identifying its conditions, both at the chronological-cultural and the environmental level. The greatest emphasis has been placed on the identification of settlement processes during the Neolithic period (6th-3rd millennium BC) as well as their any environmental conditions and consequences in areas beyond the reach of compact loess formations, i.e. within the ecological and landscape regions significantly deviating from the typical settlement preferences of early agricultural communities.

Environmental fieldwork was conducted within and around early Neolithic archaeological sites associated mainly with the settlement of early agricultural communities cultivating the Danubian cultural traditions developed between the 2nd half of the 6th and the end of the 5th millennium BC. In selected archaeological sites, non-invasive geophysical (magnetic) surveys were carried out in the preliminary phase, which revealed the existence of remnants of extensive settlements with permanent residential buildings. This was confirmed by the conducted excavation research, which led to the discovery of the relics of so-called long houses – typical residential constructions of the communities of both mentioned archaeological cultures. GIS analyses and a series of laboratory works, including: lithology, geochemistry and paleobotanical studies complemented the field studies. The spectrum of research has been extended to include radiocarbon dating.

The obtained results of the analysis were used to reconstruct the natural environment for two geomorphologically different and neighbouring regions. A different geomorphological link between the two areas is the valley of the aforementioned rivers dissecting them with a system of different-age terraces, which are rich in geo-archives of human activity in the past. Based on the obtained data, important palaeoenvironmental and cultural periods were determined, referring to the time interval from the Upper Plenivechelian (the Late Palaeolithic), through the complex Holocene (especially the Neolithic), to modern times associated with particularly anthropopressure (including erosion) of the entire study area. The most comprehensive correlation of geoarchaeological results was obtained for the Middle Holocene, and especially the Atlantic period, for which the largest amount of diverse data was collected. These results document the permanent and intensive settlement and economic activity in this period and the associated strong anthropopressure resulting in clear transformations of the local natural environment.

The study was supported by National Science Centre, Poland (grant no.: 2015/19/B/HS3/01720).

Radiocarbon of phytolith reveals rice domestication began at about 10,000 years ago

Xinxin Zuo¹, Houyuan Lu², Leping Jiang³, Jianping Zhang²

¹Fujian Normal University, Fuzhou, China, ²Institute of Geology and Geophysics, CAS, Beijing, China, ³Zhejiang Provincial Institute of Relics and Archaeology, Hangzhou, China

Abstract

Rice is one of the world's most important staple foods, sustaining more than half of the global population. Research into when, where, and in what kind of environmental background the rice was domesticated have led to a considerable amount of attention in the last decade.

Rice remains found at the Shangshan site in the Lower Yangtze may represent the first instance of rice cultivation. However, organic materials were poor-preserved at the site because of the acidic soil conditions. So, debate exists as to whether the rice is domesticated, wild, or transitional. The chronology of the Shangshan site was also unclear. Accordingly, further dating initiatives are needed to constrain the absolute-calendar time of the rice remains.

Phytoliths can occlude some organic carbon during their deposition, which is captured through photosynthesis from atmospheric CO₂ during plant growth. Carbon occluded in phytoliths thus can directly reflect the age of the organic sources exploited by humans. We carried out phytolith carbon-14 studies on three archaeological sites from Shangshan culture. The results showed that phytolith dates were consistent with their paired charcoal or seeds dates. Two phytolith dates from the early (upper layer of the eighth cultural stratum) and late stages (upper layer of the fifth cultural stratum) of the site range in age from 9,417-9,134 calibrated years before the present (abbreviated as cal yr BP) to 8,175-8,012 cal yr BP. This suggests that the initial occupation of Shangshan may have occurred at about 9,400 cal yr BP or perhaps somewhat earlier around 10,000 cal yr BP, because phytolith sample SH-8 was retrieved between the seventh and eighth cultural strata of the site.

The detailed studies on rice bulliform phytolith morphological characteristic showed that approximately 36% had more than nine fish-scales in the early occupation stages of Shangshan and Hehuashan (ca. 10000 to 9000 cal yr BP), less than the approximately 60% counted from the late stages of Hehuashan and Huxi (ca. 9000-8500 cal yr BP). However, there was a significantly larger amount of rice bulliforms with more than nine fish-scales in the early stages compared to modern wild rice ($17.5 \pm 8.3\%$), suggesting that the process of rice domestication have begun at Shangshan in the Lower Yangtze of China during the beginning of the Holocene.

Such an age for the beginnings of rice cultivation and domestication would agree with the parallel beginnings of agriculture in other regions of the world during a period of profound environmental change when the Pleistocene was transitioning into the Holocene. Climatic amelioration during these transitional periods may thus serve as key factors in the early process of rice domestication.

A chronological study of wooden columns excavated at the Mawaki archeological site of the Noto Peninsula, central Japan

Toshio Nakamura¹, Masaaki Kanehara², Masayo Minami¹, Hideki Takada³

¹Nagoya University, Nagoya, Japan, ²Nara University of Education, Nara, Japan, ³Noto-Town Board of Education, Noto, Japan

Abstract

The Mawaki site is located on the eastern coast of the Noto Peninsula, central Japan. It consists of alluvial coastal plain with area of about 11 ha. The site was discovered beneath cultivated fields and is located between a hilly terrain and the present day coastal residential area. In 1982 and 1983, an archeologically important discovery occurred owing to farmland consolidation, and many dolphin bones were discovered along with remains of Jomon pottery. Some dolphin bones were radiocarbon dated around 5600 cal BP. This was a very important discovery as regards evidence of past human subsistence strategies. The site represents a village with evidence of habitation from around 6000 to 2400 cal BP. The early part of this period was marked by a Holocene high sea level in Japan. The period corresponds to the Early through Final Jomon periods of the Japanese archaeological timescale. The archeological excavations suggested three important stages of this site: (a) a dolphin bone layer including Jomon pottery fragments as thick as 1 m (6000-5000 cal BP); (b) several tombs of human laid on the wooden plates (5200-4500 cal BP); (c) wooden pillar remains forming a structure of wooden houses and the circular array of wooden columns considered as a special monument (3500-2400 cal BP). In the study of the 3rd stage, we have excavated more than 60 pillar remains, in the area of 20 m x 20 m. We have analyzed the species of each tree and found out that the pillars were consisted of two tree species. The 2/3 was Japanese chestnut tree and the remaining 1/3 was hiba arborvitae. Radiocarbon dating all of them suggested that the calibrated ages were from 3500 to 2400 cal BP. The pillars with older ages were mainly hiba arborvitae and younger ones were Japanese chestnuts tree. This trend suggests that ancient people did a selection of tree species for building their houses. Otherwise, hiba arborvitae was growing early period and then chestnut trees became abundant later time, maybe depending on the local environmental change. A unique monument, the circular array of wooden columns made of chestnut trees, located about 30 m north from this area were dated to be about 2800 - 2500 cal BP. The monument was constructed by ancient people lived the place. In addition, as a second example in Japan, a wooden plate (39.1 cm long, 5.5 cm wide, 1.8 cm thick) used as a tool to make fire by friction rotating wooden stick on it was detected in the same area of wooden pillars. The species of the plate was Japanese cedar. It was dated to be 3300 cal BP, consistent with the ages of wooden pillars.

Abstract

A detailed vegetation and environmental reconstruction for the Weichselian Lateglacial interstadial in the Moervaart area (NW Belgium) is discussed in relation to former human occupation patterns. The reconstruction is based on a multi-disciplinary research carried out on calcareous deposits of one of the largest palaeolakes (~25 km²) that existed during the Lateglacial interstadial in NW Europe. The combination of geophysical (magnetic susceptibility, micromorphology, organic matter, calcium carbonate), botanical (pollen, macrofossils, diatoms), zoological (chironomids, molluscs, ostracods) and geochemical analyses (stable carbon and oxygen isotopes) allowed for a highly detailed reconstruction of the lake ecosystem and vegetation surrounding the lake. The chronology of the lake record was provided by radiocarbon dating and comparison with the nearby Rieme sites and regional biostratigraphy.

During the Weichselian Lateglacial (GI-1), as result of climate amelioration, the vegetation and geomorphology of the Moervaart coversand landscape changed from a tundra landscape to boreal forest with initially birch but later also pine. In the Bølling period (GI-1e), the Moervaart palaeolake started to form caused by a major rise of the groundwater table in the area. Waterlevel rise continued during the early Allerød phase (GI-1c) and a rich waterflora and fauna developed in the lake, while in the lake environment birch woodlands expanded. From this period onwards, the area provided a suitable landscape for the *Federmesser* Culture hunter-gatherers with fresh drinking water, extensive and fertile woodlands and lake edges for wild game hunting, plant gathering and fowling. Waterlevels rose to a maximum at the end of the early Allerød. Thereafter, an outlet for the lake was formed in the east. As a result, water levels gradually decreased during the middle to late Allerød and eventually the Moervaart lake turned into a swamp and ceased to exist. In combination with the prevailing colder conditions, this led to a marked population decrease with probably temporary abandonment of the region.

Abstract

The project comprises an interdisciplinary approach combining archaeopedological and archaeological methods for the reconstruction of Bronze Age settlement patterns and land use practices in three landscapes in SW-Germany (Hegau, Western Allgäu, Baar), which are different in physical-geographical conditions and archaeological records. Hegau is assessed as favourable and both Western Allgäu and Baar as unfavourable for prehistoric subsistence. However, since favourability is not exclusively a function of natural deterministic conditions, we assume that material and immaterial requirements such as agricultural practices, knowledge, religious and cultural beliefs may have changed through time and space. The presentation focuses on first archaeopedological and archaeological results at the study site Anselfingen (Hegau).

Bronze Age archaeological structures like post holes or fire places and findings like pottery, bones and metals within the settlement and its vicinity are discussed. Hence, based on first ¹⁴C-datings of settlement features and typological analysis, initial conclusions can be drawn about settlement chronology, duration and activity areas.

Archaeopedological data acquisition is based on the analysis of multi-layered colluvial deposits (Zádorová et al., 2018, Henkner et al., 2018, Pietsch and Kühn, 2017). They can be interpreted as the correlative sediments of human-induced soil erosion and as archives to reconstruct land use practices and landscape evolution (Henkner et al., 2017, Lepeold and Völkel, 2007). First chronostratigraphies comprising luminescence dating techniques (OSL), AMS-¹⁴C radiocarbon datings and typological classification of archaeological findings are presented for the study site. The results from field work provide us with archaeological and archaeopedological assumptions for all three landscape units. Supplemented by pedological data (SOC, pH, CaCO₃, grain size distribution, pedogenic oxides), phases of geomorphological stability (pedogenesis) and activity (soil erosion) of colluvial deposits will be discussed. Data sets of heavy metals, phosphorus, enzymatic activity (e.g. urease), black carbon and steroids (sterols, stanols, stanones) are used to decipher human-environment interactions like ore processing, intensified anthropogenic input (waste, dung), fire management and domestication practices in the settlement complex.

Guatemala's tropical lowlands yield many of the most famous Maya archaeological sites. Today covered by the tropical forest of Petén, the adaptation of Mayan societies to such a closed environment raises many questions for paleoenvironmentalists. The study of vegetation dynamics, in response to climatic and anthropogenic forcing, is particularly complicated due to the absence of bio-proxies such as pollen or charcoal, poorly preserved in this tropical region. Phytoliths offer an important alternative fossil records for landscapes reconstruction in the Maya zone for many reasons: i. They are formed in plant tissues and therefore have a taxonomic signature, ii. Their siliceous nature allows a better preservation in terrestrial sediments. iii. The deposition processes, by in-situ decomposition of the plant, make them excellent local vegetal indicators. Although little studied, they have a great potential for the vegetation dynamics reconstruction, as evidenced by their richness on the Naachtun sediments.

The classic Mayan site of Naachtun (150 BC - 950 BC) is located in the middle of the central lowlands of Petén. It is bordered to the north by a large karstic polje (bajo) recording deposits covering the Mayan settlement period of the city. Using a general approach, this study was conducted on 150 phytolith samples. The preliminary work linking current botanical ecosystems to the phytolith assemblages from current soils was necessary to test the potential of phytoliths in such closed environment. Thus, 40 samples from current forest environments of the Naachtun site and 30 samples from current agricultural fields in the village of Uaxactun were studied to build a modern phytolith reference. Finally, that allowed us to study a hundred fossil samples from the bajo and intra-site deposits of Naachtun territory.

Results indicate than opening of the bajo forests to the preclassic period as supported by the dominance of herbaceous morphotypes (GSCP - Grass Short Cell Phytoliths) and the presence of Cyperaceae and Commelinaceae. This opening of the environment is also found in intra-site soundings where the herbaceous signal is present. The phytoliths in Naachtun deposits also allow us to study the dynamics of the wetland (sival) in the centre of the bajo. The high proportions of Cyperaceae and aquatic bioindicators (molluscs, sponges spicules, diatoms) in the more carbonate layers of the boreholes are witnesses to it. While many hypotheses remain to be tested, particularly concerning agriculture, our study demonstrates the potential of phytoliths in the Maya zone. These observations applied to both in-situ and offsite scale, help to understand the socio-environmental dynamics on a territorial scale.

P-4230

Size Distribution of Neolithic Sites in the Middle Reaches of the Yangtze River

LI Fengquan, ZHU Lidong, WANG Tianyang, YE Wei

College of geography and environmental science, Zhejiang Normal University, Jinhua, China

Cultural sites are relics of human activity and they are also the product of the interactions between human and nature. The size of cultural sites could reflect the population size and grade of the ancient settlements. The study of cultural sites could help us to deepen the understanding of the relationships between human and nature. This paper established the spatial database of the Neolithic cultural sites in the middle reaches of Yangtze River from 9000 a BP to 4000 a BP by using ArcGIS software. Overlay analysis and statistical method were employed to examine the spatial relationships between the size of archaeological sites and elevation, slope, the distance to the river in different periods. The results showed that, from the early Neolithic period to the late Neolithic period, the number of sites, the size of sites and the spatial distribution range of the sites showed an increasing or expanding trend, and the proportion of overlapping sites increased; Sites with different sizes generally had low altitude, gentle terrain and near river selection tendency. For sites of the late Neolithic Age, while there existed the above-mentioned selection tendency, the selection of altitude, slope and the distance to river tended to show the characteristics of diversification. There were some differences in location selection of Neolithic cultural sites with different sizes in the late Neolithic period. Small sites were mostly located on the gentle slope of 6-15 degrees. The large or medium-sized sites tended to be distributed on the flat land with a slope of 2-6 degrees; From small to large sites, Neolithic sites was dominated by an elevation of 30-50 m. The elevation of super sites was mainly in a range from 50 m to 100 m. The super sites were located in the area less than 1 km far from the river; The Neolithic culture was greatly influenced by the natural factors such as climate, water resources and topography in the early and middle Neolithic Age, and the adaptation ability of culture in the late Neolithic period was gradually enhanced.

Human-environmental interactions during the Early Holocene in the central region of Eastern Iberia: settlement dynamics and foraging adaptations

Javier Fernandez-Lopez de Pablo^{1,2}, Elodie Brisset^{1,2}, Magdalena Gómez-Puche^{1,2}, Ana Polo-Díaz^{1,2}, Francesc Burjachs^{1,2,3}

¹Institut Català de Paleoecologia Humana i Evolució Social (IPHES), Tarragona, Spain, ²Àrea de Prehistòria, Universitat Rovira i Virgili, Tarragona, Spain, ³Catalan Institution for Research and Advanced Studies, Barcelona, Spain

Understanding the variable impacts of Early Holocene climatic and environmental shifts on prehistoric hunter-gatherers is often challenged by the paucity of integrated research programs analyzing human and climatic systems.

In this paper we present a synthesis of an interdisciplinary research program to study human-environmental interactions along the Early Holocene in the central region of Eastern Iberia. This sub-regional unit provides a unique opportunity to examine the effects of the postglacial sea level rise, expansion of forests and aridity events on human subsistence and mobility strategies.

Within this region, two different local units -located in the coastal and inland extremes of a regional settlement network- have been investigated producing primary paleoecological and archaeological data from Mesolithic human settlement areas: the Pego-Oliva marsh, in the south of the Valencian Gulf, and the Upper Vinalopó Valley, 90 km away inland. The analyzed palaeoecological records provide robust evidence of significant environmental transformations, in both coastal and inland locations, along the Early and Late Mesolithic periods.

In the Pego-Oliva marsh, the inland migration of the coastline was associated to the progressive disappearance of coastal plains and the dramatic contraction of lagoon biotopes. Zooarchaeological and bioarchaeological records show a decrease on shellfish productivity, species diversity of game and shifts in human paleodiets, particularly with a decreasing contribution of marine-origin proteins. These transformations on subsistence patterns seem to be driven by a dramatic drop in environmental carrying capacity, prompting a change in the occupation strategies of this area during the Late Mesolithic.

In the Upper Vinalopó Valley, the multi-proxy analysis of two lake records show the progressive expansion of evergreen and deciduous *Quercus* woodlands during the Preboreal, as well as recurrent events of aridity affecting the palaeo-hydrological budget. This pattern of recursive aridity events is interrupted during the Boreal chrono-zone when the archaeological radiocarbon records clearly reflect an increase of human activity in Early Mesolithic residential camps. Finally, the 8.2 kya event is clearly identified in both lake records and archaeological stratigraphic sequences signaling a short period of increasing aridity and hypersaline lake conditions.

The observed transformations are consistent with the settlement and population dynamics at regional scale, reflecting a dramatic drop in the number open-air residential sites and the radiocarbon activity signals during the 8.2 kya climatic event.

Use of GIS technology for the analysis of Prehispanic settlement patterns in the Holocene Paraná Delta (Argentina)

Jimena Roldan^{1,2}, Daniela M. Kröhling^{1,3}

¹CONICET, Santa Fe, Argentina, ²FICH. Universidad Nacional del Litoral, Santa Fe, Argentina, ³Universidad Nacional del Litoral, Santa Fe, Argentina

The research of Prehispanic cultures in the Paraná Delta (PD), a system that evolved after the mid-Holocene sea-level high stand (17.400 km²), has received a recent increase. More than 90 archaeological sites were registered, being in different study stages. Their economy was predominantly hunter-gather-fisher type, with high territorial mobility. The study scale used in archaeological investigations is spatially restricted and doesn't allow a good overview of the relationship established between those settlements and the landscape all over the PD. The analysis of the areal distribution of settlements indicates a significant geomorphological control. Archaeological and geological data were used to elaborate a geo-archaeological map for understanding the complex relationships between the population dynamic along the Holocene PD and the paleoenvironmental conditions. The methodology employed was the use of free GIS software (QGIS, GRASS) and satellite images, with field control, also chronological data obtained by others authors in some landforms of the Holocene PD were considered. Most of human settlements are found on fluvial levees, over which mounds of complex stratigraphy were in general anthropically built, and partially modified by river flooding. Those settlements tend to concentrate at the upper and lower parts of the Holocene PD. This pattern could be related to the geomorphological characteristics of the delta and the associated dynamic, or/and to the present-day anthropic activity that had not allowed the recognition of archaeological sites at the middle part of it (wave-dominated growth stage of the PD). At the lower part, most of the sites concentrate where the anthropic activity has recently increased, few of them are found on the Tidal plain and the Distal zone with cheniers geomorphological units (middle-lower part of the PD). In the upper part of the Holocene PD (fluvial-dominated growth stage with inter-distributary bays), sites distributed on fluvial landforms. Few sites are found at the mid-Holocene Beach ridges geomorphological unit (wave-dominated part of the PD), even though local people refer some archaeological findings. The first populations settled between 2.0 and 1.7 ka. BP, after that the settlements diversified along the PD. The oldest found settlements are on the Tidal plain geomorphological unit, at the middle part of the PD. Moderate wind to windy environmental conditions were deduced from geomorphological indicators for that period. After 1.7 ka. BP, the PD developed its lower part (fluvial-dominated). Warmer and less windy conditions allowed human occupation of the lower delta plain, and its dispersion through the entire delta system. The study scale of geoarchaeology allows to collect valuable data for the archaeological record, especially when there are many human settlements in a very dynamic landscape such as the PD. This work can contribute to a better understanding of groups organization and their relationships with the landscape.

Human-environment interactions in northeast Iceland: the impact of baseline environmental conditions on post-settlement system responses

William Hiles, Ian Lawson, Richard Streeter, Katherine Roucoux
University of St Andrews, St Andrews, United Kingdom

The impact of a forcing mechanism on a system may be affected by the system's baseline conditions, and in pristine and unsettled environments these baseline conditions will in large part be controlled by long-term climatic conditions. Perturbations can be caused by natural processes such as climatic deterioration and tephra fall, and human activity such as deforestation, burning, and grazing by domesticated animals. Increasing elevation and decreasing temperature may increase the vulnerability of a system to change, and this is particularly important in marginal areas where organisms exist close to their ecological limits. Settlement in such marginal environments can be risky and unsustainable, and understanding the responses of these environments to interacting natural drivers and human activities presents a challenge in palaeoenvironmental reconstructions. Comparative studies with sites at varying distances from a margin can provide insights into these issues, but such comparisons are often hindered by chronostratigraphic uncertainties.

Iceland presents a well-controlled environment in which to develop understanding of human impacts on environments over large spatial scales. Precisely dated tephra layers allow the construction of robust chronologies with smaller uncertainties than other dating techniques and provide isochrons that permit chronostratigraphic correlation of sequences across large areas. This allows inter-site comparisons to be made with enhanced confidence. The late settlement in the late AD 9th Century provides a long-term, human-free baseline against which to compare subsequent changes. The relatively simple subarctic flora, with only *Betula pubescens* forming significant woodlands, permits past vegetation and land-use to be inferred relatively straight-forwardly. Finally, the Norse settlers imposed a system of land-use developed in other regions, introducing grazing herbivores to Iceland for the first time. This marked a significant change in the pressures on local ecosystems. Overall, Iceland presents a case study for the rapid introduction of human pressures on an environment that to that point had developed in isolation from human activity. It should preserve significant anthropogenic signals in both terrestrial and lacustrine systems that may be relevant to understanding human activity in regions with more complex settlement histories and more diverse ecosystem responses.

This paper presents palaeoenvironmental reconstructions from five lakes distributed along a 30 km transect spanning a 350 m elevation range in Mývatnssveit, northeast Iceland. Multiproxy data, including pollen, non-pollen palynomorph and carbon:nitrogen ratio data, are used to develop understanding of baseline pre-settlement vegetation and lake systems and changes to these upon settlement. These reconstructions are then compared on a regional scale to test the hypothesis that more marginal upland sites were more susceptible to human-induced change. This study develops one of the densest networks of palaeoenvironmental reconstructions in the North Atlantic region and significantly enhances knowledge of the complexity of regional landscape responses to the onset of human activity.

P-4234

Environmental evolution of the Murgab delta as an important factor of Bronze age population dynamics (Margiana civilization)

Redzhap Kurbanov^{1,2}, Mikhail Svistunov¹, Robert Sataev³, Nadezhda Dubova³

¹Institute of Geography RAS, Moscow, Russian Federation, ²Geography Faculty, Moscow State University, Moscow, Russian Federation, ³Institute of Anthropology RAS, Moscow, Russian Federation

A huge necropolis, dating back to the III Millennium BC, was found in the Mary oasis (Turkmenistan) during the Margian archaeological expedition under the leadership of V. I. Sarianidi in 1972. The monumental cult complex, excavated at Gonur Depe settlement, was a large regional Zoroastrian center in Margiana. The complex was located on a low hill on the right Bank of the Murgab riverbed. It was a capital city, with the Palace and several temples, able to compete with the buildings of Assyria and Babylon. It is the largest settlement in Margiana. The area of the ancient settlement ranges from 20 to 50 hectares. The Temple city existed until the end of the XVI century BC. Its Central part is the Kremlin with a Palace in the center, which is surrounded by walls with rectangular towers. The earliest of the famous Temples of Fire was built outside these walls on the East-side. The system of two basins, the main of which has a size of 100 to 60 m was adjoined from the South to the walls of the settlement. Almost all the authors agree that the important factors determining the historical processes in the III-II thousand. B.C., are natural and demographic: intense aridization in the middle of the III Millennium B.C. (including that caused by believed intensive farming), and high population density in the "Crescent of fertility", formed as a result of the Neolithic revolution (Bar-Matthews et al, 1997; Gibbons, 1993; et al). This situation definitely influenced the increase in mobility of the population, called it a significant move. These processes have not been fully studied in Turkmenistan. A special place in understanding, in particular, the possibilities of extensive migrations from the Eurasian steppes to the southern agricultural areas, takes information about the hydrological regime of large rivers in the region. We have analyzed the space images of the Murghab Delta, performed a field geomorphological study of ancient channels. Highlighted the main pagliarulo, located to the West of the settlement from which in ancient times there was a canal to a large receiving pool. Apparently, the desolation of Gonur-Depe is associated with the development and movement of this channel to the West by 15 km. New data on the morphology and age of development of the Gonur-Depe paleoruseel system will give a new look at the history of the Margiana civilization.

Reconstructing human-induced fire from archaeological sites of Belan valley, north-central India

Deepak Jha, Rahul Samrat, Prasanta Sanyal

Department of Earth Sciences, Indian Institute of Science Education and Research Kolkata, Mohanpur, India

Fire disturbance appears to be one of the vital processes in shaping vegetation composition and landscape dynamics of an area. It is an important driver of ecosystem structure, in close association with environmental conditions. Environmental factors, as well as human, can equally induce the fire at the stand. Untying the natural and anthropogenic factors is important to comprehend the paleoclimatic conditions at a regional and global scale. Therefore, identifying the fire events from archaeological sites would provide an opportunity to decode its cause and impact on the terrestrial environment. Hence, the present study is conducted on middle Paleolithic to Neolithic archaeological sites preserved in alluvial soils of Belan valley, north-central India.

In this study, 48 paleosols sampled from six archaeological sites of Belan River. Paleosols were analyzed for *n*-alkane distribution pattern and micro-charcoal as a paleofire proxy. To understand the fire-vegetation linkage, $d^{13}C_{C29}$ of *n*-alkanes has also been measured. The *n*-alkane distribution pattern, carbon preference index (CPI_{25-33}) and average chain length (ACL_{15-33}) helps in delineate the source apportionment of organic matter (OM) in the alluvial soils which suggest a dominant contribution from terrestrial plants. Three samples of lower CPI_{25-33} (~1.0) and ACL_{15-33} (~23.0) observed which suggest enhanced degradation of OM. The lower CPI_{25-33} sample shows a particular predominance of mid to short-chain even-numbered carbon (maximum at *n*-C₁₆ or *n*-C₁₈) which was also observed in the previous study from the archaeological site (Eckmeier et al., 2009). Additionally, micro-charcoal analyses in paleosols (n=48) were performed. The degraded paleosols exhibit micro-charcoals which endorse its exposure to fire. However, micro-charcoal concentration peaked at ~8 ka BP. Hence, the paleofire observed in the Belan valley at i) ~97 ka BP, ii) ~58 ka BP, iii) ~26 ka BP and iv) ~8 ka BP. The $d^{13}C_{C29}$ of *n*-alkanes showed the dominance of grassland between ~30 to ~25 ka BP with the cool and dry environment due to Large Glacial Maximum (LGM) which was favorable for wildfires. Further, the fire event at ~26 ka BP temporarily overlaps with Mahagara and Koldihwa archaeological site. The absence of any major sign of thermal alteration of paleosols (supported by *n*-alkanes) in Koldihwa and Mahagara indicates the local nature of the paleofire events. Therefore, the present study observation of paleofire events was mostly induced by hominin groups living in the Belan valley. The fire disturbance increases in the early Holocene to mid-Holocene overlaps with the timing of domestication of agriculture in the Belan valley.

E. Eckmeier., GLB.Wiesenberg., 2009. Short-chain *n*-alkanes (C₁₆-C₂₀) in ancient soil are useful molecular markers for prehistoric biomass burning. *Journal of Archaeological Science*, 36, 7, 1590-1596.

P-4236

Sex-specific protein markers as a tool for exploring animal population structure and dynamics

Eden Richards-Slide^{1,2}, Matthew Collins^{1,3}, Marc Dickinson², Kirsty Penkman²

¹University of Copenhagen, Copenhagen, Denmark, ²University of York, York, United Kingdom, ³University of Cambridge, Cambridge, United Kingdom

Faunal remains hold a wealth of information and can provide important insights into animal populations from the past. In order to study population structures and changes, faunal assemblages need to provide key pieces of information: species ID, sex and age at death. Age can be determined through traditional morphological methods, while species ID and sex can be more problematic as they rely on certain elements of the skeleton surviving and being associated with other morphologically identifiable parts. Analytical methods can be applied to these faunal assemblages to help provide species identification and sex, allowing information about population structure and diversity over a variety of time periods and environments. For example, ancient DNA (aDNA) analysis can be applied to provide both identification and sex information, but it is dependent on the level of molecular preservation, which is greatly influenced by age and environmental factors. Zooarchaeology by mass spectrometry (ZooMS) can provide good species distinction based on the more stable proteins in cases where aDNA preservation is poor; however the sex of an animal can not currently be identified. ZooMS is also a relatively rapid and inexpensive testing method allowing larger collections and assemblages to be analysed.

The goal of this research is to further develop a method of sex identification based on current proteomic methods applying nanoflow-liquid chromatography coupled with tandem mass spectrometry (nanoLC-MS/MS) to large assemblages of ancient teeth. Enamel, which commonly survives in archaeological sites, contains low concentrations of endogenous protein. One of the proteins present is amelogenin, which is expressed from genes on both the X and Y chromosome. The peptide sequences expressed differ between these genes, and therefore could be used as a possible indicator of sex. Through a combination of amino acid composition, racemisation and proteomic analysis of modern and subfossil tooth enamel, we are going to explore the preservation of sex-specific sequence differences to provide an alternative method for sex identification. This method, coupled with ZooMS and morphological analysis could result in the age, species and sex of an individual being identifiable from one single tooth. The potential of this method is that it will allow the rich faunal assemblages from palaeontological and archaeological deposits to yield more detailed information about mammalian population structure. This will allow better interrogation of the responses of ecosystems to human occupancy (particularly with respect to domestication and migration).

Carbon source and production rate influence carbon sequestration in Rostherne Mere

Evelyn M Keaveney¹, Alan D Radbourne², David B Ryves², Suzanne McGowan³, Paula J Reimer¹

¹Queen's University Belfast, Belfast, United Kingdom, ²Loughborough University, Loughborough, United Kingdom,

³University of Nottingham, Nottingham, United Kingdom

We explored the roles of phytoplankton production, carbon source, and human activity on carbon accumulation in a eutrophic lake to understand how catchment management can influence carbon sequestration in lake sediments. Water samples were analysed to investigate contemporary carbon sources. $\Delta^{14}\text{C}$ measurements from dissolved organic carbon indicated a terrestrial source linked with roadway construction in the catchment. We used multiple proxies to determine production rates and carbon sources in a 55 cm sediment core from Rostherne Mere ((RM), UK). Alterations to net primary production were linked with nutrient input from sewage treatment works in the catchment. Stepped combustion radiocarbon was used to separate carbon fractions by sequentially combusting the sample at 400°C and 850°C and collecting the CO_2 after each combustion. This method identified that RM sediment comprised between 11% and 69% recalcitrant carbon in the depths analysed, with changes in carbon character coinciding with peaks of accumulation rate. The quantity of autochthonous carbon buried was related to diatom biovolume accumulation rate (DBAR) and decreased when diatom accumulation rate and valve size declined, despite an overall increase in net carbon burial. High performance liquid chromatography pigment analysis indicated that the changes in diatom accumulation were related to proliferation of non-siliceous algae. We found that total algal accumulation rate controlled sediment organic carbon accumulation rate while DBAR was correlated with how much of each carbon source was buried.

To further delineate carbon sources in the lake, sediment samples will be analysed in the new Ramped Pyrolysis/Combustion facility in the ¹⁴CHRONO Centre in Queen's University Belfast. Ramped Pyrolysis (RP) is a technique that incrementally heats a sample, and allows for collection of the CO_2 produced for isotopic and radiocarbon analyses. CO_2 is produced from sediment according to the degradative properties of the sample analysed as temperatures increase. RM sediment will undergo this method and CO_2 will be collected from multiple fractions as CO_2 peaks are identified. Labile and recalcitrant carbon identified with stepped combustion can be attributed to multiple autochthonous or allochthonous sources using RP. Water DOC and POC will also undergo RP to distinguish contemporary carbon sources in the lake.

P-4238

The diatom-inferred pH reconstructions for an alpine lake in the Tatra Mountains using two different training sets

Elwira Sienkiewicz¹, Michał Gąsiorowski¹, Ladislav Hamerlik²

¹Institute of Geological Sciences P.A.S., Warsaw, Poland, ²Department of Biology and Ecology, Matej Bel University, Banská Bystrica, Slovakia

The reconstruction of water pH based on diatom communities (diatom-inferred pH; DI-pH) for Przedni Staw Polski (PSP) was performed using AL:PE training set and the Polish-Slovak training set (POL_SLOV). A modern AL:PE diatom pH calibration dataset consists of diatom data together with water environment parameters from 118 high-latitude or high-altitude lakes in the Alps, Norway, Spain, Svalbard, Kola Peninsula, Slovak, Poland, Slovenia, Portugal and UK. The POL_SLOV training set consists of data from 11 lakes located in the Polish part of the Tatra Mts. and 22 lakes located in the Slovak part of the Tatra Mts. To reconstruct of the water pH in PSP was used the weighted average method (WA) with the inverse deshinking, as this method gave the highest squared correlation between inferred and observed values (R^2) and the lowest root mean squared error for the training sets (apparent RMSE). The WA pH-inference model based on AL:PE dataset gave R^2 of 0.78 and RMSE of 0.36 units pH. However, for the POL_SLOV training set these parameters of reconstruction were better to compare with AL:PE dataset; R^2 equaled 0.94 and RMSE – 0.16 units pH. Fossil diatom flora from PSP is well represented in the modern POL_SLOV training set: the species that occurred in both the fossil samples and the training set varied between 93.5 and 100 %. The values of DI-pH based on AL:PE dataset were wider range (DI-pH = 6.69-7.07) than based on the POL_SLOV dataset (DI-pH = 6.65-7.28). General trend of the pH curves is similar with the exception of period since the end of the 1960s to today. In this time, PSP was dominated by planktonic *Discostella pseudostelligera* (Hustedt) Houk & Klee and *Fragilaria nanana* Lange-Bertalot. The reconstruction of water pH based on AL:PE training set indicates decreasing trend in contrast to curve of pH performed using POL_SLOV dataset. Probably, it is an effect of big differences in frequency of some diatoms in the modern training set and fossil samples. In AL:PE dataset, the maximal frequency of *Discostella pseudostelligera* and *Fragilaria nanana* amounted to 3.7 and 3.4 %, respectively, while in the sediments of PSP these diatoms occurred at between 52 to above 28 %. The maximum frequency of both diatom species noted in POL_SLOV dataset was approximately 50 %. For that reason the values of DI-pH based on AL:PE training set should be treated with caution (worse fit between modern and fossil diatoms).

P-4239

Regional scale synthesis to separate human impacts from variability – floodplain lakes of the River Murray, Australia

Peter Gell¹, Michael Reid², Kattel Giri³, Neeraj Mall¹

¹Federation University Australia, Ballarat, Australia, ²University of New England, Armidale, Australia, ³University of Melbourne, Melbourne, Australia

Sediment records have been extracted from over fifty floodplain and coastal lakes down the length of the Murray River. The sequences from several lakes extend for 1000 -5000 years suggesting that they were inundated permanently through that time. These largely comprise large oxbow lakes located towards the humid uplands or near the confluence of large rivers, or coastal lakes and lagoons. The records of most others extend only to ~ 200 years or even as recently as since the onset of water resource development which had commenced by the 1890s.

The long records provide evidence of the historical range of conditions experienced by the more permanent floodplain lakes before the arrival of European settlers. Upland sites were perennially fresh supporting rich communities of aquatic plants while others in the lowlands experienced episodes of salinity as well as close connection with the River likely in response to a variable climate. The climate also mediated the balance between tidal and river waters in the coastal lakes near the River mouth. In general, sedimentation rates were low and there is little or no evidence for eutrophication or acidification despite the floodplain and its resources being utilised, and even managed, by first peoples.

Floodplain lake sequences pose particular challenges for radiometric and other dating and so the identification of the first point of impact by European settlers remains unclear. In Australia however, the relatively late settlement by technologically rich European cultures saw abrupt, substantial and extensive changes to rivers and their catchments and these are evident in lake records. Sedimentation rates increased universally on account of forest clearance and intensive grazing, but also owing to the mobilisation of many million cubic metres of topsoil during the goldrush times in Victoria and NSW. The impact of the mobilisation of fine clays included increased turbidity and the release of nutrients into water columns, both of which likely played important roles in the collapse of aquatic plant communities.

The diatom-inferred state of all wetlands is currently outside their long term ecological character attesting to the pervasive impact of European catchment development and hydrological change on the lake ecosystems. That some wetlands responded soon after settlement, yet others responded much later, suggests a variable resilience to the catchment-scale drivers of change owing to lake morphology and hydrological setting. Here, naturally variable lakes may have been able to resist the impact of the increased flux of sediments, at least until the regulation of flow and shift to permanence from a natural wet-dry regime reduced their capacity to reset ecologically.

P-4240

6600 years of human impact on lake-catchment and vegetation at Lake Bohinj (Julian Alps, Slovenia)

Maja Andrič¹, Pierre Sabatier², William Rapuc², Nives Ogrinc³, Fabien Arnaud², Ulrich Von Grafenstein⁴, Andrej Šmuc⁵

¹ZRC SAZU, Institute of Archaeology, Ljubljana, Slovenia, ²Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, EDYTEM, Chambéry, France, ³Jožef Stefan Institute, Department of Environmental Sciences, Ljubljana, Slovenia,

⁴LSCE, Université de Versailles Saint-Quentin, Commissariat à l'Énergie Atomique–CNRS, Gif-sur-Yvette, France,

⁵University of Ljubljana, Department of Geology, Ljubljana, Slovenia

The Holocene vegetation history and sedimentary processes in the catchment area of Lake Bohinj (Julian Alps, Slovenia) were investigated in order to better understand the impact of people (agriculture, grazing and mining) on the environment, and climate-human interactions. A multi-proxy study of a 12-m-long sedimentary core which was collected in central part of the Lake Bohinj basin included mineralogical, sedimentological, geochemical, stable isotope ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$), and pollen analyses to reconstruct environmental changes in the last 6600 years.

Sedimentological research (Rapuc et al. 2018) identified 29 homogenite-type deposits related to earthquakes, including a major seismic event at 6617 ± 94 cal. BP (4.4–10 m) that partially reworked previously deposited sediment. Therefore, a detailed palaeoenvironmental reconstruction was performed only for the top 4.4 m of the core (i.e. the last 6600 years).

The results of palynological research suggest that at ca. 6000 cal. BP Lake Bohinj was surrounded by mixed forest (*Picea*, *Abies*, *Quercus* and *Fagus*, which became dominant after ca. 3300 cal. BP). In the Bronze and especially the Iron Ages (3500–2500 cal BP), when the region was densely populated, a substantial clearing of forests due to metallurgical activities, agriculture and livestock production (*Cerealia* t. pollen, *Plantago l.*, decline of *Abies*), was detected. These probably triggered soil erosion and faster sedimentation rates. In the subsequent centuries human impact on the environment continued (increased), but it seems that the watershed was not destabilised again. Several periods of high terrigenous input were recorded (6100–6000, 5700–5550, 5000–4600, 3900, 3700–3550, 2300–2200 cal. BP) with a different mineralogical and geochemical composition of the sediment (high content of quartz and illite, K, $\delta^{13}\text{C}$, *Fagus*, and low pollen concentration). These events could be associated with a mobilisation of inflow from the eastern, flysch bearing catchment due to river migration during periods of wetter climate.

P-4241

Carbon burial variability in high altitude Pyrenean Lakes during the last two millennia

Blas Lorenzo Valero-Garces¹, Alejandra Vicente de Vera¹, Maria Pilar Mata-Campo², Ona Sociats³, Marisol Felip³, Marcel Galofre³, Ramon Copons⁴

¹Instituto Pirenaico de Ecología - CSIC, Zaragoza, Spain, ²Instituto Geológico y Minero de España - IGME, Madrid, Spain, ³Universidad Autónoma de Barcelona, Barcelona, Spain, ⁴Institut d'Estudis Andorrans - CENMA, Andorra, Andorra

Lakes are a central component of the carbon cycle and several paleolimnological studies have shown organic carbon burial rate increases during the last century, although, the rates and controls on OC burial by lakes remain uncertain, as do the possible effects of future global change processes. We used short sediment cores from eight high altitude lakes along a West - East transect in the Pyrenees to reconstruct the OC production and preservation during the last two millennia. Several sediment cores from the lakes - Acherito, La Sierra, Sabocos, Marboré, Urdiceto, Basa de la Mora, Cregüeña and Montmalús - were retrieved to characterize the depositional environments. The cores were dated with ²¹⁰Pb, ¹³⁷Cs and ¹⁴C techniques, sedimentologically described and analyzed for textural, mineralogical and geochemical properties, including TOC, TN, TS, XRF scanner, $\delta^{13}\text{C}$, and $\delta^{15}\text{N}$. Sediment traps were deployed and limnological parameters (temperature, pH, conductivity, oxygen content) were measured in mid Summer and early Autumn. The drainage network, geology, geomorphology and soils of the watersheds were characterized from available information and field surveys. Climate variability during the last millennia in the Pyrenees was summarized from instrumental data and available regional reconstructions.

Sediment traps data show that recent sediment fluxes range between 16 and 400 g/m²/yr. The TOC content in the lake sequences ranges between 1 and 13 %. Sediment trap samples show lower C/N and $\delta^{13}\text{C}$ than surface and core sediment samples. Relatively high C/N ratios suggest a significant contribution of terrestrial carbon, even in lakes located at high altitude with watersheds almost devoid of soils, likely due to the low bioproductivity in these settings. Most lakes show changes in carbon dynamics associated to the Roman period, the Medieval Ages, the Little Ice Age and the Current Global Warming, with higher carbon accumulation in the sediments during warmer phases and higher clastic sediment input during colder periods with increased glacial activity. During the last decades, higher TOC and Br/Ti, lower $\delta^{13}\text{C}$ and C/N suggest an increase in carbon accumulation in most sites. The $\delta^{15}\text{N}$ signatures show a large variability likely controlled by site-specific limnological parameters: several lakes show a decreasing trend, others have a smaller variability, but lower $\delta^{15}\text{N}$ during the recent decades that could indicate an increase in atmospheric deposition of reactive nitrogen due to human activities in the valleys. The effects of damming are clear in Urdiceto Lake as finer, relatively more organic sediments dominate since 1930s. Climate change seems to be the main responsible of increasing carbon deposition fluxes during the last two millennia. However, recent trends in carbon accumulation could also have been favored by higher productivity as fluxes from anthropically-derived nutrient have increased even in these high altitude settings.

P-4242

Ecological regime shifts of shallow lakes in the middle and lower Yangtze floodplain under coupled natural and human disturbance

Xuhui Dong¹, Xiangdong Yang²

¹Guangzhou University, Guangzhou, China, ²Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Global lake systems have undergone rapid degradation over the past century. Scientists and managers are struggling to manage the highly degraded lake systems to cope with escalating anthropogenic pressures. Improved knowledge of how lakes and social systems co-evolved up to the present is vital for understanding, modeling, and anticipating the current and future ecological status of lakes. Here, we showcase the long-term ecological dynamics of >10 shallow floodplain lakes in the middle and lower reaches of Yangtze River (China), which evidenced by monitoring records and using a multi-proxy palaeolimnological approach to statistically analyse time series. Records on water quality and ecological structure over the past five decades from four typical lakes (Taihu Lake, Poyang Lake, Donghu Lake and Honghu Lake) illustrated the type and magnitude of such changes. Palaeolimnological record from ten lakes in Yangtze floodplain exhibited two rapid shifts occurred in synchrony during the 1950s and 1980s, suggesting common large-scale extrinsic drivers (hydrological modification and nutrient enrichment). However, significant discrepancy on the time and rate of shifts was found among different biological communities (e.g. diatom, chironomid and cladocera) and different lake types (geographical background or ecological type). This inconsistent response pattern, even exist in a single lake (different basins), reflects the intrinsic ecological process may vary due to the different resilience and ecological mechanisms. Understanding the drivers and mechanisms leading to regime shifts is crucial for developing ecosystem-based management strategies and establishing early-warning systems to avoid catastrophic ecosystem changes.

P-4243

Recent history of anthropogenic metals accumulation in NE China lake sediments

Kunshan Bao

State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Cores (15 to 40 cm of depth) were collected from 11 lakes of the Songnen Plain in northeastern China to reconstruct changes in potentially harmful trace element (PHTe) inputs as tracers of human activities. In each profile, most PHTe enrichment factors do not differ significantly from the pre-industrial values ($EF < 1.5$), except for Cd ($EF = 2-5.5$). This shows that detrital material accounts for a large part of the PHTe supply to the Songnen Plain lakes. Radiometric dating of the cores (^{210}Pb , ^{137}Cs) showed that Cd contamination started from the mid-20th century and sharply increased in the 1980s', a pattern that matches the rapid economic and industrial growth of China. Comparison with other records in China suggests that a large part of the anthropogenic Cd in these lakes is likely local in origin. Although the Cd inputs, controlled by carbonate minerals, probably originated from a combination of sources, an intensification in agricultural practices, through the use of chemical fertilizers, manure and wastewater would explain these discrepancies between records. These findings highlight the importance of local factors on the Cd geochemical cycle in China. The large anthropogenic component of the Cd inventory compared to other PHTes (Cu, Ni, Pb, Sb, V, Zn) and its high toxicity indicate that it should be prioritized in future environmental management.

P-4244

Recent eutrophication and deposition of varved sediments in lakes: case study of Lake Dubie in northwestern Poland

Anna Poraj-Górska¹, Magdalena Suchora², Agnieszka Szczërba¹, Wojciech Tylmann¹

¹University of Gdańsk, Gdańsk, Poland, ²Maria Curie-Skłodowska University, Lublin, Poland

Recent environment history is profoundly affected by human activity and climate change. Land-use changes such as deforestations, agriculture development, and higher nutrient inputs are affecting biological, chemical and physical processes in lakes. Most commonly, these changes lead to eutrophication and oxygen depletion in the bottom waters. What is more, current climate change induces stronger thermal stratification of lakes, making them more suitable for the formation of laminated sediments.

In our study, we analyzed a 1 m-long topmost sediment core from Lake Dubie (northwestern Poland). The lake is relatively small (12.5 ha) and deep (27.5 m). Its catchment land-use is characterized by mixed forest and agriculture. The sediment core shows a significant change from homogenous to laminated structure. In order to identify the timing and reasons of this change, we performed detailed investigation of geochemical composition (μ XRF) and biological proxies (cladocerans, diatoms). Sediment chronology is based on varve counting, Pb-210 and Cs-137 dates. Obtained results were confronted with existing cartographic materials and documentary sources.

The basal part of the core shows highly organic sediments of homogenous structure. First major change was observed at 60 cm sediment depth, where faintly laminated sediments occur. This is a transition from stable trophic state towards higher variability and eutrophication. Moreover, paleoecological diversity began to decrease, while an input of minerogenic matter from the catchment started to increase. A second distinct change occurred at around 20 cm sediment depth, where faint lamination is replaced by well-preserved annual lamination. Such differentiation came about most probably due to the strong eutrophication that occurred after 1945 CE. At this time, the catchments input decreased, resulting in formation of typical biogenic (calcite) varves. According to historical data, changes in land cover and land-use could be regarded as the drivers of the observed transitions in sediment structure.

Lake Constance: Reconstructing the Eukaryotic community using SedhDNA

Anan Ibrahim¹, Eric Capo², Dietmar Straile¹, Axel Meyer¹, Laura Epp¹, David Schleheck¹

¹University of Konstanz, Konstanz, Germany, ²Umeå University, Umeå, Sweden

In the second half of the 20th century, the once oligotrophic Lake Constance was exposed to major inputs of matter associated with population growth in the form of untreated sewage and agricultural runoff. This caused a dramatic eutrophication of the lake starting in the 1950s until the 1990s. As a consequence, damage control measures were implemented by the authorities most specifically in the form of waste water treatment plants. Soon after, the water quality indices returned to their 1950s levels.

Since multiple decades, the lake has been closely monitored by plankton sampling and identification using microscopy methods and an extensive long-term dataset exists.

Complimentary to the existing data, the current study aims to investigate the effect of environmental change, i.e. changes in anthropogenic phosphorus loads, on the local eukaryotic community applying a metabarcoding approach to sedimentary historical DNA spanning the past century. DNA extracts covering a high resolution time series of the lake's different trophic phases were processed according to conformed environmental DNA restrictions. A universal assay was then used to amplify and sequence a portion of the V7 region of the 18S rDNA gene representing the major plankton communities.

A total of 7 757 taxa, were retrieved in the complete dataset of which 2 408 were taxonomically assigned to diverse phyla following strict bioinformatics filtering steps. Overall changes in the communities recovered with sedimentary DNA trace the different trophic phases of the lake through time very well. Diversity measures (Shannon diversity, Simpson dominance, Chao richness estimate) indicate a return to pre-eutrophication biodiversity after lowering of phosphate levels in the lake, indicating reversibility of perturbations in diversity.

However, further in-depths analysis of the different phyla detected, demonstrate that those perturbations may not only be due to fluctuations of existing biota but also due to the introduction of new taxonomic groups during the eutrophic phase. Distinct patterns were also observed in response to the changes in phosphorus loads with several taxonomic groups, i.e. Lophotrochozoa, Bacillariophyta, Chrysophyceae, Chlorophyta and Ciliophora. Despite the reversibility of the disturbances in diversity inferred, the marked variations in the structure of the lake community following eutrophication and its stagnancy in the following years, indicate a non-resilient system.

The patterns revealed by this genomic data will further be compared with existing long-term and ongoing routine sampling datasets for method comparison purposes.

Understanding human-driven ecosystem change in a tropical Southeast Asian wetland

Jack Lacey¹, John Boyle², Charlotte Briddon³, Stefan Engels⁴, Mushrifah Idris⁵, Melanie Leng¹, Melody Li⁶, Suzanne McGowan³, Keely Mills¹, Virginia Panizzo³, David Ryves⁶, Muhammad Shafiq⁵, Christopher Vane¹, Lara Winter⁶

¹British Geological Survey, Nottingham, United Kingdom, ²Department of Geography and Planning, University of Liverpool, Liverpool, United Kingdom, ³School of Geography, University of Nottingham, Nottingham, United Kingdom, ⁴Department of Geography, Birkbeck, University of London, London, United Kingdom, ⁵Tasik Chini Research Centre, Faculty of Science and Technology, Universiti Kebangsaan Malaysia, Bangi, Malaysia, ⁶Centre for Ecological and Hydrological Science, Department of Geography, Loughborough University, Loughborough, United Kingdom

Tropical areas are undergoing rapid environmental change as a combined result of climate change and human impact on the landscape, which significantly threatens the quality and biodiversity of freshwater ecosystems. Tasik (Lake) Chini is a flood pulse wetland located on the Malaysian Peninsula, and is a critically endangered site comprising twelve interconnected lake basins. The natural vegetation of the lake's catchment and surrounding area has become increasingly influenced in recent years by rubber and oil palm plantations, mining, fruit farms, logging, and tourism, which have resulted in pollution, soil erosion, and external nutrient loading to the lake. The main outflow river was also dammed in 1995 to help stabilise the water level. Together, these activities have changed the hydrological balance of the lake, influenced biodiversity causing species and habitat loss, and decreased the sustainability of the ecosystem due to eutrophication. To understand the influence of major changes in catchment land use on the lake and to investigate the key drivers of ecosystem degradation, gravity cores were recovered in 2015 from three sub-basins of Tasik Chini. The first core is from a site adjacent to a tourist resort, the second core is from a basin situated close to mining activity and rubber plantations, and the final core was retrieved from a site furthest from major catchment disturbance. An established chronology based on ²¹⁰Pb dating shows each gravity core dates back to the late 19th century and covers the transition to enhanced human impact within the catchment. Organic geochemistry (%C, C/N, $\delta^{13}\text{C}$, Rock-Eval pyrolysis), diatom assemblage, elemental concentrations, and sedimentary pigments have all been analysed on each core to reconstruct past environmental conditions within the basin. Data show how past variability compares to recent anthropogenic-induced environmental change and define how different catchment disturbances have contributed to ecological change at this internationally important wetland site. This information is vital to assess ongoing human impacts at the site as a means to provide future science-based management and conservation strategies and thereby counter the main drivers of ecosystem degradation.

P-4247

Ecological response of a shallow mesotrophic lake to multiple environmental stressors

Michael Murphy, Jesse Vermaire
Carleton University, Ottawa, Canada

White Lake is a large, shallow (mean depth 3.1 m) mesotrophic (total phosphorous $\sim 10\mu\text{g/L}$) lake located in Eastern Ontario, Canada, and an important recreation and tourism site in the region. Similar to many lakes in the area White Lake is experiencing multiple environmental stressors including nutrient enrichment, climate warming, and the recent colonization by the invasive zebra mussels (*Dreissena polymorpha*). Lake users and property owners are increasingly concerned about water quality changes in the lake and management plans for the lake require an understanding of how these multiple environmental stressors are interacting to impact water quality. Unfortunately monitoring data for White Lake only begins in 2014 and therefore no information exists on pre-impact conditions in the lake and how these environmental stressors have interacted to alter water quality in the system. To assess long-term water quality changes in White Lake in response to these multiple environmental stressors, two sets of replicate sediment cores have been obtained from the lake, dated using ^{210}Pb , and sectioned at 0.5 cm intervals for organic content and diatom analysis. Two distinct shifts in the diatom community occurred, both showing changes in the ratio of benthic to planktonic diatoms. Recent communities are dominated by benthic species, suggesting lower water levels and clear water conditions. These data, along with the colonization of zebra mussels, suggest that White Lake is becoming an increasingly benthic system and that colonial benthic algae and/or macrophyte cover will expand within the lake. This research provides insight into how multiple stressors impact primary producers in shallow lakes that are sensitive to shifts in nutrients and turbidity.

P-4248

Regional heterogeneity in the sediment signals of atmospheric deposition in alpine lakes of southeast Tibet

Guangjie Chen¹, Linpei Huang¹, Jules M. Blais², Carsten Meyer-Jacob³, John P. Smol³

¹Yunnan Normal University, Kunming, China, ²University of Ottawa, Ottawa, Canada, ³Queen's University, Kingston, Canada

It has been established that atmospheric deposition can significantly impact pristine lakes in high-latitude and alpine regions in the context of climate warming over the last century. Specifically, nitrogen isotopic and contaminant signals derived from lake sediments have been widely used in tracking the temporal trajectory of regional atmospheric deposition. However, recent studies have revealed strong spatial heterogeneity in regional deposition and sediment signals. Processes such as climate change can also modulate lake response to atmospheric deposition through altering catchment and lake properties. Therefore, it is necessary to refine the independent roles and interaction of atmospheric deposition and confounding factors in altering lake biogeochemical cycling and ecological changes over time. In this study, trace metal and associated index for air-borne pollutants revealed that atmospheric deposition started from the late 19th century with an accelerating increase since the middle of 20th century, well consistent with the trajectory of regional atmospheric deposition. Furthermore, this process has led to the change of lake-water chemistry (i.e. acidification). However, the nitrogen isotopic variation was strongly associated with the fluctuation of sediment organic matter (OM) and catchment runoff. Meanwhile, algal production, predominantly enhanced by warmer climate, showed a significant increase over the last few decades. Increased temperature was linked with the decrease of planktonic diatoms, while the intensification of acid deposition and catchment erosion caused an increase in acid-tolerant benthic taxa. Our sediment evidence collectively revealed the significant impact of climate and catchment processes on lake-water chemistry, contaminant concentration and algal shift in the context of atmospheric deposition in SE Tibet, and highlighted an increasing link of external forcing with in-lake processes in driving sediment signals over the last few decades.

P-4249

Assessing feral animal impacts on World Heritage sub-Antarctic Macquarie Island

Krystyna M Saunders^{1,2}, Stephen J Roberts³, Christoph Butz⁴, Martin Grosjean⁴, Dominic A Hodgson^{3,5}

¹Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, ²University of Tasmania, Hobart, Australia, ³British Antarctic Survey, Cambridge, United Kingdom, ⁴University of Bern, Bern, Switzerland, ⁵University of Durham, Durham, United Kingdom

Animals introduced by human activities to remote islands can be ecologically devastating as they often have a large proportion of endemic species with limited resilience to non-indigenous ones. Sub-Antarctic islands are remote, small islands in the vast Southern Ocean. Most have experienced some form of impact from non-indigenous fauna (e.g. rabbits, rats, mice, cats) that became feral pests soon after their deliberate and unintended introductions. Conservation and management efforts are increasingly focused on their control and/or eradication.

World Heritage UNESCO Biosphere listed Macquarie Island (54°S) is one of the most impacted sub-Antarctic islands, in particular due to the introduction of rabbits in 1879, to the extent that its World Heritage values were considered threatened in the early 2000s. The values relate to Macquarie Island's geological, geomorphic and physiographic features, and exceptional natural beauty and aesthetic importance. The latter includes the presence of a large number of lakes, tarns and ponds, and extensive peat beds.

The largest rabbit and rodent eradication program for any sub-Antarctic island was undertaken from 2010-2014. Monitoring to assess recovery focused on geomorphological (including erosion) processes, vegetation and some fauna (i.e. invertebrates, burrowing petrels and albatross species) using previous studies as baselines. All of these studies were undertaken after rabbits were introduced, and no pre-introduction data exist beyond some limited historical documents after its discovery in 1810. No monitoring to assess recovery of the lakes, tarns, ponds or peat beds was undertaken.

In the absence of long term data, palaeoecology may be used to determine the nature, magnitude and spatial extent of impacts in the context of long term natural variability. To provide a long-term context for assessing the island's pre-invasion state, invasion impacts, and to provide baseline information for the waterbodies, we undertook a palaeoecological study using high-resolution x-ray fluorescence scanning and hyperspectral imaging together with biological (diatoms), geochemical (total organic carbon and nitrogen) and sedimentological (grain size) analyses of lake sediment cores in two different areas of Macquarie Island.

Results showed that Macquarie Island lakes have undergone unprecedented and statistically significant environmental changes since the introduction of rabbits in 1879. Sediment accumulation rates increased by more than 10 times at one site, 100 times at another, due to enhanced catchment inputs and within-lake production. Total organic carbon and total nitrogen contents of the sediments increased by a factor of four. The diatom flora became dominated by two previously rare species in both lakes.

This study provides an example of how palaeoecology may be used to determine baseline conditions prior to the introduction of non-indigenous species, quantify the timing and extent of changes, and help identify a basis for monitoring the recovery of waterbodies following successful non-indigenous species eradication programs

P-4250

A Holocene high-resolution multi-proxy record of aquatic productivity, soil erosion and meromixis from varved Lake Rzesniki, NE Poland

Giulia Wienhues^{1,2}, Wojciech Tylmann³, Hendrik Vogel^{2,4}, Stamatina Makri^{1,2}

¹Institute of Geography, University of Bern, Bern, Switzerland, ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ³Department of Geomorphology and Quaternary Research, Institute of Geography, University of Gdansk, Gdansk, Poland, ⁴Institute of Geology, University of Bern, Bern, Switzerland

Climate change and anthropogenic activities are influencing aquatic ecosystems (IPCC, 2013). The physical and biochemical cycles in water bodies are tightly linked to environmental and climatic conditions, so that they respond sensitively to changes in these background conditions. Emerging anoxia and meromictic conditions in lakes have substantial consequences on lake ecology (Jenny et al. 2016, Steffen et al. 2015) and it is important to understand their development and effects on ecosystems over long time-scales. Understanding of the paleoenvironmental history provides important insights into natural and environmental factors, which is important in light of future development of freshwater systems. To date only few studies aimed at a better understanding of factors contributing to and ecosystem consequences of meromixis have been conducted so far.

Lake Rzesniki, a small dead ice lake in NE Poland, is an interesting site to study how productivity and meromixis operated in tandem in lake system characterized by a dense forest catchment with limited runoff and input of soil substrates. Almost the entire sedimentary record of Lake Rzesniki is varved making it suitable for a high resolution paleoenvironmental study. The aim of this study is to reconstruct the environmental history of Lake Rzesniki in course of the Holocene, specifically with the focus on the evolution of meromixis and paleoproductivity in the context of a low erosional input and mass movement events. Key question to be tackled include: Are changes in productivity and meromixis climate-related, human-induced, related to within-lake processes or influenced by changes in catchment dynamics? To what extent are the specific background conditions of the lake displayed in the proxy record and how are these influencing the in-lake productivity and meromixis?

We use high-resolution hyperspectral imaging (HSI) proxies, total chlorophyll for aquatic primary production and bacteriopheophytin *a* (Bphe *a*) for meromixis (Butz et al. 2016). The pigment degradation product Bphe *a* is produced by anoxygenic phototrophic bacteria in the chemocline of meromictic lakes. Additionally, sedimentary pigments are extracted and measured by the HPLC to calibrate the HSI data. The multi-proxy record is completed by scanning XRF data and measurements of total organic and inorganic carbon, and biogenic silica determined by Fourier transform Infrared Spectroscopy (FTIRS) (Vogel et al. 2008). The core chronology is based on radiocarbon dating of abundant terrestrial plant macrofossils.

Preliminary analysis of the XRF data reveals extraordinary low lithogenic input (extremely low lithogenic element intensities) throughout the Holocene. The most productive phase is indicated by enhanced counts of Si (here biogenic Si in the absence of lithogenic silicates), Ba and Br during the mid-Holocene. A detailed multi-proxy data analysis focusing on these high productivity phase is in progress with concomitant changes in land use and climatic conditions being determined by palynological analyses.

P-4251

Assessing the impact of aquaculture in the Philippines using palaeolimnology

Charlotte Briddon¹, Suzanne McGowan¹, Sarah Metcalfe¹, David Taylor², Wayne Bannister², Melandro Cunanan³, Melanie Leng^{1,4}

¹University of Nottingham, Nottingham, United Kingdom, ²National University of Singapore, Singapore, Singapore, ³Angeles University Foundation, Angeles City, Philippines, ⁴British Geological Survey, Nottingham, United Kingdom

In the Philippines, aquaculture in freshwater lakes contributes significantly to its economy, food security and employment. However, intensive aquaculture often leads to degradation in lake ecosystem integrity because of nutrient fertilisation resulting in harmful algal blooms (HABs), introduction of toxins and invasive species. The few limnological studies that have been carried out to date demonstrate a link between aquaculture activity and degraded water quality. However, the functioning of lakes in the warm tropics is generally poorly understood, with detailed limnological research and long runs of monitoring data relatively rare. In particular, there is a lack of information to help define how lakes have reacted over time to changing intensities of aquaculture and other drivers of aquatic change, including variations in catchment and climate conditions. This research, adopts a palaeolimnological approach to assess the impact of aquaculture on the Seven Lakes of San Pablo (Luzon Island). A multi-proxy approach is employed to reconstruct environmental change in several lakes over the last c. 100 years, specifically, using chlorophyll and carotenoid pigments as indicators of algal communities (including possible HAB taxa) and carbon and nitrogen isotope ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$) and C/N ratios to link ecosystem state with organic matter cycling. The lakes have been subjected to different timings and intensities of aquaculture, allowing comparisons between the farmed and 'control' (no aquaculture) lakes over the past century. Such comparisons allow the lake-specific effects of aquaculture to be disentangled from effects of regional drivers. Using this experimental design across individual lake ecosystems allows more critical interpretation of the pigment and isotope records. Preliminary results suggest that $\delta^{15}\text{N}$ show an increase proportional to the development of aquaculture leading to the possibility that $\delta^{15}\text{N}$ could be an effective marker for aquaculture. Furthermore, the scale of change in the algal communities is higher in the intensively farmed lakes (Sampaloc) compared to the 'pristine' lakes (Yambo) suggesting higher development of aquaculture causes larger changes in lake ecology. The ultimate goal of the research will be to determine the aquaculture densities at which each lake exceeded critical loads to define sustainable aquaculture targets.

P-4252

The impacts of intensive mining on terrestrial and aquatic ecosystems: a case study from cool temperate Tasmania, Australia

Kristen Beck^{1,2}, Michela Mariani^{2,3}, Michael-Shawn Fletcher², Patricia Gadd⁴, Hendrik Heijnis⁴, Krystyna Saunders⁴, Atun Zawadzki⁴

¹University of Lincoln, Lincoln, United Kingdom, ²University of Melbourne, Melbourne, Australia, ³University of Nottingham, Nottingham, United Kingdom, ⁴Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia

Mining has caused extensive damage to aquatic systems worldwide with acidification, heavy metal pollution, increased sediment loading and Ca decline of freshwaters. While some aquatic ecosystems are thought to be recovering from past mining, a long-term context is needed to determine if pre-impact conditions have been restored. Here we explore the palaeoenvironmental history of Owen Tarn, western Tasmania, to assess the impacts of mining from Mt. Lyell on aquatic ecosystems. Analysis of a new sediment core using radiometric dating, sediment geochemistry, pollen, and diatoms are used to examine the full extent of mining and heavy metal pollution on aquatic and terrestrial ecosystems pre- and post-mining in this region. Our analysis indicates four key phases of environmental change: (1) A pre-mining phase (550-1160 CE); (2) an early impact phase (British invasion) shows land clearance and vegetation removal by burning during mineral exploration; (3) an intense mining period (1950 CE) had severe negative impact on the diatom community in which sediment pollution from a lack of vegetation and heavy erosion, rather than acidification, was the main driver of change; and (4) a post-mining phase (2006 CE) in which vegetation on the landscape began to recover and aquatic productivity increased. Despite this apparent recovery of the system, the aquatic community continues to experience impacts from mining. The diatom community has not returned to its pre-impact state, but rather there is evidence of a secondary impact from declining Ca in the system. The relevance of these findings demonstrates the importance of well dated palaeoecological records to inform management and mitigate human impacts on the environment.

P-4253

Beginning of the anthropogenic change and the Anthropocene in the Lake Ladoga basin.

Tatyana Sapelko

Institute of Limnology RAS, St.Petersburg, Russian Federation

Lake Ladoga is the largest lake in Europe and changes of its ecosystem is a great importance for the lots of people living on Ladoga catchment area. Numerous studies of the sediment sequences of Ladoga and small lakes in its basin have made it possible to establish the first anthropogenic changes sediments. The study of archaeological site in the Lake Ladoga basin of the studied lakes helps to separate anthropogenic changes from natural. According to the pollen data it has been established that substantially changes in lake landscapes from the Atlantic period is associated with anthropogenic influence, and these changes are confirmed by a comprehensive study of the lakes. The beginning of the industrial period in the region about 300 years ago is recorded in the change in the composition of lake sediments, changes in flora and fauna. This period can be called the beginning of the Anthropocene. The novel method for separating the influence of natural and anthropogenic factors on lake ecosystems according to paleolimnological data has been developed over the past time at the Institute of Limnology of the Russian Academy of Sciences. Method is developed on the base of lithological, geochemistry, pollen, diatom, chironomid, radiocarbon data and other analyses data. Age is determined by pollen and radiocarbon analyzes. It considers qualitative and quantitative characteristics. As a result, we are able to calculate the probability of anthropogenic impact on the accumulation of organic matter, phosphorus and metals in the lake sediments. As a result, we can to quantify the timing and onset of human disturbance in lake systems and to disentangle this from other signals recorded in lake sediment. The study is being performed within the framework theme № 0154-2019-0001(Institute of Limnology RAS).

P-4254

Sediment and heavy metals flows recorded across an altitudinal transect in the central Pyrenees for the last 2 millennia

Alejandra Vicente de Vera¹, Juan Pablo Corella^{2,3}, Mario Morellón⁴, Ana Moreno¹, Rocío Millán⁵, Maria Jose Sierra⁵, María del Pilar Mata⁶, Alfonso Saiz-Lopez², Carlos Alberto Cuevas², Blas Lorenzo Valero-Garcés¹

¹Pyrenean Institute of Ecology, Zaragoza, Spain, ²Department of Atmospheric Chemistry and Climate, Institute of Physical Chemistry Rocasolano, Madrid, Spain, ³Universite Grenoble Alpes, Grenoble, France, ⁴Complutense University of Madrid, Madrid, Spain, ⁵CIEMAT — Environmental Department, Madrid, Spain, ⁶Instituto Geológico y Minero de España, Zaragoza, Spain

In this work, a comparative study has been undertaken in three lakes across an altitudinal gradient within the Southern Central Pyrenees: Lake Estaña (located in the External Ranges, close to the northern boundary of the Ebro River Basin) and the alpine lakes Basa de la Mora and Marboré (located in high-elevation areas of the Pyrenees Axial Zone).

Mountain lakes register atmospheric pollution with great efficiency. Nevertheless the biogeochemical cycles including heavy metals are specific to each individual lake. Therefore, a site-specific detailed understanding of metal depositional processes should be achieved before using these natural archives as proxies for past regional pollution. For this reason, we compared the depositional evolution of the lake systems during the last millennia with the MAF (Mass Accumulation Flux) variability and changes in the lead concentration of the lakes.

The MAF shows a large spatial and temporal variability, both in each lake and along the transect, likely due to the different environmental processes and varied climate and anthropic forcings. Estaña, located at lower altitudes, showed a large increase in sedimentation rates during medieval times, mainly due to deforestation and agropastoral activities that increased run-off processes in the watershed. Recent rural depopulation in the Pyrenean mountains does not seem to have a strong impact in sediment delivery to Estaña lake, as farming in the watershed has not decreased. On the other hand, Basa de la Mora and Marboré are hardly affected by anthropic activity in their watersheds and their sedimentation is more dependent on climate and surface hydrological processes.

Lead shows similar behavior in these lakes, with low Pb enrichment in the central Pyrenees during the pre-industrial period, a progressive increase since the end of the eighteenth century, paralleling the industrialization process in Europe, and peaking at the late twentieth century. Between 1860 and 1930, the mining and smelting activities in the Central Pyrenees would have been the main Pb source in the area. The sharp drop in Pb in the mid 20th century is probably related to the reduction of emissions associated with the economic recession and the closure of the local Pb mines. The use of leaded gasoline is the main factor controlling the Pb enrichment increase during the Great Acceleration (since 1950), and the subsequent reduction after 1990s.

The integration of the depositional evolution of the lake systems with the heavy metal fluxes demonstrates how local environmental conditions are key to understand changes in heavy metal fluxes and erosion and deposition of sediments from the watersheds. This integrated approach exemplifies the different sensitiveness of lacustrine systems to record past changes in sediment, heavy metal fluxes and biogeochemical cycles and highlights the need of multi-archive studies to conduct regional environmental reconstructions.

P-4255

Exploring the main drivers of change in western Uganda crater lakes: separating anthropogenic from climatic impacts

Tessa Driessen¹, Dave Ryves¹, Keely Mills²

¹Loughborough University, Loughborough, United Kingdom, ²British Geological Survey, Keyworth, United Kingdom

Tropical freshwater lakes are critical natural systems of global importance. In western Uganda, crater lakes and their catchments provide vital ecosystem services (e.g. potable water, aquaculture, and ecotourism) to some of Earth's fastest growing and most vulnerable human populations. However, these key services are under increasing threat due to climate change and the impact of human activities. Anthropogenic impacts include rapid change in many crater lake catchments as a result of clearance and land use alteration, while climatic impacts consist of an increase of temperature (0.9°C in the last 20 years in Uganda) and has also led to alterations in aquatic ecosystems in crater lakes. Both climatic and anthropogenic impacts on these fragile ecosystems, such as ecological and biogeochemical functioning, are largely unknown.

Previous research done on these crater lakes has focussed upon the use of lake sediment records as palaeoclimatic archives, with little attention given to the effect of human-driven changes on lake ecosystem structure and functioning. This project targets a number of crater lakes in western Uganda (Bunyaruguru region) with contrasting catchments (i.e. "natural" vs heavily impacted by human activity) to test the hypothesis that agricultural intensification in these lake catchments has led to a significant increase in aquatic primary production, with climate change a subordinate factor. Sediment cores (spanning the last c. 100-200 years) will be analysed for fossilized pollen, charcoal, and diatoms to study the impact of human activity and recent surface water warming on biogeochemical cycling and its associated impacts on the ecological functioning of these lake systems. Contemporary remote sensing, vegetation and pollen data will be used to develop a pollen-land cover calibration set for understanding landscape change over the past ~20 years, which will then be applied to the palaeoecological records of vegetation through pollen analysis.

Preliminary results demonstrate that these crater lakes are sensitive to environmental change in the recent past, and have experienced substantial changes in lake level. New results show that lakes heavily impacted by humans also have substantial changes in lake level over the past 100 – 200 years, however, these changes are dissimilar compared to the more "natural" lakes. Understanding past anthropogenic and climatic influences on these ecosystems can act as a guide to their future resilience and sustainability as natural resources providing vital ecosystem services for local populations under increasing environmental change.

Plata, La Plata, Argentina, ⁴Department of Earth Sciences, ETH-Zürich, Zürich, Switzerland, ⁵Instituto Dom Luiz (IDL),

Faculdade de Ciências,, Universidade de Lisboa, Lisbon, Portugal, ⁶Institute of Plant Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ⁷Department of Mining, Topography and Structure Technology. University of León, León, Spain

Understanding past environmental change and identifying its main drivers is essential to predict how watersheds will respond to climate change under increasing human pressure. To achieve this goal, we need to extend our temporal records back in time to pre-industrial conditions, so we can understand the natural variability of the main processes involved.

The Cantabrian region (N Spain) represents a perfect playground to address these questions as it has experienced high human pressure during the last centuries, especially when compared to other areas of Iberia. This research aims at understanding how recent (19th to 21st centuries) warming and increasing human activities have affected the geomorphological and geochemical dynamics of the Cantabrian watersheds. In this work, we use a multi-archive and multi-site approach, integrating high-resolution lake (Somiedo, Ausente, Isoba, Enol, Fuentes Carrionas, Pozo-Tremeo and Antuzanos) and estuarine (Tina-Menor, San Vicente, Rabia, Suances, Maruca, Santander, Santoña, Muskiz and Urdaibai) records located across a W to E longitudinal and altitudinal (0-2200 m.a.s.l.) transects, covering a wide range of climatic conditions and land uses in this region. To unravel human and climate drivers of environmental change, we use a multidisciplinary strategy, including geomorphological and paleolimnological approaches. Thus, we investigate current and past dynamics at both watershed and lake/estuary scales, current and past dynamics using geomorphologic analyses, long-term instrumental climate records, limnological surveys and multiproxy analyses of sediment cores (sedimentology, geochemistry and paleoecology) and socioeconomic data. We particularly focus on three main components of watershed dynamics: i) sediment delivery and depositional dynamics, ii) heavy metal loads and iii) carbon fluxes. Available data indicate increasing sedimentation rates in lakes and estuaries since the mid-20th century, coinciding with the Great Acceleration.

This research will contribute to understand the nature, timing, spatial variability and consequences of the synergistic effects of human activities and climate change on watershed scale, helping environmental stakeholders and policymakers to design adaptation and mitigation policies on global change.

P-4257

Vulnerability of small lakes in the district of Ouinhi (Benin republic) to the effects of climate change and human pressures

Ibouraima Yabi¹, Blaise Donou¹, Maman-Sani Issa²

¹LACEEDE/DGAT/UAC, Abomey-Calavi, Benin, ²LACEEDE/CIFRED/UAC, Abomey-Calavi, Benin

Inherent in the more or less recent hydro-geomorphological processes in southern Benin, the small lakes of the district of Ouinhi are of ecological and socio-economic importance and deserve to be preserved. But these ecosystems are not immune to the combined effects of natural and human pressures. The present research aims to analyze the vulnerability of these small lakes to the effects of climate change and human pressures already visible or to come.

The climate datas (rainfall and temperature) for period 1941-2015 period, and those for remote sensing (Landsat TM 1988, ETM + 2002 and OLI TIRS 2017) are used without forgetting information from observations / field surveys. The use of frequency analysis, standardized indices and the non-parametric Pettiit test made it possible to characterize the current climatic variability in the environment. Cartographic software (IDRISI SELVA and ARC GIS) was used to analyze the dynamics of land use around small lakes. To describe the future climatic physiognomies, the scenarios IPCC (2013), RCP 2.6 (optimistic) and RCP 8.5 (pessimistic), were used by 2050. The " pessimistic " and " optimistic " modeling was made to explore the environmental degradation levels of the environment at the same time horizon.

The environment of small lakes is currently characterized by unambiguous thermal warming associated with instability of annual rainfall totals with a high occurrence of extreme values. Added to this is the degradation of vegetation cover due to human activities which exposes the soil to any kind of degradation. The result is a tendency to fill small lakes and reduce their services. All climate scenarios predict an uncomfortable hydro-climatic context by 2050, coupled with a degradation of the lake environment. If the trend continues 20 to 35% of small lakes could disappear and the rest will be seriously affected. These observations suggest the definition of a concerted adaptation policy to reduce the socio-economic and environmental vulnerability of small lakes to future hydro-climate shocks.

Climate change and erosive dynamics around Lake Ahiémé in Benin, West Africa

ETENE Cyr Gervais
UAC, Cotonou, Benin

Abstract

Climate change effects and extreme climate events have various impacts on water bodies and rivers. Lake Ahiémé has been exposed in recent decades to the adverse effects of storm erosion, the direct consequences of which are bank erosion, fillings and sedimentation of the lake. The purpose of this research is to study the relationship between climate change and erosive dynamics around Lake Ahiémé.

To assess the effects of climate change and the manifestation of land erodibility in the study environment, rainfall, demographic and land use data are collected. Field surveys were used to identify vulnerable areas and public perception of the phenomenon of rainfall erosion. Descriptive statistics and the PEIR model were used to analysis the results. Areas of vulnerability to storm erosion have been mapped.

As a result of this study, the “Ahiémé” Lake area was the centre of several climate changes over time. Comparative study of climatological data between normal 1991-2010 and 1961-1990 shows an increase in extreme rainfall frequency of about 16% as temperatures increased overall by +1°C in the study area. These changes are at the root of the lake’s vulnerability to storm erosion. For 60 % of the population, clearances for season crops, destruction of vegetation by wildland fire and exploitation of galleries for firewood expose the lake’s banks to erosive. According to 55 % of respondents, eroded particles are transported and deposited in the lake, contributing to ecosystem sedimentation. As a result, local authorities and people are forced to spend more than 20 % of their annual budget to develop a sustainable shoreline management scheme for future climate change. In doing so, the populations and the town hall have developed adaptation strategies that deserve to be improved.

Keywords: Lake Ahiémé, storm water erosion, climate change, sedimentation

Environmental degradation of lakes in the middle Yangtze Basin since the 1980s

Linghan Zeng¹, Suzanne McGowan¹, Xu Chen²

¹School of Geography, University of Nottingham, Nottingham, United Kingdom, ²School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, China

Intensification of human activities and associated pollutant transport into freshwater bodies have resulted in the deterioration of lake ecosystems. The middle and lower reaches of the Yangtze Basin, inhabited by more than 300 million people, is one of the most developed areas in China. Over the last several decades, lakes in this area have suffered from problems such as eutrophication and declines in biodiversity due to strong human perturbations. In addition, hydrology is a key factor controlling ecosystem wellbeing of floodplain lakes. Because long-term monitoring of these lakes is lacking, we used paleolimnology to understand the extent and consequences of the rapid intensification of human impacts. Analysis of chlorophyll and carotenoid pigments remains in dated sediment cores allowed us to track ecological changes in the lakes. Our study based on six lakes spanning the middle Yangtze Basin illustrates that pigments showed a sharp breakpoint around the 1980s consistent with an increase in primary producers, including potentially bloom-forming cyanobacteria. This change coincides with the major period of rapid development in the region when nutrient loading increased due to agricultural and industrial development and urban expansion. The changes recorded by our sediment cores record an unambiguous and widespread degradation of environment across the middle Yangtze Basin lakes, which probably increased the size and frequency of cyanobacterial blooms around 35 years ago. In addition, pigment biomarkers of N₂-fixing (aphanizopyll) and colonial (canthaxanthin) cyanobacteria showed a spatial pattern along the middle Yangtze River with low concentrations in the upper stream and high concentrations in the lower stream. This may be attributed to the different source of N and P in the Yangtze Basin and the variable effectiveness of upstream lakes and reservoirs at reducing pollutants from point and non-point sources.

Danube floodplain lakes formation and evolution in the Mid and Late Holocene: natural versus anthropogenic influences

Laurentiu-Florin Tuțuianu¹, Alfred Vespremeanu-Stroe², Florin Pendea³, Cristian Panaiotu^{4,5}, Luminița Preoteasa², Tiberiu Sava⁶, Cătălin Lazăr⁷, Sabin Rotaru⁸, Mihaela Dobre⁹

¹GEODAR Research Center for Geomorphology, Geoarchaeology and Paleo-Environments, University of Bucharest, București, Romania, ²Sfântu Gheorghe Marine & Fluvial Research Station, Faculty of Geography, University of Bucharest, Sfântu Gheorghe, Romania, ³Lakehead University, Sustainability Sciences Department, 500 University Avenue, Orrilia, Canada, ⁴Faculty of Geology and Geophysics, Bucharest University, București, Romania, ⁵Faculty of Physics, Bucharest University,, București, Romania, ⁶RoAMS Laboratory, Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering, Măgurele, Romania, ⁷National History Museum of Romania, Calea Victoriei, București, Romania, ⁸GeoEcoMar National R&D Institute for Marine Geology and Geoecology, București, Romania, ⁹Faculty of Geography, Bucharest University, București, Romania

Floodplain lakes are very important archives for reconstructing fluvial dynamics associated with climate changes and human impact (land use changes). In this study, we present the preliminary results of the multi-proxy analysis of the Danube floodplain lakes which allow for the reconstruction of the landscape changes occurred during the last 5000 years which is the average age of the floodplain lake inception. The methodology includes geochronological (AMS), sedimentological (grain-size, loss on ignition, magnetic susceptibility), geochemical and paleo-ecological (pollen, seeds, ostracods, dinoflagellates) analyses focused on the changes in the sedimentary record of the 7 lakes. In each lake, we sampled sealed tubes from medium deep cores (the bottom of the core is between 8 and 18 m which in all cases is lower than the lacustrine unit), which position was chosen using several historical maps (1770; 1849; 1916; 1970) and satellite images. The preliminary results allowed for the identification of the main common phases characterizing the floodplain lake formation and evolution. Thus, most of the lacustrine stratigraphies and age-depth models show similar patterns with turning points correlated with human history and marked differences in sedimentation rates and organic matter content imposed mainly by human activities mainly through forest clearings, agriculture, grazing and later through dredgings and canal. Recently, seeds and cereals spores analyses enabled the assessment of agricultural activities practices which further contributes to tracing the ratio between the natural and anthropogenic sedimentation drivers (e.g. in Somova Lake Neolithic age cereals have been found which together with the organic dark layers provide information on sedimentation rates influenced by human activity through deforestation, crops and later, through civil works) (e.g. in Somova Lake Neolithic age cereals have been found which together with the organic dark layers provide information on sedimentation rates influenced by human activity through deforestation, crops and later, through civil works).

Water quality changes in Eastern Ontario recreational lakes over the last 150 years in relation to climate and land-use changes

Mubashshera Rahman, Jesse C. Vermaire
Carleton University, Ottawa, Canada

Eastern Ontario, Canada, is lake-rich region whose economy benefits from tourism associated with aquatic recreational activities. Residents of this region are becoming increasingly concerned about water quality changes including nuisance algal bloom despite fairly low total phosphorus (less than $20\mu\text{mTP}$) concentration. Land-use and climate change are known to negatively impact water quality by increasing the likelihood of algal blooms. Changing climate may lead to a variety of different environmental conditions such as increasing ice-free seasons, warmer water temperatures and increasing precipitation. However, the combined impact of TP and climate change on water quality in this region is not clearly understood. To investigate the combined impact on water quality in Eastern Ontario lakes, Diatom based paleolimnological records (top and bottom layer of sediment core) from 15 nutrient poor (on an average $12.5\mu\text{mTP}$), non-acidic lakes of this region were analysed. Paleolimnological records detected shifts in the composition of diatom species assemblages, mostly from benthic taxa, such as *Fragilaria* or tytoplanktonic *Aulacoseria* groups, to more planktonic-dominated taxa, such as *Cyclotella* and elongated diatom taxa such as *Asterionella* in the study lakes. Climate change induced warming causes extensions in photic zones as well as stable water columns, which are known to be favorable for small planktonic diatoms. These conditions favour planktonic species as opposed to tytoplanktonic and benthic diatoms. Therefore, this study reveals a strong climate change signal across the study region. Furthermore, a sharp declining trend in Chrysophytes cyst to Diatom ratio was observed since pre-impact (pre-1850) age to the present days. Chrysophytes are abundant in oligotrophic conditions and therefore declining trend in cyst to diatom ratio suggests a shift to nutrient rich aquatic ecosystem.

P-4262

Reconstructing Lake ecosystem history using carbon stable isotopes in resting *Daphnia* eggs

Desiree Helmer¹, Karl-Otto Rothhaupt¹, Elizabeth Yohannes²

¹Limnological Institute, Konstanz, Germany, ²Limnological Institute, Konstanz, Germany

Freshwater ecosystems are under severe pressure through multitude of anthropogenic stressors. Lake Constance, one of the largest Lake in Europe, has been affected by several environmental stressors including eutrophication and climate change. Eutrophication as an ecological stressor has been the main concern during the 1960s to 1980s, after which the lake has attained its oligotrophic level and beyond. The effects of these long-term changes on the lake ecosystem is archived as a 'unique fingerprint' in stable isotope values of *Daphnia* resting eggs (ephippia), remaining egg shells, and sediment core bio-chemistry. These values provide important information on past changes in diet of invertebrates and higher level consumers. Here, using carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) of multiple ephippia from sediment core and surface sediments over 1960-2000, we show a significant change in stable isotope values. Ehippia $\delta^{13}\text{C}$ values are close to values typical for algae and living daphnia (-35.4‰) during recent oligotrophic phases. This variability is likely driven by seasonal and inter-annual variability in algae $\delta^{13}\text{C}$ values. When using shell $\delta^{13}\text{C}$, we identify two distinct isotopic patterns, which may reflect separate production peaks and resource uses between the eutrophication and oligotrophic process. For both resting eggs and shells, we report a significant shift (increase) in $\delta^{15}\text{N}$ values between the years 1960 and 2000. These results assist refining the assessments of past *Daphnia* trophic level and nitrogen cycling in the Lake food webs. Further investigation using sediments and multiple isotopes is being considered.

Criticism of fantastic ideas about the extraordinary antiquity of the first ceramics in the Transbaikal, Russia

Mikhail V. Konstantinov¹, Masami Izuho², Fumie Iizuka^{2,3}

¹Transbaikal State University, Chita, Russian Federation, ²Tokyo Metropolitan University, Tokyo, Japan, ³University of California, Merced, Merced, USA

In some recent publications (Razgildeeva et al., 2008, 2013), early pottery recovered from the Studenoe 1 and Ust'-Menza 1 sites of the Transbaikal region (Russia) are radiocarbon dated to be from the late Pleistocene. Ceramics from layer 7 at Ust-Karenga-12 in the Transbaikal are suggested to have appeared about 14 to 13 thousand years ago, claimed as among the oldest in East Asia (Kuzmin and Vetrov 2007; Vetrov, 2008, 2010, 2011). However, we argue that the true age of the oldest ceramics in the Transbaikalia is about seven thousand years ago.

At Studenoe 1 and at Ust'-Menza 1, cultural layers belong to the late Upper Paleolithic, Mesolithic, Neolithic, and Bronze ages. The oldest ceramics, in the early Neolithic, were excavated from layers 8 and 9 at Studenoe 1, and from layers 7 and 8, at Ust'-Menza 1. Ceramics have pointed- and rounded-bases, and stamped decorations. The pottery-containing cultural layers are associated with thin black layers developed during the Atlantic optimum. The age assignment of these deposits by geologists, S.M. Tseitlin, D.B. Bazarov, LD Bazarova, I.N. Rezanov, A.F. Yamskikh, and others, agrees with ours. We suggest the antiquity of the cultural layers of the early Neolithic in the lower part (but not at the base) of the deposits of the Atlantic optimum to be seven to six thousand years ago.

Additionally, a comparison of artifact chronology and stratigraphic contexts suggests that below the Neolithic horizons, there are layers of the late Mesolithic corresponding to the beginning of the Atlantic optimum, and the early Mesolithic and the late Upper Paleolithic corresponding to later stages of the Sartan glaciation. If the stratigraphy-based artifact chronology is valid, the assignment of Neolithic horizons to the late Pleistocene requires an explanation.

At Ust-Karenga-12, the ceramic materials are associated with a humus-rich, very black layer of the middle to the second half of the Atlantic optimum. This led us to attribute those layers to about 6-4 thousand years ago. Ceramics with combed decoration are found from this context. These ceramics are similar to the pottery technology of the middle Neolithic in Yakutia.

In the Baikal region, radiocarbon dates, and deposits and archaeological materials from the Atlantic optimum and sub-boreal clearly have up to a thousand years of time gap (Konstantinov et al., 1989, Konstantinov, 1994, p. 110, Konstantinov, 2009a, 2009 b, Konstantinov M., Konstantinov A., p. 20-21). Failure to understand this problem leads to a mixture of different time periods, and creates a ground for misunderstanding the true ages of the earliest pottery there. We suggest that ceramics began to be produced in the Transbaikal when the Taiga forest and favorable natural environment developed, and continental Neolithic hunters and fishers changed their subsistence economy.

P-4264

The nature and timing of the dispersal of *Homo sapiens* in the western region of southern Patagonia (52°)

Fabiana M. Martin¹, Luis A. Borrero², Dominique Todisco³, Joel Rodet³, Carole Nehme³, Igor Girault³, Francisco Prevosti⁴, Manuel San Román¹, Flavia Morello¹, Claudia Mansilla¹, Robert D. McCulloch⁵, Valentina García-Huidobro⁶
¹CEHA, IPA, Universidad de Magallanes, Punta Arenas, Chile, ²CONICET, Buenos Aires, Argentina, ³University of Rouen, Department of Geography, Rouen, France, ⁴CRILAR-UNLaR, Anillaco, Argentina, ⁵Centro de Investigación en Ecosistemas de la Patagonia, Coyhaique, Chile, ⁶FONDECYT 1180272, Punta Arenas, Chile

The Late Pleistocene cold environments of southern Patagonia were classically considered geographically marginal and relatively difficult to colonize. The extensive Patagonian ice sheet continuously present from 44° to 52° S added further difficulties to western regions near the Andean cordillera. Finding the habitats first occupied by *Homo sapiens* at the end of the Pleistocene along the Andes is challenging, since most of the areas near the Andes were only occupied at the beginning of the Holocene. Most of the early archaeological evidence was obtained in the eastern Patagonian steppes. The only region in Southern Patagonia where Late Pleistocene human occupation was detected, in the vicinity of the Pacific Ocean is at Cerro Benitez, Ultima Esperanza, Chile. Approximately one millenium after the retreat of the Pleistocene glaciers, the region of Cerro Benitez was successfully colonized from the east by a rich fauna that included *Mylodon*, *Hippidion*, *Macrauchenia*, *Lama gracilis* and other camelids, two hyper-carnivores -*Smilodon* and *Panthera onca mesembrina*- and *Arctotherium*. During the Late Glacial there is evidence, such as ice wedge casts and vegetation changes to suggest a return to cold conditions coeval with the Antarctic Cold Reversal (ACR). However, the continuous presence of the diverse fauna made it a viable habitat for *Homo sapiens*, although it was only by the end of the ACR that the first indications of human habitation were present. Human habitation for the period 10.8-10.4 ka BP has been established at Cueva del Medio, with important complementary information from Cueva Lago Sofía 1 and Cueva del Milodón in the form of hearths, projectile points, a diversity of stone tools, some of them made on exotic rocks and cut-marked bone fragments dated by a suite of 46 radiocarbon dates. These are clear signals of interaction with *Hippidion* and camelids, including an extinct clade of *Lama guanicoe*. It remains an open question whether people arrived before to the southern latitudes (Support from FONDECYT 1100822, 1180272).

Cultural Interactions between the Late Stone Age and Iron Age at the Island of Deserters

Elizabeth Kyazike

Kyambogo University, Kampala, Uganda

The Island of Deserters located in south western Uganda is at a spot where the Kagera river turns west in an area popularly known as Nsongezi. Herodotus suggested that the Island of Deserters was where the Nile turned to the Western direction. Given that there is a thinking that the Nile might be hailing from the Kagera this place was named the Island of Deserters. While Nsongezi is where the first Stone Age artefacts were identified in Uganda, not much has been done in this place in terms of examining its ceramic potential and its implications as if the Late Stone Age people simply disappeared and never interacted with the Iron Age people. The objective of this paper is therefore to justify the use of the name Island of Deserters. Secondly, it also shows the interaction between the Late Stone and Iron Age cultural periods. This is because the Island of Deserters is a site with evidence spanning from the Middle Stone Age to the Iron Age where typical Kansyore a Late Stone Age pottery tradition co-exists with the Iron Age pottery tradition. The study employed archaeological survey and excavation and ancient historical records. The finds indicated that this is probably the Island of Deserters talked about in ancient historical records with evidence of interaction between the Late Stone and Iron Age periods that is instrumental in examining theories of cultural interactions such as displacement and coexistence, with reference to the Island of Deserters in south western Uganda.

The southernmost Neanderthals? Stone tool technologies from Shukbah Cave

J Blinkhorn

Royal Holloway, University of London, Egham, United Kingdom, Max Planck Institute for the Science of Human History, Jena, Germany

The expansion of modern humans out of Africa has led our species to colonise a variety of habitats, engaging with a diversity of extreme environments that is unparalleled amongst our closest relatives and ancestors. Yet, examining the ecological range and the geographical extent of our closest, extinct relatives offers an important approach to understanding what constituted extreme environments to Pleistocene hunter-gatherers, as well as to illuminate the similarities and differences between alternate hominin populations' behavioural responses to such environments. This presentation focuses on Shukbah Cave, where Dorothy Garrod undertook the first in a series of excavations in Palestine. While many of the later sites excavated by Garrod have become pivotal in debate surrounding hominin occupation and behaviour in the Levant during the later Middle and Late Pleistocene, the Middle Palaeolithic occupation of Shukbah Cave has been overlooked. The small number of hominin fossils recovered at the site have been attributed to Neanderthals, making them the southernmost specimens of the species, and Garrod drew close comparisons between stone tool assemblages from Shukbah and the late Mousterian layer D at Tabun. The results of ongoing analysis of the stone tool collections from Shukbah will be presented and placed in the modern research landscape to explore questions regarding ecological engagement and expansion of alternate hominin populations in South-West Asia during the Late Pleistocene.

P-4267

Millennial-scale climate fluctuations in the Shuidonggou site in north China and influences on human's occupation during the last 40-10 ka

Junyi Ge^{1,2,3}, Hao Xie¹, Fei Peng¹, Xing Gao^{1,2,3}, Chenglong Deng⁴

¹Key Laboratory of Vertebrate Evolution and Human Origins, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China, ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ³University of the Chinese Academy of Sciences, Beijing, China, ⁴State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

During the last 40-10 ka, the northern Hemisphere has experienced a series of dramatic climatic fluctuations including the last glacial maximum (LGM) and coupled millennial-scale climate changes known as Dansgaard-Oeschger (D-O) and Heinrich (H) events, with temperature shifted as much as 15-20°C. Studies indicate that the extreme cold climate may have played a significant role in modern human evolution. However, how did these abrupt, millennial climate changes influence human's occupation and migration in north China especially in the desert areas are still ambiguous. To address this issue, the Shuidonggou Locality 2 paleolithic site located near the Mu Us desert was studied, where a large number of artifacts including Levallois, mammalian fossils and decorations have been unearthed. In this study, reliable chronological framework was firstly constructed using the optically stimulated luminescence (OSL) dating and climatostratigraphic correlation, and then the detailed climate changes were reconstructed by sediments grain size and pollen analysis.

Our results show the quartz grains are well-bleached and qualified for OSL dating, and then yielded an independent chronology of 43-14 ka generated by 24 OSL samples, which is rather consistent with the chronologic sequences by the AMS¹⁴C dating and climatostratigraphic correlation. Thus we obtained the detailed ages for the seven artifact layers of 42-40ka, 37-36ka, 36-35ka, 34-33ka, 33-32ka, 32-31ka and 30-28ka based on this high-resolution dating sequence, indicating millennial cyclic occupation of human in this areas, similar to rhythm of the global climate fluctuations. Our dating results also suggest that the occurrence of blade artifacts representing the Levallois technology from the Europe took place in this place at 40 ka ago and then was replaced by the typical flake technology carried by the local population in north China. Combined with sediments grain size data and pollen data, we found that the human's occupation in this area during the last glacial period mainly occurred in periods of relatively warm and humid climate conditions when drainage area expansion and the forest-steppe landscape development facilitated the occupation. While in the relatively cold climate, the sandstorm intensity enhanced due to desert expansion and the vegetation cover declined, thus caused the migration of the human. In addition, the Heinrich event obviously had played an important role in modulating human's occupation in Shuidonggou areas, during which ancient human was obliged to leave owing to the harsh environment. When the H3 and H4 event terminated, humans reoccupy this areas quickly, however, after the H2 event, the subsequent LGM prolonged the extremely cold climate and severely deteriorated environment and caused Shuidonggou area discarded by human for a long while until the early Holocene.

The Initial Dispersions of Modern Humans into the Siberian Arctic: A View from Archaeological and Paleo-environmental Research

Jun Takakura¹, Yasuhisa Kondo², Hiroyuki Kitagawa³

¹Archaeological Research Center, Hokkaido University, Sapporo, Japan, ²RIHN Center, Research Institute for Humanity and Nature, Kyoto, Japan, ³Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan

Understanding of the dispersal processes of modern humans into various regions of the Arctic can provide us with key information about their adaptive capabilities in extreme environmental conditions. This is also important to know the processes of the initial peopling of Americas occurred during the Late Pleistocene. Recent archaeological research in the Upper Paleolithic sites of Siberia can allow us to examine when and how the initial expansions of modern humans into the Siberian Arctic occurred. In this paper, I attempt to review the current state of the archaeological studies concerning this topic and evaluate environmental constraints of modern human dispersals into the Siberian Arctic by comparing the archaeological evidence and the paleo-environmental reconstruction for the time period and region of interest. Here, I would like to present contradictory hypotheses examining the patterning of archaeological records in the Siberian Arctic during the Marine Isotope Stage 3. Furthermore, I introduce the analytical procedure to predict the dispersal routes into the Arctic regions from southern Siberia and elucidate research- and/or taphonomic bias responsible for preservation and visibility of archaeological materials. The results of such integrated assessment may provide new insights into the studies of site formation processes in the Siberian Upper Paleolithic.

P-4269

The projection of the high-altitude settlement-subsistence patterns in the past temperate region from the modern hunter-gardener's behaviour in Taiwan

Atsushi Nobayashi

National Museum of Ethnology, Osaka, Japan, Osaka, Japan, SOKENDAI (The Graduate University for Advanced Studies), Kanagawa, Japan

The purpose of this paper is to project the high-altitude settlement-subsistence patterns in the temperate region in the past from the modern hunter-gardener's behavioral adaptation to the forest environment in mid-latitude regions.

Tadao Kano, who practiced ethnographic and biogeographic research, conducted a survey of the fauna in the mountainous area of Taiwan in the 1920-30s. He concluded from his research that Taiwan's high-altitude fauna had the feature of northern Mainland China in Pliocene and low-altitude fauna did the feature of the subtropical zone of Mainland in Pliocene. He hypothesized that they were transferred to Taiwan early in Pleistocene and subsequently divided into Taiwan island after late Pleistocene (Kano 1933).

The list of mammals that Kano showed when conducting this study includes hunting games for Taiwan indigenous people who have lived in the area. Taiwan indigenous tribes have been engaged in hunting activities in mountainous areas and slash-and-burn farming for millet and cultivation of root crops such as taro and sweet potato. On the other hand, they have the diversity on language, religion, social organization and settlement pattern. It means that different ethnic population existed simultaneously and independently in the same niche.

In this study, the author analyzed the correlation between mammalian altitude distribution and the tendency of indigenous population inhabitation. The obtained results can be summarized as follows:

1) The residence of the indigenous populations tended to place in the range 1000 to 1500 m sea level. 2) Some groups which residence placed in relative lower altitude introduced rice cultivation and practiced marine fishing and gathering. 3) Fauna lower than 1500 m sea level had the diversity of low rank resource such as muntjac, flying squirrel, masked mustang except for wild boar. 4) The peak of distribution of middle-sized mammals such as deer, bear and mountain goat was in more than 1500m sea level. It placed higher than human residential areas.

From ethnographic research, we understand that hunting activities of the indigenous populations had two types; one was to hunt wild boars or forage the low rank animals around their villages and the other was by the hunting trip departing from the villages. They also hunted low rank animals by the hunting trips. The decision making for the selection of residential place might be concerned with the distribution of their hunted games.

This paper shows the correlation between the distribution of fauna and that of indigenous residential areas and hunting behaviours to project the high-altitude settlement-subsistence patterns in the temperate region in the past.

Pleistocene geomorphology and geology of the Hrazdan valley, Armenia: linking volcanism and the Palaeolithic archaeological record in the Southern Caucasus

Jenni Sherriff¹, Keith Wilkinson¹, Daniel Adler², Emily Beverley³, Simon Blockley⁴, Darren Mark⁵, Samvel Nahapetyan⁶, Katie Preece⁷, Rhys Timms⁴, Boris Gasparyan⁸

¹Department of Archaeology, Anthropology and Geography, University of Winchester, Winchester, United Kingdom,

²Department of Anthropology, University of Connecticut, Storrs, CT, USA, ³Department of Earth and Atmospheric Sciences, University of Houston, Houston, TX, USA, ⁴Department of Geography, Royal Holloway, University of London, Egham, United Kingdom, ⁵Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom, ⁶Department of Cartography and Geomorphology, State University of Yerevan, Yerevan, Armenia, ⁷Department of Geography, Swansea University, Swansea, United Kingdom, ⁸Institute of Archaeology and Ethnography, National Academy of Sciences, Yerevan, Armenia

The Southern Caucasus, lying at the intersection between Africa, the Levant and Eurasia, is of considerable paleogeographic significance in our understanding of hominin population dynamics and behaviour during the Pleistocene. Several archaeological sites in the region attest to its importance, including Dmanisi, Georgia, in which earliest evidence for *Homo* species outside of Africa has been recovered (Ferring et al., 2001), and Nor Geghi-1, Armenia, in which there is early evidence for local technological evolution (Adler et al., 2014). However, a further understanding of the chronology and nature of climatic and geomorphic changes in the region is needed to fully understand its rich archaeological record.

The Hrazdan river valley, central Armenia, has the potential to offer unique insights into geomorphic, volcanic and archaeological behaviour in the Southern Caucasus during the Pleistocene. It possesses extensive fluvial and lacustrine archives, and a rich Palaeolithic record, while chronometric dating and geochemical correlation of volcanic deposits, enable the development of precise chronologies. This presentation discusses the Pleistocene record of the Hrazdan valley based on the results of extensive geological and geomorphic mapping, archaeological survey and excavation within the valley. Using these mapping data and published chronometric results (⁴⁰Ar/³⁹Ar and K-Ar), we present a stratigraphic framework for environmental change and hominin activity during the Middle Pleistocene. We demonstrate that the onset of volcanic activity in the Gegham range to the east of the valley occurred around 700 ka BP, after which there were several phases of volcanism lasting until 200 ka BP. Interbedded with lava emplaced by these eruptions are sedimentary sequences, several of which have yielded archaeological remains. Sedimentological analysis of these sequences suggests that lava emplacement in the Hrazdan valley led to damming of the palaeo-Hrazdan and the subsequent development of lakes. This was followed by a period of predominately fluvial deposition and the development of floodplain soils. Based on our current stratigraphic framework, it is clear that this cycle was repeated at least seven times. Chrono- and lithostratigraphic evidence from these sequences indicates that during this period, hominin populations were exploiting the floodplain during humid interglacial conditions. Despite the fragmentary nature of the sequences they collectively provide a record covering an important phase of early Human development and dispersal during the Middle Pleistocene.

The Late Pleistocene hunter-gatherer adaptation to altitude differences? : a case in the Central Highland in the Japanese Archipelago

Atsushi Noguchi

The University Museum, The University of Tokyo, Tokyo, Japan

The number of archaeological sites in the early phase of Upper Palaeolithic (EUP) in the Japanese Archipelago shows abrupt increasing while only a few assumed and controversial Middle Palaeolithic sites are recognized. It indicates rapid growth of population size during the period by immigration to almost unoccupied niche.

According to the comprehensive Palaeolithic site database by JPRA (JPRA-DB), the distribution of EUP sites is observed among entire the Palaeo-Honshu Island consisted of 3 major islands and adjacent small ones in the present. EUP sites are located in the high altitude zone including over 1,600m A.S.L. mainly in the Central Highland region. It is continued from the initial stage of EUP to the transition of UP and the Incipient Jomon, or the earliest stage of Holocene.

In this paper, the settlement pattern in the Central Highland region is examined upon quantified data from JPRA-DB in comparison with the pattern in the Plain region for discussion of long-term dynamics of hunter-gatherer adaptation to altitude differences in the late Pleistocene.

The focal reason of exploitation of high altitude zone in the region is the existence of the sources of fine obsidian. Utilization of obsidian from those sources are identified by geochemical provenancing. Perhaps the clusters of sites are recognized surrounding those obsidian sources from EUP to LUP. However there are archaeological sites in another high altitude zones and intermediate zones apart from obsidian sources. Distribution pattern shows continuous occupation from lower area, piedmont zone to highland. Lithic assemblage and technology in different altitudal zone looks almost similar. It indicates that adaptation to different altitude zone by the Pleistocene hunter-gatherer while sites in the higher zone were beyond timberline and the highest ones were beyond snow line during the LGM. This means that hunter-gatherer groups adapted to different ecological niches in different altitude zone.

In the terminal Upper Palaeolithic, distribution pattern of site shows changing. Site cluster surrounding obsidian sources disappeared while other site cluster appeared in different high altitude zone apart from obsidian sources. Average height of site location in the high altitude zone is also decreased. It would be corresponded to the change of vegetation and other environmental aspects during the terminal Pleistocene with change of lithic technology to the microblade assemblage.

There are few long, continuous, terrestrial Pleistocene records from eastern Africa, so it is difficult to establish the relative influences of different climate forcings on the region's hydroclimate and to understand the climatic conditions through the time interval of anatomically modern human (AMH) origin and dispersal out of Africa. To address these gaps in our knowledge, we have cored lake sediments from Chew Bahir in southern Ethiopia, close to the Omo-Kibish, site of the oldest known eastern African AMH fossils. A 40 metre core is estimated to span the last 116 kyr. The proxy data show highly variable hydroclimate conditions from 116-66 kyr, with rapid shifts from very wet to extreme aridity. From 58-32 kyr, the proxies suggest a drier but much more stable regional hydrological setting, which facilitated the development of more habitable ecosystems. This shift, from more to less variable hydroclimate, may help account for the timing of the dispersal of some AMHs out of Africa. A longer, c. 280 m core from Chew Bahir is estimated to cover the past ~600 kyr, and the oxygen isotope data suggest significant fluctuations in water balance through this time period.

Coring for climatic context of human origins key sites: The ~600,000-year climate record from Chew Bahir, southern Ethiopia

Verena E. Foerster¹, Asfawossen Asrat², Andrew S. Cohen³, Melissa S. Chapot⁴, Alan Deino⁵, Daniel M. Deocampo⁶, Walter Duesing⁷, Christina Guenter⁷, Annett Junginger^{8,9}, Henry F. Lamb⁴, Christine Lane¹⁰, Christopher Bronk Ramsey¹¹, Helen M. Roberts⁴, Céline Vidal¹⁰, Frank Schaebitz¹, Martin H. Trauth⁷

¹University of Cologne, Institute of Geography Education, Cologne, Germany, ²Addis Ababa University, School of Earth Sciences, Addis Ababa, Ethiopia, ³University of Arizona, Department of Geosciences, Tucson, USA, ⁴University of Aberystwyth, Department of Geography and Earth Sciences, Aberystwyth, United Kingdom, ⁵Berkeley Geochronology Center, Berkeley, USA, ⁶Georgia State University, Department of Geosciences, Atlanta, USA, ⁷University of Potsdam, Institute of Geosciences, Potsdam, Germany, ⁸Eberhard Karls Universität Tübingen, Department of Earth Sciences, Tuebingen, Germany, ⁹Senckenberg Centre for Human Evolution and Palaeoenvironment, Tuebingen, Germany, ¹⁰University of Cambridge, Department of Geography, Cambridge, United Kingdom, ¹¹University of Oxford, Oxford Radiocarbon Accelerator Unit, Oxford, United Kingdom

In order to understand the climatic component in human-climate interaction studies, the Chew Bahir Drilling project as part of the *Hominin Sites and Paleolakes Drilling Project* has recovered a ~280 m long sediment core from the Chew Bahir Basin in the southern Ethiopian Rift, in close proximity to some of the key hominin sites. Our age model for the core, based on Ar/Ar, OSL and radiocarbon ages, shows that the Chew Bahir record covers ~600,000 years of climatic history, a time period that includes the transition from the Acheulean to the Middle Stone Age, and the origin and dispersal of anatomically modern humans.

The Chew Bahir record shows long-term trends and cycles, wet-dry oscillations on shorter time scales, and pronounced climate events. We used a multi proxy approach to climatic reconstruction, including MSCL, grain-size analysis, XRF geochemistry and XRD. The results suggest dramatic shifts in eastern African climate between extreme aridity with vanishing water bodies, strongly decreased vegetation cover and highly alkaline and saline paleolakes, and returning humid phases, such as the well documented African Humid Period (~15-5 ka BP), marked by extensive fresh water lakes, a more extensive vegetation cover and plentiful resources for human populations. The high core recovery, the well-dated and independent age model and our developing understanding of site-specific proxy formation, give us a comprehensive record of environmental history on decadal to orbital timescales.

P-4274

The timing of humid phases on the southwestern Arabian coast: the chronological and palaeoenvironmental record of an archaeology-rich tufa basin.

Abi Stone¹, Robyn Inglis², Diana Sahy³, Ian Candy⁴, Abdullah Alsharekh⁵, Anthony Sinclair⁶

¹Quaternary Environments and Geoarchaeology Research Group, Department of Geography, University of Manchester, Manchester, United Kingdom, ²Department of Archaeology, University of York, York, United Kingdom, ³British Geological Survey, Keyworth, Nottingham, United Kingdom, ⁴Department of Geography, Centre for Quaternary Research, Royal Holloway, University of London, Egham, United Kingdom, ⁵Department of Archaeology, King Saud University, Riyadh, Saudi Arabia, ⁶Department of Archaeology, Classics and Egyptology, University of Liverpool, Liverpool, United Kingdom

The south-eastern Red Sea region may have served as a refuge during Quaternary arid phases for hominin populations migrating out of the Saharo-African region (Bailey, 2009). Wadi Dabsa, within the volcanic landscapes of Harrat al Birk contains the richest and highest density of lithic artifacts (~3000) in southwestern Saudi Arabia (Fould et al., 2015; Inglis et al., 2019). It drains the western side of the Harrat Al Birk for a few 10s of km and the southern tributary opens into a basin (where the lithics are located) that is dominated by a tufa sedimentary unit indicating significantly, and consistently, wetter conditions at various points during the Late Quaternary, making it an attractive site for hominin populations. The range of tufa morphologies within the basin indicate that these wetter phases involved both standing and running water. The stratigraphies include units of large tufa-cemented basalt bedload (boulder-sized) recording phases of high-energy fluvial flow, and units of tufa with little, or no bedload, recording a lower-energy surface water environment.

We investigate both a basalt handaxe that is partially encased in tufa as well as tufa units on which the surface lithic archaeology is located, in addition to a tufa unit ~ 1.5 m below the surface and a large tufa cascade downstream from the Wadi Dabsa basin. The palaeoenvironmental and chronological context of the tufa and the associated lithics can be reconstructed using facies descriptions in hand section and thin-section, geochemical analysis and stable isotopic data, alongside ²³⁴U-²³⁰Th dating. Here we present the analysis of 12 tufa samples across the basin, including the surface units associated with the lithic finds, a deeper unit (~1.5 m below the surface) and a fan, containing a large tufa cascade at the distal end of the basin. The results indicate wetter conditions during MIS 7 and MIS 5 (into MIS4), from a meteoric water source (not deep thermal groundwater) and a catchment covered in C3 vegetation. Comparisons are made with the timing and composition of tufa deposits on the western side of the Red Sea.

P-4275

Interpreting the palaeoenvironment of archaeological sites within the Nihewan Basin, North China: a new multi-proxy approach.

Cat Langford¹, Steffen Mischke¹, Hailong Zhao², Chengjun Zhang³

¹School of Engineering and Natural Sciences, University of Iceland, Reykjavik, Iceland, ²Institute of Nihewan Archaeology Research, Hebei Normal University, Hebei, China, ³School of Earth Sciences and Key Laboratory of Mineral Resources in Western China, Lanzhou University, Lanzhou, China

Important archaeological sites regarding the spread of early humans are situated in the fluvio-lacustrine Pleistocene stratigraphy of the Nihewan Basin. The Nihewan Basin is one of the most intensively studied areas of human occupation in higher latitude areas, due to the concentration and availability of archaeological sites between 2.0-0.8 Ma. However, for sites without an established geochronology correlation proves difficult, as the nature of the sediments impedes accurate correlation. Nonetheless, preliminary results have shown that it is possible to correlate sites without prioritising the use of magnetostratigraphy. New and previously studied sites have been investigated using a range of analyses. The sites that have been analysed with this multi-proxy approach include Majuangou (MJG) and Banshan, Shigou (SG), Xiantai, Xiaochangliang, Feiliang, Madigou and Cenjiawan.

The micropalaeontological analysis includes a systematic approach to analysing ostracod taxa that has revealed 13 different species that occur within both MJG and SG. The ostracods *Ilyocypris* and *Leucocythere/Limnocythere* are the most dominate in both sections, suggesting a environmental relationship between the two sites. However, taxa including *Heterocypris*, *Eucypris*, *Fabaeformiscandona*, *Pseudocandona* and *Cytherissa lacustris*, occur within both sections, providing evidence that the environment within the both sites fluctuated regularly. The microfossil and macrofossil data have allowed for a more accurate palaeoenvironmental reconstruction and the results of the palaeontological analysis suggest that the overall palaeoenvironment was changeable. The ostracod analysis and results confirm that the studied sites were part of a semi-stable aqueous environment

Sedimentary analysis has provided detailed sedimentary logs of the Nihewan Basin, revealing erosive, transitional and sharp boundaries, aiding in correlation of sediments. Analyses and results show that it is possible to correlate MJG and SG using two erosive boundaries in SG, *Cytherissa lacustris* (used as a marker ostracod in both MJG and SG) and sedimentary features indicative of flooding, such as mud balls and silt drapes. With the use of this new multi-proxy approach, it is hoped that this project will help develop a method with the ability to efficiently correlate exposed sediment sections within the Nihewan Basin without the prioritisation of magnetostratigraphy. Furthermore, these results will help aid the interpretation of the palaeoenvironment in which early hominin occupied higher northern latitudes.

The earliest evidence of hominin occupation in North Africa: chronological framework of Ain Boucherit site, Algeria

Mathieu Duval^{1,2}, Josep M. Parés², Jan van der Made³, Mohamed Sahnouni^{2,4}

¹Griffith University, Brisbane, Australia, ²CENIEH, Burgos, Spain, ³Museo Nacional de Ciencias Naturales, Madrid, Spain, ⁴CNRPAH, Alger, Algeria

Sahnouni et al (2018) recently reported the discovery of Oldowan lithic tools and cut-marked bones from two archaeological levels at Ain Boucherit locality, Algeria. A multi-method dating approach based on magnetostratigraphy, Electron Spin Resonance and biochronology was used to chronologically constrain the deposits. This combination provided an Olduvai and early Matuyama age for the upper (AB-Up) and lower (AB-Lw) archaeological levels, respectively. Refined age estimates of 1.92 ± 0.05 Ma (AB-Up) and 2.44 ± 0.14 Ma (AB-Lw) were finally derived from the sediment accumulation rate values. This discovery pushes back by about 0.6 Ma the earliest evidence of hominin occupation in North Africa, which was previously documented at the nearby site of Ain Hanech (~1.8 Ma).

Details of the dating study published by Sahnouni et al (2018) will be presented, and the different sources of uncertainty that may impact the dating results will be evaluated and discussed.

P-4277

A new chronology for the Middle Stone Age site of Florisbad, South Africa, using luminescence dating

Robyn C. Pinder¹, Geoff A.T. Duller¹, Helen M. Roberts¹, James S. Brink^{2,3}, Rainer Grün⁴, Nigel A. Spooner⁵

¹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, SY23 3DB, United Kingdom, ²Florisbad Quaternary Research Department, National Museum, Bloemfontein, South Africa, ³Centre for Environmental Management, University of the Free State, Bloemfontein, South Africa, ⁴Australian Research Centre for Human Evolution, Griffith University, QLD 4111, Australia, ⁵Institute for Photonics and Advanced Sensing & School of Physical Sciences, University of Adelaide, Adelaide, SA 5005, Australia

Florisbad is a key Middle Stone Age (MSA) archaeological site in South Africa. It is primarily known for the discovery of a well-preserved cranium of a late archaic *Homo sapiens*, in addition to abundant MSA artefacts. Grün *et al.* (1996) provide a limited chronology for the Florisbad sequence using optically stimulated (OSL) and electron spin resonance (ESR) dating, suggesting that the cranium dates to ca. 259 ka. This makes it similar in age to newly discovered *H. sapiens* remains from Jebel Irhoud, Morocco, dated to ca. 315 ka by Richter *et al.* (2017). However, at Florisbad there are no technical details or analysis of the OSL or ESR data, and only part of the sequence was dated. This makes evaluation and interpretation of these ages problematic. Significant developments in luminescence dating over the last 20 years, particularly the development of the single-aliquot regenerative-dose (SAR) protocol, make it timely to establish a new chronology at Florisbad.

A set of 33 samples covering the whole sedimentary sequence preserved at Florisbad have been collected for luminescence dating. Three sections (Pit 3, the Dreyer section and the Western Eye section (Toffolo *et al.*, 2017)) were sampled. Luminescence ages based on analysis of two signals from quartz have been determined for samples taken above the Middle Stone Age occupation horizon. The signals used were derived from multiple and single grain optically stimulated luminescence (OSL), and thermally transferred optically stimulated luminescence (TT-OSL) measurements. The three sets of ages agree well, giving confidence in the reliability of the ages and of both signals. The quartz OSL signal in samples from beneath the Middle Stone Age occupation horizon is affected by saturation, and hence cannot be used for reliable dating. Instead, the TT-OSL signal from older samples is used.

These luminescence ages are used to construct the first robust chronology for the sedimentary sequence at Florisbad, allowing the archaeological record and palaeoenvironmental changes (Toffolo *et al.* 2017) to be set in the wider context of southern African palaeoclimatic changes, and providing a better understanding of the palaeoclimatic context of the Florisbad cranium.

Lake Magadi sediments: Deciphering primary and diagenetic features

Kennie Leet¹, Tim Lowenstein¹, Richard Owen², Nathan Rabideaux³, Emma McNulty¹, Andrew Cohen⁴, Mona Stockhecke⁵, Robin Renaut⁶

¹Binghamton University, Binghamton, USA, ²Hong Kong Baptist, Hong Kong, Hong Kong, ³Rutgers University, Newark, USA, ⁴University of Arizona, Tuscon, USA, ⁵University of Minnesota, Duluth, USA, ⁶University of Saskatchewan, Saskatoon, Canada

Lake Magadi, Kenya, a saline-alkaline lake located in the East African Rift valley, is known for its siliceous sediments including unique varieties of chert, magadiite, and abundant zeolites. Core drilling at Lake Magadi in 2014, as part of the Hominin Sites and Paleolakes Drilling Project (HSPDP), has provided the materials for detailed study of chert and other siliceous sediments. Two cores, 137.3 and 197.9 m in depth, drilled to trachyte bedrock, dated at 1.08 Ma, present an opportunity to interpret siliceous minerals in the context of evolving Magadi Basin paleoenvironments over the past one million years.

Cores contain terrigenous muds to sand-sized grains with abundant feldspars (albite, sanidine, and anorthoclase) eroded from surrounding trachyte bedrock. Finely laminated chemogenic layers of magadiite and chert derived from siliceous gel also occur in the cores. Magadiite is a hydrous sodium-silicate which forms distinctive 20 μm lepispheres. Biogenic-rich layers contain pollen and plant fragments; volcanogenic layers have abundant pumice fragments. Many of these deposits are overprinted by early diagenesis in the saline-alkaline environment. X-ray diffraction (XRD) of Lake Magadi sediments reveals a suite of zeolites including, analcime, erionite, philipsite, and [\[T6\]](#)clinoptilolite. Scanning electron microscopy (SEM) shows diagenetic formation of zeolites, including the replacement of pumice by Na-erionite, growth of erionite in pore spaces between sediments, and replacement of feldspars by erionite. XRD analysis of pure siliceous laminae with quartz and magadiite indicates partial conversion of magadiite to quartz (chert) with an intermediate quartz phase, moganite. Understanding the magadiite to chert timing is crucial for Uranium-Thorium radiometric dating.

Fluctuating silicate mineralogy can yield important paleolimnological data which can improve the overall paleoenvironmental interpretation of the Magadi Basin.

P-4279

The Little Ice Age and its impact on human activities in the Baiyangdian drainage, North China Plain

Yuecong Li¹, Baoshuo Fan¹, Wensheng Zhang¹, Ruchun Zhang², Xiaolan Yang²

¹Hebei Normal University, Shijiazhuang, China, ²Institute of Geographical Sciences, Hebei Academy of Sciences, Shijiazhuang, China

Climate change, especially dry and wet changes, has an important impact on human activities. In this study, based on three AMS-¹⁴C dating, the character of climate change, especially dry-wet change and its relationship with human activity intensity in the study area were discussed since the Little Ice Age with high resolution of 99 samples of pollen, charcoal and grain size. The results showed that: During the Little Ice Age (1340~1920A.D.), the pollen of the trees decreased to less than 15%, and the pollen contents of the Chenopodiaceae, *Urtica* and *Humulus* increased significantly compared with before, indicating that the climate had dried up, but there are significant differences in the degree of drying at different stages: In the early part of the LIA(1340~1580 A.D.), the percentages of *Pinus* were more than 20%, which was highest in the LIA, and some aquatic plants *Myriophyllum* can be recorded, On the contrary, the concentration of charcoal, and Chenopodiaceae which usually represented aridity environment were relatively lower, indicating that the climate is relatively humid. During this period, the crop pollen (Poaceae \geq 35 μ m) and phosphorus elements (P) contents, which related to human activities were the lowest, indicating that the lake were not shrunk very seriously, that make the human activities and land use intensity were relatively weak. In the middle of LIA (1580~1800 AD), the pollen content of *Pinus* was decreased to less than 15%, and aquatic pollen grains were very rare but the pollen percentages of Chenopodiaceae reached the highest value, shows that the climate become more arid and the lake had shrunk seriously. In the mean time, the Percentage of *Urtica*, *Humulus* and crop pollen (\geq 35 μ m), which have some relations with human activities, the charcoal concentration, and phosphorus (P) contents reached the highest value, indicating that the activities of humans were significantly enhanced because of the shrinking of the lake. In the late Little Ice Age (1800~1920 AD), the pollen content of *Pinus* was lower than 10%, and the pollen content of Poaceae and aquatic plants *Myriophyllum*, reached the highest value, indicating that the climate became humid once again. At this stage, the crops pollen(\geq 35 μ m), charcoal concentration and phosphorus (P) content were slightly lower than those of the previous period, indicating that the intensity of human activity and land use were slightly decreased confined by the enlarge of the lake.

Holocene Vegetation and Climate Change in Northeast China

Qiaoyu Cui

Institute of Geographic Sciences and Natural Resources Research, CAS, Beijing, China

Northeast China is an essential area for studying the strength of East Asian Summer Monsoon, due to its northernmost location in EASM domain. Furthermore, this region distributed by temporal mixed forests is the largest forest resource of China. Understanding ecosystem-climate dynamics at a broad range of temporal scales in this region becomes of key importance for forest managements and projecting climate changes in the future. However, lacking of a certain quantity of high-resolution paleoclimatic records, particularly pollen records hinder the quantitative reconstruction of paleoenvironment in northeast of China. Hence, we selected two sites, one peatland in Changbaishan mountains (eastern part of study area) and one closed crater lakes in the middle of Greater Khingan Range (western part of study area) for pollen analysis. The two high-resolution pollen records together with collected high-resolution pollen data in study region will be used for quantitative reconstructions of past environment in order to 1) draw a preliminary picture of Holocene vegetation-climate changes, and 2) understand the Holocene vegetation-climate dynamics in northeastern China.

P-4281

A multiple proxy approach to reconstruct landscape-scale vegetation in steppe-like environments: a case study from southern Kazakhstan

Laurent Marquer¹, Alexandra Engström Johansson¹, Erwan Messager², Maike Nowatzki^{1,3}, Nicolas de Munnik⁴, Florence Mazier⁴, Saida Nigmatova⁵, Kathryn Fitzsimmons¹

¹Research Group for Terrestrial Palaeoclimates, Max Planck Institute for Chemistry, Mainz, Germany, ²Université Savoie Mont Blanc, UMR 5204 CNRS EDYTEM, Chambéry, France, ³Department of Geography, University of Tübingen, Tübingen, Germany, ⁴GEODE, UMR-CNRS 5602, LABex DRIHM OHM Pyrénées Haut Vicdessos, Université Toulouse Jean Jaurès, Toulouse, France, ⁵Institute of Geological Sciences K. Satpaeva, Ministry of Education and Science of Kazakhstan, Almaty, Kazakhstan

Assessing landscape-scale vegetation mosaics based on pollen data is a challenge. In temperate environments, vegetation mosaics primarily correspond to the relative proportions of grasslands, crops and different types of forest cover. In steppe-like environments such as those of Central Asia, these mosaics consider the relative proportions of grasslands, *Artemisia* steppes, Chenopodiaceae steppes and semi-deserts, riverbanks and land-use categories. Most of these land cover types reflect open and semi-open landscapes, which increases the difficulties to identify some types of mosaic patterns. This leads us to the questions:

- Do pollen assemblages provide reliable information about landscape mosaics in steppe-like environments? and
- Can a multiproxy approach help us to disentangle such information?

To answer these questions, we conducted a vegetation study in the diverse semi-arid Ili River basin in southeast Kazakhstan. This area includes two national parks (Altyn Emel and Charyn Canyon) well known for their desert and canyon landscapes, biodiversity and red-listed species. It is characterized by a variety of desert, semi-desert and steppe landscapes. We sampled surface modern soils at 37 randomly selected locations within a radius of 55 km. At each site, we undertook botanical surveys within a 100 m radius from the soil samples following the protocol of the Crackles Bequest Project, as well as within a radius of 5 km from samples. A study of “relative pollen productivity estimates” is in progress. Maps of the major land cover types for the 37 sites have been created by using Sentinel-2 optical satellite images at a spatial resolution of 10 m, obtaining an iterative supervised classification approach within the remote sensing software SNAP. We extracted and analysed pollen, phytolith and biomarker assemblages from each soil sample. We compared the observed and proxy-based information using modelling and statistical methods. Indices of plant, pollen and phytolith composition and diversity, and biomarkers (distribution of GDGTs and n-alkanes in sediments), are used for comparison.

Reconstructing Holocene cultural landscapes in Australia using pollen-based models

Michela Mariani^{1,2}, MICHAEL-SHAWN FLETCHER¹, SIMON CONNOR³, CATHY WHITLOCK⁴, LAURIE STAHLE⁴, SIMON HABERLE³

¹UNIVERSITY OF MELBOURNE, MELBOURNE, Australia, ²UNIVERSITY OF NOTTINGHAM, NOTTINGHAM, United Kingdom, ³AUSTRALIAN NATIONAL UNIVERSITY, CANBERRA, Australia, ⁴MONTANA STATE UNIVERSITY, BOZEMAN, USA

Creating effective land management approaches requires having a solid understanding of the degree of past landscape alterations by climate change, wildfires and human activity. The quantification of these past changes depends on our ability to reconstruct past landscape openness. Fossil pollen is the key proxy to track past vegetation changes, but pollen spectra suffer from some important biases e.g. taphonomy, pollen productivity, dispersal capability. Many pollen records are dominated by pollen from a few high pollen-producing plant taxa, which mask the less producing taxa. In effect, there is a non-linear relationship between pollen percentages and plant cover. Estimating past vegetation cover from sedimentary pollen composition requires to correct for these biases using empirical-based models of the pollen-vegetation relationship. Such models for quantitative vegetation reconstruction (e.g. REVEALS) have yet been mostly applied in the Northern Hemisphere in the last 10 years - here we present recent applications of this methodology from Australia.

Although the semi-quantitative nature of Australian palynology based on pollen proportions has allowed inferences of vegetation change from pollen data, quantifying past landscape openness remains a challenge. Information on vegetation structure is needed to address archaeological questions about the origin of cultural landscapes, especially given the lack of direct association between archaeological remains and paleoecologic sites. Humans colonised Tasmania around 40,000 years ago, and are thought to have imposed a substantial imprint on the vegetation landscape through fine-scale fire management that has lasted to European arrival. Nevertheless, the origin and evolution of the present-day landscape in western Tasmania, as a result of climate variations and past human activity, has been debated. According to some, present-day treeless landscape, mostly dominated by buttongrass moorland, originated in the late Holocene due to climatic and edaphic changes coupled with increased burning. Others have proposed that moorland was previously established across the region during the last glacial cycle (ca. 35 kyrs) and was then maintained by anthropogenic burning throughout this period.

Here we show the quantification of land-cover changes through the Holocene epoch using the REVEALS model on one large site from the Cradle Mountain National Park within the World Heritage Area of Tasmania. This recent application of pollen-vegetation models has proven that treeless vegetation has been dominating the Holocene landscape in this region. We will then show consistent results from the REVEALS application using multiple small sites from within the same area. Both applications of REVEALS (single large site and multiple small sites) in Tasmania proved the biases inherent in previous interpretations of pollen spectra from this region and confirmed that the landscape of western Tasmania is an ancient cultural landscape.

P-4283

Exploring the potential of surface pollen deposition in the British Isles

Heather Pardoe¹, M. Jane Bunting², Michael Grant³, Michelle Farrell^{4,5}

¹Department of Natural Sciences, Amgueddfa Cymru - National Museum Wales, Cardiff, United Kingdom,

²Geography and Geology, University of Hull, Hull, United Kingdom, ³COARS, University of Southampton, Southampton, United Kingdom, ⁴School of Energy, Construction and Environment, Coventry University, Coventry, United Kingdom, ⁵Centre for Agroecology, Water and Resilience, Coventry University, Coventry, United Kingdom

Recently there has been increasing interest in the potential of surface pollen samples to improve our understanding of the pollen-vegetation relationship and to provide modern analogues for Quaternary plant communities. However, there are concerns that too few plant communities have been sampled or that certain past communities lack modern analogues.

This new initiative aims to improve our understanding of the representation of modern plant communities in surface pollen data and to refine the interpretation of Holocene pollen data. A surface pollen dataset will be created, encompassing a range of unique and diverse plant communities from across the British Isles, including deciduous woodland (Snowdonia, southern England and Exmoor), heathland (Snowdonia, north-east England and Exmoor), fen communities (eastern and southern England) and hay meadows (north-east England). While some British data are held in the Eurasian Modern Pollen Database, the majority are held by individual palynologists and much remains unpublished. Fragmentary data from many sites will be compiled to produce a more coherent dataset of British surface pollen deposition, to facilitate the identification of regional trends, to distinguish different vegetation types, to increase the range of modern analogues for British Holocene studies and to identify temporal trends. Surface pollen may be used to address numerous questions associated with the relationship with vegetation, annual changes in the representation of individual taxa and assessment of the impact of land management regime. Published surface moss sample data highlight contrasts between different plant communities and land-use practices, for example, moss samples from eastern England were used to demonstrate that fen vegetation, subject to different management regimes, produce distinctive pollen signatures.

Issues associated with surface sampling are addressed. Surface deposits available include pollen traps, moss samples, soils and lake surface sediments, but current research indicates that the sampling medium has a significant effect on the composition of the pollen assemblage.

A fundamental problem is the large annual variation in the quantity of pollen produced by many taxa, dependent on natural physiological rhythms in the abundance of flowering; a major contributor to the complex relationship that exists between the abundance of taxa in the vegetation and the quantity of pollen deposited. Only by sampling annually, to produce long records, can the typical quantity of pollen deposited by a taxon be accurately assessed. The considerable annual variation of *Quercus* pollen production in deciduous woodland is illustrated by pollen accumulation rates (PARs) obtained using modified-Tauber traps on Exmoor and in Snowdonia. On Exmoor *Quercus* PARs ranged from 3,500 to 26,000 grains cm⁻² yr⁻¹ over a 3-year period from 1996, while in Snowdonia *Quercus* PARs ranged from <500 to almost 95,000 grains per cm⁻² yr⁻¹, over a 7-year period from 1996. Such information is crucial to accurately reconstruct past plant communities.

P-4284

Relative pollen productivity estimates for main forest species in mainland Spain.

Hector Romanos¹, Graciela Gil-Romera^{1,2}, vojtech abraham³, Josu Aranbarri⁴, Maria Leunda¹, Miguel Sevilla¹, Penélope González-Sampériz¹, Eduardo García-Prieto¹

¹Pyrenean Institute of Ecology, Zaragoza, Spain, ²Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom, ³Department of Botany, Charles University in Prague, Prague, Czech Republic, ⁴Departamento de Estratigrafía y Paleontología, Universidad del País Vasco, Bilbao, Spain

Relative Pollen productivity estimates (RPPEs) are one of the critical parameters for a quantitative reconstruction of past vegetation cover from fossil pollen records, moving forward from the qualitative assessment of abundances based in percentages that hardly can be related to vegetation cover. RPPEs have been calculated for many regions of northern Europe, North America, Africa or China, however they have rarely been addressed in the Mediterranean region while this is a critical area as its current ecosystem heterogeneity is partly linked to past environmental factors as intertwined climate changes and human activities. It is indeed essential to have RPPEs for the Mediterranean region and therefore a larger collection of modern pollen rain from this area. This is especially true in the Iberian Peninsula (PI), where the physiographic settings define complex biogeographical patterns difficult to reconstruct.

We present here a pioneer study for mainland Spain as we calculated RPPEs for the main woody taxa of the Iberian forests as Pinus, both evergreen and deciduous Quercus, Juniperus, Fagus, Castanea, Oleacea or Abies. We have combined new modern pollen data from PaleoIPE palynological team and the available set from the European Modern Pollen Database (EMPD) with estimation of the woody cover in vegetation surveys and the archived information at the National Forestry Inventory 3 (IFN3). The EMPD holds more than 1000 samples in the whole studied area including modern moss polsters and top cores from fossil sites. We calculated RPPEs using the 3 Extended R-Value (ERV) models using the inverse modelling approach implemented in the REVEALS model. PPEs are then taken from the model with the lowest likelihood function score. We also considered a buffer of relevant vegetation of 60 km around each point.

In order to compare the effect that different environmental settings may have in the RPPEs values we divided the studied area in three subregions based on physiographic and climate criteria: coastal, continental and mountain area and we also compared differences among altitude for the same species.

Our results are discussed in comparison with those of the mid-latitudes of the Northern Hemisphere so the calculated RPPEs are expected to be different from those of the rest of the Europe. These results will necessarily have an impact on the way that the patchy Mediterranean landscape has been reconstructed and therefore our results are expected to be useful for spatial ecologists and in applied areas of nature conservation.

P-4285

Understanding pollen representation of rare herb taxa at the local scale.

Helen Shaw

Maynooth University, Maynooth, Ireland

Palaeoecological data needs to be applicable to ecology. Models adjusting quantities of key pollen types are now routinely used in palaeoecology. Treeline shifts and regional vegetation change can be established and linked with climate and land-use change models to predict future trajectories. At the local-scale, in high-nature-value cultural landscapes, a fundamental mainstay of ecological change data are vegetation cover and biodiversity surveys. These surveys can be detailed, using vegetation data from a suitable number of quadrats to develop site categorisations such as the National Vegetation classification and the European Habitat descriptors in the UK and Europe. Ecological data and palaeoecological data at the local scale need to be tested further to assess the ability to link the two datasets at this scale. Since much of the vegetation recorded in biodiverse sites produces pollen or spores sporadically, or sparsely, how far can we go with links between pollen survey and ecological survey? This paper presents research that has been attempting to discover the analytical limits of ecological palaeoecology. Using rare type pollen taxa surveys in cultural upland landscapes a modern pollen-vegetation analysis provides binary and semi-quantitative data to link pollen presence and abundance to vegetation presence and abundance at different spatial scales. In addition, the density of grazing animals is tested by relating abundance of animals to coprophilous fungal spore data in the samples. A range of differing source areas for rare-type pollen are evident, some challenges to previous assumptions on source area for herbaceous types are evident. Although a range of pollen types are clearly stochastic in distribution through the landscape and therefore into palaeoenvironmental sediments, there are also some useful patterns that emerge for some taxa, which allow a more rigorous basis for future palaeoecological interpretation and ecological linkages and these will be discussed.

P-4286

Discovering small scale vegetation patterns with the EDA

Martin Theuerkauf

Institute of Botany and Landscape Ecology, University of Greifswald, Greifswald, Germany

Pollen is known to be a powerful and valuable proxy of past vegetation. Yet, only over the past decade methods for true quantitative interpretation of pollen data have become available. Model development and application has hitherto focused on single pollen records from large lakes or mires, which ideally represent mean regional vegetation composition. The results are well suited for syntheses on the regional to continental scale, e.g. within the PAGES LandCover 6K Working Group. Such syntheses are instrumental for a better understanding of e.g. general post glacial vegetation history and climate-landcover interactions. Other questions, e.g. about plant migration pathways, past communities and early human impact, require reconstructions with higher spatial resolution. The extended downscaling approach (EDA) is one of the approaches designed to reconstruct vegetation patterns within landscapes. To that end, the EDA combines analysis of numerous pollen records from across a landscape with analysis of known (or constructed) patterns in the landscape, e.g. the soil or relief pattern. The approach then randomly assigns vegetation composition to each unit of that pattern (e.g. each soil type) and uses a forward-modelling algorithm to explore, which vegetation composition best explains the observed pollen deposition in all the numerous records during selected time slices. As a result the EDA calculates vegetation composition associated with each unit of the given landscape pattern (e.g. with each soil type).

The approach is illustrated with pollen data from northern Germany and Poland, covering the mid to late Holocene. Using the EDA results first a number of ecological and archaeological questions are discussed: How were forests composed before neolithization? Did open patches remain in the landscape (which might explain the persistent presence of e.g. horse)? Did neolithic and bronze age settlers prefer particular sites? How did natural factors, i.e. the expansion of *Fagus sylvatica* and *Carpinus betulus* and human activity change forest composition?

Secondly, technical and methodological issues are discussed, e.g. concerning site selection and accuracy of the results.

Finally, needs and options for the further development of the method are discussed.

Dynamics of the wildscape: human impacts and land use change within a wetland landscape

Nicki Whitehouse¹, Ben Gearey², M. Jane Bunting³, Nika Shilobod¹, Kim Davies¹, Wilmer Koster⁴, Lauren Mansell⁵, Henry Chapman⁶, Michelle Farrell⁷, Phil Barratt¹

¹University of Plymouth, Plymouth, United Kingdom, ²University College Cork, Cork, Ireland, ³University of Hull, Hull, United Kingdom, ⁴University of Utrecht, Utrecht, Netherlands, ⁵Queen's University Belfast, Belfast, United Kingdom, ⁶University of Birmingham, Birmingham, United Kingdom, ⁷University of Coventry, Coventry, United Kingdom

We explore changing dynamics and interactions between wetland landscape ecosystems and consider how archaeological activities and palaeoenvironmental records reflect land transformations and usage over time. Our focus is the Humberhead Levels, UK, (North Lincolnshire and South Yorkshire), just south of the Humber Estuary, where there has been a long history of palaeoenvironmental and archaeological study. The raised mires of Thorne and Hatfield Moors dominate the landscape, closely surrounded by the floodplains of the rivers Torne, Idle, Don and Went. The diverse and complex character of wetland development and human-environment interactions within the floodplains and mires is outlined through the combined use of extensive chronological Bayesian modelling, widespread geoarchaeological mapping, GIS and Lidar. These provide new insights into the temporal palaeogeography of the region. An extensive archaeological database of over 7000 points enables us to infer the nature and focus of human activity and land use, whilst thirteen pollen records provide detailed insights into the vegetational history and allow us to reconstruct the land cover history of key archaeological periods. Selected land cover reconstructions of prehistoric time slices together with archaeological data are presented, to highlight differing land use and land cover over time and how these compliment each other.

Early archaeological activity is focused alongside river systems and on higher elevations of dryland edges, especially during the Mesolithic and Neolithic. Oak and lime woodland likely dominated the higher elevations, with alder carr, wet grasslands and marsh dominating low-lying areas within the river valleys. Human impacts are evident from the early Neolithic (c. 3800 cal BC), whilst the development of raised mire and floodplain deposits from 3300 cal BC herald increasingly important wetland habitats. The continuing importance of these places for people is evidenced by a Neolithic pine corduroy trackway on Hatfield Moors (2800-2500 cal BC), a Bronze age trackway on Thorne Moors (1860-1300 cal BC), whilst the distribution of elaborate artefacts during the Bronze Age, frequently associated with wetlands and their edges, signify continued usage and importance of these areas. Woodland decline accelerates during the early Bronze age (c. 2300 cal BC) in the River Torne, Idle, Hampole Beck floodplains, with alluviation likely the consequence of agricultural clearance. After 500 cal BC, extensive woodland clearance occurred, especially widespread decline in lime woodlands. The development of an open landscape is supported by extensive archaeological finds and aerial photographic evidence, which shows large numbers of field systems and enclosures, and much of the evidence supporting continuity of landscape tenure from the Iron Age into the Roman period.

Only by reconstructing the dynamics of the wildscape of this region does it become possible to understand complex patterns of human impact and land use change, demonstrating the importance of such an approach to the study of past landscapes.

Fire, rain and civilizations in the Horn of Africa during the last three millennia

Mitchell Power^{1,2}, Valery Terwilliger³, Elizabeth Looby¹, W. Paul Adderley⁴, Zewdu Eshetu⁵, Tsegay Kahsay⁵, Marilyn Fogel⁶, Jeremy Jacob⁷, Zoe Walder-Hoge⁸, Catherine D'Andrea⁸

¹University of Utah, Salt Lake City, USA, ²Natural History Museum of Utah, Salt Lake City, USA, ³University of Kansas, Lawrence, USA, ⁴University of Stirling, Stirling, United Kingdom, ⁵University of Addis Ababa, Addis Ababa, Ethiopia, ⁶University of California, Riverside, Riverside, USA, ⁷UMR CEA-CNRS-UVSQ 8212, Gif-sur-Yvette, France, ⁸Simon Fraser University, Vancouver, Canada

Palaeoenvironmental records during the Pre-Aksumite and Aksumite periods in northern Ethiopia are interrogated using stable isotopic, elemental and charred plant remains in soils to provide local- and regional- scale records for environmental variability, including changes in rainfall, plant cover, & fire characteristics. This research is a multi-institutional initiative to examine patterns of past and present human-environmental interactions in the Horn of Africa. Specifically, the results from this transdisciplinary team aims to combine archaeological, paleoecological and traditional knowledge to understand early state formation during the Pre-Aksumite and Aksumite periods (1600 BC-AD 700). We have found charred plant remains to be ubiquitous in most soils throughout the mid-to-late Holocene and thus charcoal provides a valuable proxy for fire, climate forcing and land cover history. Previous work suggests that both Pre-Aksumite and Aksumite polities emerged during wet intervals and that the rise of the Pre-Aksumite followed a significant increase in C₄ relative to C₃ plant cover as well increased burning across multiple study sites on the Tigray Plateau. Increased intensity and magnitude of landscape burning prior to the Aksumite period was followed by reduced fire activity both locally and regionally. Changes in fire activity were likely modulated by increased human populations that are embedded in the natural climate variability coinciding with the Medieval Climate Anomaly (increased fire) and Little Ice Age (decreased fire) climates of the last millennia. The long-term effect of intensified human settlement is captured by changes in fire frequency, reduced fire episode magnitudes and suggests the Aksumite Polities created a fuel-limited landscape where most fires were likely managed.

Long-term vegetation dynamics in the highlands of the Hyrcanian forest in northern Iran

Leila Homami Totmaj, Kamaleddin Alizadeh, Hermann Behling
Department of Palynology and Climate Dynamics, Goettingen, Germany

The Hyrcanian forest hosts 3234 plant species including ca. 500 endemic plants. Along with the forests of northern Anatolia, Hyrcanian forests constitute the most important refugia and the last relicts of broad-leaved deciduous forests that covered the temperate zones of the northern hemisphere before the Quaternary. This area hosting many remnants of the Arcto-Tertiary and Indo-Malaysian flora, make this area as a centre of biodiversity with global importance. Anthropogenic forces have extensively modified the vegetation in the last centuries. Occurring in such changeable environmental conditions, investigating the Hyrcanian environmental history, including vegetation, plant diversity, climate, fire, human impact and sea level change, are of crucial importance. The isolated southern coast of the Caspian Sea to western Eurasia and its vegetation history can provide new insights into the refugium hypothesis for the west Eurasian temperate deciduous forest.

This study applies innovative multi-proxy analysis (pollen, spores, charcoal, geochemistry, and radiocarbon dating) on the Pounel sediment core, which is located in the highlands (2284 m a.s.l.) of Alborz mountain in Gilan, in order to reconstruct the alteration of vegetation since Bronze Age.

P-4290

Vegetation dynamics since ~16ka from monsoon dominant region of western Himalaya: Inferences on glacial and landcover changes

PARMINDER SINGH RANHOTRA¹, Ipsita Roy¹, Mayank Shekhar¹, Shailesh Agarwal¹, Amalava Bhattacharyya¹, Pankaj Kumar², S.K. Patil³

¹Birbal Sahni Institute of Palaeosciences, LUCKNOW, India, ²Inter University Accelerator Centre, New Delhi, India, ³KSKGRL, Indian Institute of Geomagnetism, Allahabad, India

The geographical position and orientation of the Himalayas deeply governs the monsoon distribution and the vegetation and glacial dynamism. Absence of long continuous temporal vegetation records from various monsoon zones of the region limit the understanding on the vegetation and glacial dynamics in relation to major global climate events as well as landcover assessment. Here we reconstructed a continuous post LGM (~16ka to recent) vegetation based on the pollen data from a 2.5 m deep sandy to peaty sequence of subalpine meadow (~3500 masl) within the monsoon dominant Dokriani glacial valley, Uttarakhand, western Himalaya. Changes in the pollen assemblage correspond well with the major global climate events, also providing the glacial and landcover scenario since ~16ka. A major shift in the pollen assemblage at ~11.8ka differentiate the cool-dry pre-Holocene and warm-moist Holocene epochs. The pre-Holocene (~16 to 11.8ka) sequence recovered high pollen frequency of dry/steppe taxa (*Ephedra* 1-2%, Chenopodiaceae 5-20%, *Artemisia* 2-5%, Liguliflorae 2-10%, Tubuliflorae 1-4%) and conifers (*Pinus* 15-70%, *Abies* 3-9%, *Picea* 2-4% and *Cedrus* 1-3%) contrary to low frequency of broadleaved (*Betula* <1%, *Quercus* 5-15%, *Alnus* 1-3%) and mesic/moist taxa (Ranunculaceae, Apiaceae, Polygonaceae, Pteridophytes etc). Valley experienced less ground vegetation cover, mainly with the growth of steppe taxa at meadow site. Also the sandy/silty lithology indicates high erosion and deposition under fluvial environment. Pre-Holocene tree line remained much downstream than its present limit (~3500 masl) with *Pinus* and *Abies* as main treeline elements. Glacier snout was also much downstream than its present altitude of ~3900 masl. Climatically the valley experienced weak summer monsoons and strong westerlies. Commencement of the Holocene is significant at ~11.8ka by the sharp decline of arid/steppe taxa and diversification of mesic/moist ground vegetation (Ranunculaceae 5-10%, Apiaceae 10-40%, Polygonaceae 5-15%, Gentianaceae 2-5%, Cyperaceae & Pteridophytes 5-10%) that added in the development of peaty sequence under moist conditions due to strengthening of monsoon. Following the glacial retreat under warm conditions, tree line advanced to higher reaches with *Abies* (5-15%), *Betula* (1-3%) and *Quercus* (15%) as early Holocene treeline elements. *Pinus* (5-20%), *Picea* and *Cedrus* declined to their lowest limit. By ~8.5ka *Quercus* (40-55%) dominantly occupied the valley and the treeline might reached its present limit by mid-Holocene (5-4ka). Decreasing trend in the *Quercus* with increase of *Pinus* since ~1.5ka could indicate the monsoon weakening or high evapotranspiration due to rise in temperature at higher altitudes. Further, globally related pre-Holocene climate episodes (Older Dryas, Bolling-Allerod and Younger Dryas) are strongly captured by the proxies as compared to Holocene climate variability. This signifies a strong ITCZ interplay during pre-Holocene time and weak impact of Holocene North Atlantic cooling episodes (8.2ka, 4.2ka and LIA) at the monsoon dominant regions of Himalaya.

Quantifying Holocene human impact using pollen-indicator indexes: identifying pitfalls and possible solutions

Mara Deza-Araujo^{1,2}, César Morales-Molino^{1,2}, Willy Tinner², Marco Conedera¹

¹WSL Switzerland, Cadenazzo, Switzerland, ²University of Bern, Bern, Switzerland

Anthropogenic pollen indicators in pollen records have been a traditional tool to reconstruct the history of human impact on the landscape and the biosphere. In addition, human indicators are essential to disentangle the influence of human activities and climatic variability on ecosystems. In this respect, the comprehensive anthropogenic pollen indicator approach developed by Behre (1981), has been widely used over extensive regions, in certain cases beyond its original geographical scope of Central and Western Europe. Uncritical adoption for other areas is risky because it might be that certain pollen-types considered as adventives (i.e. plant species introduced by humans, deliberately or not) in one region might actually be apophytes (i.e. native plant species favoured by human disturbances) in other regions, making the meaning of their presence and/or abundance very different across time and space. Some research efforts have been done to compile more specific lists of pollen types associated to human activities for well-defined parts of the world (e.g. Brun, 2011), while in other cases selected anthropogenic pollen indicators have been combined into index-like algorithms to infer anthropogenic disturbance (e.g. Tinner et al., 2003). We have reviewed the most commonly used approaches to quantify anthropogenic impacts from pollen records in Europe and we assess their performance at five sites spanning a continental gradient. We present insights on how these methodologies can assist in the interpretation of pollen records, and on how a careful selection of both pollen types and their combination according to the specific geographical scope of each study is key to get meaningful reconstructions of human activity through time. We conclude that alongside the increasing wealth of pollen datasets there is a need for developing novel tools that may assist for numeric human-impact reconstructions.

Pollen based quantitative reconstruction of landscape before and after the construction of Yin Ruins, Anyang, China

Wei Shen¹, Qinghai Xu², Zhichun Jing³, Xianyong Cao⁴, Shengrui Zhang², Yuecong Li²

¹Institute of Nihewan Archaeology, Hebei Normal University, Shijiazhuang, China, ²College of Resource and Environmental Sciences, Hebei Key Laboratory of Environmental Change and Ecological Construction, Hebei Normal University, Shijiazhuang, China, ³Department of Anthropology, The University of British Columbia, Vancouver, Canada, ⁴Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Yin Ruins is the capital of the late Shang Dynasty located in the Anyang City, occupies an important position in the history of Chinese civilization. In what climatic and environmental background of the Yin Ruins was constructed? And how does climate and environment affect the culture of the late Shang Dynasty? In order to solve these problems, we quantitative reconstructed the regional landscape before and after the Yin Ruins was constructed based on pollen data and LRA method (Landscape Reconstruction Algorithm). The result shows that: Before the construction of the capital (4000-3600 cal year BP), forest developed in the Anyang region (34%); large areas of forest around the Yin Ruin area (42%), farmlands scattered along the Huan River and about 15% of regional landscape, mixed broadleaf-coniferous forest associated with evergreen broadleaf species occupied the western mountains and hills (47%), and extensive wetlands developed in the downstream of the Huan River. After the construction of the capital (ca. 3400 cal year BP), forest reduced (13%) and farmlands increased (33%) in the Anyang region. Combined with the archeological data and geological evidence, we suggested that: Before the construction of the capital, the climate around the Anyang City was warm and humid, and the region was rich in forest resources, which provided sufficient building materials and fuel resources for ancient Shang people; Villages and farmlands scatter distributed along the Huan River, which provided plentiful food for the people, and human resource for the city construction. In addition, regional topography and hydrological condition also provided favorable guarantee for the construction of the city. The construction of the capital, the expansion of human activities, especially the intensification of cultivation, had a significant influence on the natural landscape.

P-4293

Inferring natural vegetation before reclamation from historical literature : cases in China

Xiuqi Fang, Xue Zheng

Faculty of Geographical Science, Beijing Normal University, Beijing, China

The records on natural vegetation or landscape extracted from the historical literature could be used as proxy for reconstructing historical natural vegetation. China has an advantage in such a research for rich in historical records. The historical records that could be used to reconstruct the historical natural vegetation are mainly classified as following types : (1) the descriptions on both vegetation forms and distributions, which could be directly used to infer the natural vegetation; (2) the records on vegetation destruction for reclamation, which could indicate the natural vegetation before reclamation and the time to be destructed; (3) the information on the boundaries of the reclamation in different periods, beyond where the natural vegetation state could be maintained; (4) the productive activities associated with some specific types of forests, grasslands, etc., which could indicate the corresponding type of vegetation. Employing the GIS technology, and combining with modern vegetation maps or potential vegetation distribution, the above-mentioned records could be used to infer a broadly range of vegetation types. Some case studies are made by using the historical records to infer the regional natural vegetation or landscape distribution in the history of China.

¹Research Group for Terrestrial Palaeoclimates, Max Planck Institute for Chemistry, Mainz, Germany, ²GEODE, UMR-CNRS 5602, LABex DRIIHM OHM Pyrénées Haut Vicdessos, Université Toulouse Jean Jaurès, Toulouse, France,

³Department of Geography, University of Tübingen, Tübingen, Germany, ⁴Institute of Geological Sciences K. Satpaeva, Ministry of Education and Science of Kazakhstan, Almaty, Kazakhstan

Land cover and land use influence the climate system from regional to global scales through biogeochemical (e.g. CO₂) and biophysical (e.g. energy exchanges in the biosphere) feedbacks. Quantitative information about these changes are critical for accurate vegetation and climate modelling in order to quantify their impacts on the climate system.

A long-term perspective (centuries to millennia) of changes in land cover and land use can be assessed by using pollen-based modelling approaches such as the REVEALS model. REVEALS estimates are now available for much of the northern Hemisphere. However, few data exist for the vast area in the centre of the Eurasian continent, the Central Asian steppes and piedmonts. Since this region is situated at the intersection between the major northern hemispheric climate subsystems, it is necessary to apply REVEALS to Central Asia in order to understand vegetation-climate feedbacks and dynamics on the world's largest continent.

Central Asia is characterized by a variety of environmental (deserts/steppes to forests) and topographical (ranging between 3000-7500 m for the highest peaks) factors that affect pollen-vegetation relationships and thereby REVEALS estimates. Available pollen records in this region substantially overestimate pollen types deriving from lowlands and steppe-like environments, in particular *Artemisia* and Chenopodiaceae taxa. Relative pollen productivity estimates (RPPs) of these taxa have been difficult to assess so far and correspond to a vast range of values. The greatest challenge for RPPs in this region include the selection of sites and approach to vegetation collection; the inclusion of different species into a unique pollen type and landscape characteristics may play an additional role.

The present study explores the pollen-vegetation relationships of steppe- and desert-like plant taxa, focusing on *Artemisia* and Chenopodiaceae pollen types. The study area is located in the Ili River basin lowlands of southeast Kazakhstan. We undertook botanical survey, created vegetation maps and took modern pollen samples at thirty-seven randomly selected locations dominated by steppe- and desert-like vegetation within a radius of 55km. Here, we 1) discuss pollen taphonomy in terms of preservation, production, dispersion and deposition, 2) estimate the relevant source area for pollen and 3) calculate RPPs for the major plant taxa. We used the Extended R-value model coupled with the Lagrangian Stochastic Model (LSM) and Gaussian Plume Model (GPM) for modelling. RPP outcomes based on both LSM and GPM models are required to analyze the effects of wind-driven uphill transport and the differential vertical dispersion of pollen, as well as the long-distance transport of pollen in the mountain ranges of Central Asia, and therefore to get accurate land-cover reconstructions for this region of the northern Hemisphere.

P-4295

Towards quantifying Holocene changes in forest cover in the Araucaria forest grassland mosaic of southern Brazil

Daniela Piraquive Bermudez¹, Martin Theuerkauf², Thomas Giesecke^{1,3}

¹Georg August Universität Göttingen, Göttingen, Germany, ²Universität Greifswald, Greifswald, Germany, ³Utrecht University, Utrecht, Netherlands

Pollen based local and regional land cover reconstructions have been successfully carried out in the high latitudes of the northern Hemisphere, while tropical and subtropical settings with many insect pollinated taxa still provide a challenge. Southern Brazil is characterized by a natural mosaic of open grasslands and woodlands characterized by *Araucaria*, which has changed in proportion during the Holocene possibly due to changes in precipitation and fire regime. In order to estimate the changes in woodland cover quantitatively we studied the modern pollen deposition in two natural remnants of the mosaic of Grasslands with *Araucaria* forest to estimate the first rPPE's for this region. Surveys of surface pollen deposition and vegetation cover were carried out in Aparados da Serra National Park, Rio Grande do Sul State and Vila Velha State Park, Parana State. Preliminary results show that woodland taxa other than *Araucaria* are strongly underrepresented by their pollen, while some shrubs frequently occurring at the forest edge have a good pollen representation. We will compare the results from the two regions with different woodland composition and discuss the challenges of reconstructing the forest cover in this region. Applying the results to published Holocene pollen data from the region we will explore the strength of this approach for the area.

P-4296

Pollen-based quantitative land-cover reconstruction for northern Asia during the last 40 ka

Xianyong Cao¹, Fang Tian¹, Furong Li², Marie-José Gaillard², Natalia Rudaya^{1,3,4}, Ulrike Herzschuh^{1,4,5}

¹Alfred Wegener Institute for Polar and Marine Research, Potsdam, Germany, ²Department of Biology and Environmental Science, Linnaeus University, Kalmar, Sweden, ³Institute of Archaeology and Ethnography, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russian Federation, ⁴Institute of Earth and Environmental Sciences, University of Potsdam, Potsdam, Germany, ⁵Institute of Biochemistry and Biology, University of Potsdam, Potsdam, Germany

We collected the available relative pollen productivity (RPP) estimates for 27 major pollen taxa from Eurasia and applied them to estimate plant abundances during the last 40 cal. ka BP (calibrated thousand-year before the present) using pollen counts from 203 fossil pollen records in northern Asia (north of 40°N). These pollen records were organised into 42 site groups; and regional mean plant abundances were calculated using the REVEALS (Regional Estimates of Vegetation Abundance from Large Sites) model. Time-series clustering, constrained hierarchical clustering, and detrended canonical correspondence analysis were performed to investigate the regional pattern, time, and strength of vegetation changes, respectively. Reconstructed regional land cover for each site group is generally consistent with *in situ* modern vegetation in that vegetation changes within the regions are characterized by minor changes in the abundance of major taxa rather than by invasions of new taxa, particularly during the Holocene. We argue that pollen-based REVEALS estimates of plant abundances should be a more reliable reflection of the vegetation as pollen may overestimate the turnover, particularly when a high pollen producer invades areas dominated by low pollen producers. Comparisons with vegetation-independent climate records show that climate change is the primary factor driving land-cover changes at broad spatial and temporal scales. Vegetation changes in certain regions or periods, however, could not be explained by direct climate change, for example inland Siberia, where a sharp increase in evergreen conifer tree abundance occurred at ca. 7~8 cal. ka BP despite an unchanging climate, potentially reflecting their response to complex climate-permafrost-fire-vegetation interactions and thus a possible lagged climate response.

P-4297

Insect assemblages and the development of culture steppe

EVA PANAGIOTAKOPULU

School of GeoSciences, Edinburgh, United Kingdom

The impact of insect species which are linked with man-made habitats and human dispersal has been of global significance. Their early expansion from their original niches into Europe is related to discussions of climate change, origins of domesticated plants and animals, the spread of agriculture and infectious diseases. In order to establish the possible development of anthropogenic landscapes from an insect point of view this paper will collate and examine assemblages from different periods, having as baseline the mesolithic prior to the introduction of agriculture, utilising the collation of data in the Bugs database. The importance of human induced change as a driver for changing insect faunas, the expansion of once marginal habitats into widespread ones and the restriction of others is evident from the Holocene fossil record, with the expansion of invasive species into new geographic areas. The results, in different chronological slices, show the development of faunas shaped by settlement pastoralism and farming. They also show links between mobility of farming groups and distribution of synanthropic insect species and produce a roadmap for the different cultural periods of the Late Holocene, based on dispersal of anthropochorous species. From storage of cereals and the introduction of domestic animals and agriculture to the spread pastoralism and expansion of exchange networks in the Neolithic, the distribution maps of these taxa provide evidence for biogeographic change and the first wave of ecological imperialism in Northwest Europe, the origins of the culture steppe. Alien insect introductions linked with itineraries of armies conquered the old world. The footsteps of the Roman army at the most northerly parts of the Empire are closely mapped by the recovery of granary weevils from well dated assemblages, but introductions also include less obviously synanthropic species, able to hitch a lift on the baggage and fodder train. From the Roman period onwards the assemblages become more strongly synanthropic, as a culture steppe develops, and this pattern continues up into the 19th century, where a transition begins to more homogenised industrially farmed environments. Urban as well as rural faunas show similar transitions as part of the development of anthropogenic environments, and these include pathogens and insect borne diseases which find new reservoirs and their distribution expands with the complexity of networks and settled areas from the first urban centres. From the medieval period, the fossil insect records indicate further expansion and changes which parallel the spread of epidemic diseases and the great biotic exchange which began with the settlement of the Americas. The overview of the expansion of human impacted faunas, its timing, geographic range and rate of change, provides information about the development of synanthropic environments and an understanding of the process leading to the current era of globalisation.

P-4298

High resolution simulations of climate and vegetation in Europe at the Last Glacial Maximum

Patricio Velasquez^{1,2}, Jed O. Kaplab³, Martina Messmer^{1,2,4}, Patrick Ludwig⁵, Christoph C. Raible^{1,2}

¹Climate and Environmental Physics, University of Bern, Bern, Switzerland, ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ³ARVE Research SARL, Pully, Switzerland, ⁴School of Earth Sciences, University of Melbourne, Melbourne, Victoria, Australia, ⁵Institute of Meteorology and Climate Research, Karlsruhe Institute of Technology, Karlsruhe, Germany

This work presents a new gridded dataset of surface conditions in Europe during the Last Glacial Maximum (LGM, 21 kya) including climate, vegetation cover, and soil temperature. To obtain the new dataset, we carried out a 30-years simulation for LGM conditions performed by an iterative asynchronous coupling between the Weather Research and Forecasting (WRF) model and the Lund-Potsdam-Jena Dynamic Global Vegetation Model version LMfire (LPJ-LMfire). The domain encompasses Europe at 18 km spatial resolution. The iterative asynchronous coupling design consists of four parts: (i) the fully coupled Community Climate System Model version 4 (CCSM4) provides global atmospheric variables for the LGM conditions to generate the first approximation of land cover with LPJ-LMfire on a coarse grid (ca. 100 km), (ii) WRF is driven by CCSM4 and uses the surface variables obtained in step (i) to generate the first downscaled atmospheric variables for the LGM at 18 km grid size, (iii) LPJ is run with the downscaled atmospheric variables (of step ii) to produce the land cover at 18 km, (iv) same as in (ii) but WRF uses surface parameters at 18 km resolution. Parts (iii) and (iv) were carried out asynchronously over 8 iterations to achieve a stable equilibrium between land cover and climate. Focusing on vegetation and land use, the results show that vegetation cover is reduced progressively in each step of the iteration. The vegetation fraction decrease strongly from 60 to approximately 20 % from the present to the LGM conditions. The MODIS land use category of bare/sparsely vegetated land is mostly observed over Europe in the LGM compared to cropland in the present. Our results compare favourably with pollen-based land cover reconstructions for LGM Europe, and show that asynchronous coupling is still a valuable method for preparing high-resolution reconstructions of past land cover and climate. Thus, the new LGM surface cover at 18 km grid spacing enables us to have insights of the regional vegetation pattern, which together with reconstructed datasets can improve the characterisation of the LGM climate. The resulting dataset can not only be used by atmospheric models as an input to make the representation of the surface fluxes more realistic, but it will also be valuable for a range of studies that consider the environmental history of Europe including climate, ecology and biodiversity, and anthropology.

Historical land cover changes in Pannonia as inferred by REVEALS modelling of pollen spectra from Lake Balaton

Enikő Magyar^{1,2,3}, Luca Szádovszky^{2,3}, Petr Kuneš⁴, Vojtěch Abraham⁴, Zoltán Szabó², Gábor Csüllög², Árpád Bihari⁵
¹MTA-MTM-ELTE Research Group for Paleontology, Budapest, Hungary, ²Eötvös Loránd University, Department of Environmental and Landscape Geography, Budapest, Hungary, ³MTA Centre for Ecological Research, GINOP Sustainable Ecosystems Group, Tihany, Hungary, ⁴Department of Botany, Faculty of Science, Charles University in Prague, Prague, Czech Republic, ⁵Isotope Climatology and Environmental Research Centre (ICER), Institute for Nuclear Research, Hungarian Academy of Science, Budapest, Hungary

Pollen records from large lakes are ideal to infer regional vegetation cover (LRA-REVEALS), and in association with several small lakes they can be used to reconstruct local vegetation composition from small lakes in the same landscape (LRA-LOVE). Balaton is the largest lake in Central Europe with nearly 600 km² surface area. In scope of an ongoing project (GINOP-2.3.2-15-2016-00019) three continuous cores were retrieved from the lake with a special focus on the reconstruction of anthropogenic land cover changes (ALCC) in the area over the last 2000 years. ²¹⁰Pb and ¹³⁷Cs dating was applied in conjunction with AMS ¹⁴C dating on pollen extracts and terrestrial plant macrofossils. These provide a firm absolute chronology for the sediment sequences. High resolution pollen study of the last 500 year deposits was used to run the REVEALS algorithm and obtain regional plant abundances using a set of 26 pollen types for which pollen productivity estimates were calculated in the neighbouring Moravia Region (Kuneš *et al.*, in review). This was followed by the comparison of the percentage share of land cover classes (deciduous forest, conifer forest, pasture/grassland) in the surface samples with the CORINE Land Cover inventory. Increasing the radius of the modern land area around the lake in consecutive circles, the best match between the surface pollen sample inferred modern land cover and the REVEALS based land cover was obtained at 200 km suggesting that the pollen source area of Lake Balaton is ~200 km.

If we look at the last 500 years, the most conspicuous change is the rapid decrease of beech forests around 1870 following the Austro-Hungarian Compromise in 1867, its partial replacement by oaks that shows very good agreement with the forestry literature. Forest industry favoured oak due to its valuable timber and good growth performance in beech forest habitats. The second drastic landscape change took place during the onset of the 2nd World War, around 1939 when the Pannonian landscape showed a massive decrease in all forests types, but particularly in oak forests. This change shows also good correspondence with the written sources.

Another significant result of the ALCC reconstruction was the demonstration of forest cover decrease between AD 1500 and today; the original 70% forest cover (excluding plough land) decreased to 35% at its minimum at the turn of the 20th century and during the Second World War and subsequent two decades. Forest cover increased since the 1970's to a small extent.

The significance of this research lies in the demonstration of good correspondence between written sources and reconstructed ALCC for the last 500 yrs. Our next attempt is to extend the LCC reconstruction back to the entire Holocene and identify periods with ALCC.

Reconstructing spatial and temporal dynamics of slash-and-burn cultivation practiced in Central Russia

Ekaterina Ershova¹, Elena Ponomarenko², Varvara Bakumenko¹, Leonid Vyazov³, Mikhail Blinnikov⁴

¹Moscow State university, Moscow, Russian Federation, ²University of Ottawa, Ottawa, Canada, ³Kazan Federal University, Kazan, Russian Federation, ⁴St. Cloud State University, St. Cloud , USA

It is believed that the slash-and-burn cultivation (SABC) was practiced at least since the Bronze Age. Numerous archaeological cultures were associated with the SABC subsistence based on the evidence for plant cultivation in the absence of agricultural implements and frequent changes in the location of dwelling sites. Given the short cropping phase and a long rotation cycle of SABC, it is assumed to have been ubiquitous in the past, affecting many forested landscapes. However, its diagnostic features in the soil were formulated only recently, thanks to the work of Tomson et al (2018) who found sites affected by the SABC in 19th century, localized them in the landscape and showed the importance of soil charcoal assemblages for determining whether a site was involved in the SABC cycle in the past. A multi-proxy analysis of the historically documented swiddens (Ponomarenko et al. 2018) showed that the swidden layers appeared as 5 to 10cm thick, dark-coloured “humus” layers with a characteristic scalloped lower boundary, formed by numerous constructions of fossorial insects, predominantly sweat bees (Fig. 1). The dark coloration originates from high concentrations of charcoal fragments with a median length of 4 to 5 mm, pebbly shape and silt coating, uniformly distributed within the swidden layers. Swidden charcoal assemblages contained a low proportion of bark (<10%), with foliage (buds and needles) being a common component, in contrast to the products of forest fires dominated by charred bark. Phytolith content of SABC layers varied from tens to hundreds of thousands per gram of soil, with up to 50% of phytoliths being charred. SABC layers contained dendritic and/or panicoid phytoliths and cereal glumes and paleas indicative of in situ cultivation of crops. These diagnostic features laid a methodological base for our current project “Temporal and Spatial Dynamics of SABC in Central Russia” (RFBR project 19-04-01246A) using a network of sites located along the major waterways that acted as traditional migration routes and presented opportunities for swidden cultivation on river banks. According to the analysis of the first 20 sites within this network, the oldest traces of the Early Iron Age SABC were found so far in the sites located on Mid-Volga, within a modern forest-steppe zone. A greater number of sites will be analyzed to create a preliminary map of SABC and draw possible routes of the swidden technology transfer/migration within the Russian Plain. All interested researchers are invited to collaborate on the project, contributing locations of sites where the soil morphology diagnostic of SABC (Fig. 1) was recorded to the database.

Fig.1. Cinder-grey swidden layer (Apyr) dotted by numerous chambers of sweat bees, found under a burial mound of 11th century, Busharino, Russia.

Enhanced surface melting of the Fennoscandian Ice Sheet during periods of North Atlantic cooling leads to Heinrich Events

Steven Boswell¹, Samuel Toucanne², Timothy Creyts¹, Frederique Eynaud³, Germain Bayon²

¹Lamont-Doherty Earth Observatory, Columbia University, New-York, USA, ²IFREMER, Unité de Recherche Géosciences Marines, Plouzané, France, ³UMR CNRS 5805 EPOC, Université de Bordeaux, Pessac, France

Heinrich Events (HEs) are dramatic episodes of ice melting and rafting during periods of exceptionally cold North Atlantic climate. However, the causal chain of events that leads to their occurrence is unresolved. Here, we demonstrate that enhanced summertime melting of the Fennoscandian Ice Sheet (FIS) is a recurring feature of Heinrich Stadials (HSs), the cold periods during which HEs occur. We use neodymium isotopes to show that the Channel River transported detrital sediments from the eastern interior of Europe to the Bay of Biscay ca. 158 to 154 ka. Based on similar evidence from the last glacial period, we infer that this interval corresponds to the melting and retreat of the southeastern Fennoscandian Ice Sheet (FIS) margin despite contemporaneous cooling in the North Atlantic and central Europe. The FIS melting episode occurred just prior to a HE, consistent with findings from the more recent HSs 1, 2, and 3. In this way, we elucidate the sequence of events that leads to HEs. Precursor melting of North Atlantic-adjacent ice sheets induces an initial AMOC slowdown. Atmospheric changes during the resulting HS cause the summertime warming in northern Europe that drives enhanced FIS surface melting. Subsequent meltwater injection to the North Atlantic causes further weakening of the AMOC and the warming of intermediate water masses that triggers HEs.

P-4402

Melting of the Alpine Ice Sheet during Heinrich Stadials: A view from the Danube sediment routing system

Ruth Martinez Lamas^{1,2}, Samuel Toucanne², Maxime Debret¹, Guillaume Soulet³, Ewan Pelleter², Sandrine Cheron², Julien Deloffre¹, Vincent Riboulot²

¹Université de Rouen, Rouen, France, ²IFREMER, Plouzané, France, ³Durham University, Durham, United Kingdom

During the last glacial period, the Black Sea was a giant lake that collected sediment-laden meltwater from the Fennoscandian (FIS) and Alpine (AIS) ice sheets through the Dnieper and Danube rivers, respectively, making this basin a suitable location to investigate past fluctuations of the European ice-sheets. As a prominent example, the Black Sea sediments revealed abrupt drainage cycles of the FIS at the end of the last glacial period, and during Heinrich Stadial 1 (~18-15 ka BP) in particular (Soulet et al., 2013). In contrast, the evolution of the AIS has never been explored from the Black Sea sediments and the Danube depositional system. Here we bridge this gap by studying the Calypso long-piston core GAS-CS01 (33.4 m), collected by 240 meters water depth during the GHASS cruise (Ifremer, 2015), and ideally located next to the Danube Canyon (NW Black Sea). The chronological framework reveals that GAS-CS01 core extends back to ~32 cal kyr BP with sedimentation rates reaching up to ~6 m/kyr. Core GAS-CS01 consists of even, parallel clastic rhythmites, with ~3050 silty to sandy laminae revealed by X-ray imagery. Accurate observations of the sandy beds reveal well-developed inversely graded facies, sedimentary structures and erosional contacts characteristics of hyperpycnal turbidity-current deposits. Hence, GAS-CS01 core provides a high-resolution flood record of the Danube River. The precise count of clastic rhythmites per time interval (250 years) suggest four main periods, each of 2-3 kyr duration, of enhanced flood frequency between ~32-15 ka BP, precisely at ~32-29 (Heinrich Stadial -HS- 3), 25-24 (HS 2), 21-19 (end of the Last Glacial Maximum) and 17.5-16 ka BP (HS 1). Interestingly, during the same periods, the sedimentary record also displays significant changes in clay mineralogy assemblage, with prominent (*i.e.* metamorphic) Alpine signatures (except for the HS 1 event that shows a Fennoscandian origin; Soulet et al., 2013). Such increases in flood frequency require an increase freshwater volume in the upper Danube drainage area, and because HSs are coeval with general cold, arid conditions in Central Europe (*e.g.* Fletcher et al., 2010), we assume Alpine melting episodes during HSs in response to summertime warming. These results, consistent with those obtained for the Fennoscandian Ice-Sheet during HS1, HS2 and HS3 (Toucanne et al., 2015), confirm that HSs were highly seasonal in character.

P-4403

Using Bayesian techniques to reconstruct the Antarctic Ice Sheet at the Last Glacial Maximum.

Fiona Turner¹, Richard Wilkinson¹, Caitlin Buck¹, Julie Jones¹, Louise Sime²

¹University of Sheffield, Sheffield, United Kingdom, ²British Antarctic Survey, Cambridge, United Kingdom

Understanding the way ice sheets are affected by warming is vital for accurate projections of climate change. By better understanding the past size and shape of the Antarctic ice sheet, we may be better able to understand how it may change in the future. This research uses a combination of Bayesian analysis and proxy data to create a model of the Antarctic ice sheet at the Last Glacial Maximum (LGM). We do this by finding the relationship between the ice sheet shape and water isotopes measured in ice cores.

A prior model developed using existing reconstructions of the ice sheet describes its size and shape during the LGM. Outputs of this model, determined by a consultation with experts, have been run through the general circulation model HadCM3, providing us with a set of water isotope estimates. The relationship between ice sheet shape and water isotopes is explored using a Gaussian Process emulator of HadCM3 and water isotope observations collected from ice cores. We can then find an ice sheet shape that will create isotopic values that match as closely as possible to the observations collected from ice cores, and therefore create a more accurate estimate of the ice sheet at the LGM. This allows us to quantify the uncertainty in the shape and incorporate expert beliefs about the Antarctic ice sheet.

P-4405

Estimating climate variability during the last Glacial and Holocene from pollen records

Nils Weitzel^{1,2}, Kira Rehfeld¹

¹Institut für Umweltphysik, Universität Heidelberg, Heidelberg, Germany, ²Institut für Geowissenschaften und Meteorologie, Universität Bonn, Bonn, Germany

Climate variability influences the probability of extreme events and is therefore of great importance for risk management. Nevertheless, the changes of climate variability over time are much less studied than changes in the mean state of the climate system, especially for the hydroclimate. Proxy records can be used to estimate the dependency of climate variability on the state and timescale, but their climate signal is perturbed by non-climatic processes and dating uncertainties. Studies show that climate variability during the last Glacial was much larger than in the Holocene and that the changes in variability depend on latitude. Our goal is to estimate climate variability on centennial to millennial time scales during the last Glacial and the Holocene at mid-to-low latitudes from pollen records. This complements previous estimates from ice cores and marine sediments. The proxy-based estimates can be used for benchmarking climate models and to give new insight on the mismatch between climate simulations and proxy based reconstructions.

Based on existing approaches from the literature, we apply Bayesian reconstruction models for pollen percentage data which can include multiple types of uncertainty stemming from the pollen-climate relation and age-depth modelling. The statistically rigorous quantification of transient uncertainties facilitates robust estimates of climate variability. Joint reconstructions of temperature in the growing season and moisture availability are planned. To account for the effect of lower CO₂ concentrations during the last Glacial, analytic corrections of the modern calibration will be incorporated in the Bayesian framework. The method is applied to publicly available pollen records.

An extension of the Bayesian framework to multi-proxy reconstructions by inverting forward models for other proxy types is envisaged in later stages of the project to borrow strength of the estimates.

P-4406

A Bayesian statistical model for reconstructing and analysing former sea levels

Niamh Cahill¹, Andrew Kemp ², Benjamin Horton³, Andrew Parnell¹

¹Maynooth University, Kildare, Ireland, ²Tufts University, Medford, USA, ³Nanyang Technological University, Singapore, Singapore

In order to understand the present we must first gain insight into the past. Therefore, to understand and have historical context for current rates of sea-level rise we need to be informed about past changes that have occurred. Sea-level reconstructions can provide this information by giving us insight into the magnitude and rates of past sea levels.

We have produced sea-level reconstructions along the U.S Atlantic East coast using biological and geochemical sea-level indicators preserved in dated cores of salt-marsh sediment. I have developed statistical models that can help us to bridge the gap between the information held in these raw proxy data and a high-resolution sea-level reconstruction. Using a Bayesian framework for these models aids in the understanding and quantification of the uncertainty that is inherent in these data and the resulting records of former sea levels.

We present A Bayesian transfer function modeling approach that is used to produce reconstructions of past sea level through the calibration of a biological proxy (e.g., foraminifera) into tidal elevation. The first step in the transfer function approach is building a model that captures the relationship between a biological proxy and tidal elevation in a modern environment. The second step uses this relationship to produce estimates of paleo-tidal elevation with uncertainty for each layer in a sediment core. Additional proxies (e.g., ¹³C) can be used to further constrain these estimates and potentially reduce uncertainty.

Combining output from the Bayesian transfer function with a core chronology provides us with a reconstruction of relative sea level through time. With the aim of estimating rates of sea-level change, reconstructions are analyzed using an errors-in-variables integrated Gaussian process model. Ultimately, through the combination of these statistical models we can capture the continuous and dynamic evolution of rates of RSL change with a full consideration and propagation of available uncertainties. Results show that 20th century sea-level rise along the U.S. Atlantic coast is the highest it's been in at least the last 15 centuries.

Spatial patterns of ocean circulation and their uncertainty: Combining Bayesian statistics and climate networks

Jasper G. Franke^{1,2}, [Reik V. Donner](#)^{1,3}

¹Potsdam Institute for Climate Impact Research, Potsdam, Germany, ²Humboldt-University, Berlin, Germany,

³Magdeburg-Stendal University of Applied Sciences, Magdeburg, Germany

Correlations between time series lay at the core of many techniques of multivariate time series analysis, for example, EOF analysis or functional climate networks. Still, comparing paleoclimate time series is complicated by a variety of typical features, including irregular sampling, age model uncertainty (e.g., errors due to interpolation between radiocarbon sampling points) and time uncertainty (uncertainty in calibration), which, taken together, result in unequal and uncertain observation times of the individual time series to be correlated. Several methods have been proposed to approximate the joint probability distribution needed to estimate correlations, most of which rely either on interpolation or temporal downsampling.

Here, we compare the performance of some popular approximation methods using synthetic data resembling common properties of real world marine sediment records. Correlations are determined by estimating the parameters of a bivariate Gaussian model from the data using Markov Chain Monte Carlo sampling. The results of these pseudoproxy experiments are used to construct functional climate networks from a set of benthic foraminifera stable isotope records from the Atlantic ocean over the last deglaciation.

We find that methods based upon interpolation yield better results in terms of precision and accuracy than those which reduce the number of observations. In all cases, the specific characteristics of the studied time series are, however, more important than the choice of a particular interpolation method. Relevant features include the number of observations, the persistence of each record, and the imposed coupling strength between the paired series. In most of our pseudoproxy experiments, uncertainty in observation times introduces less additional uncertainty than unequal sampling and errors in observation times do. Thus, it can be reasonable to rely on published time scales as long as calibration uncertainties are not known.

By constructing functional climate networks based upon 33 records covering the last deglaciation, we find that the Bayesian approach yields robust and reliable results in real world applications. In order to enable a meaningful comparison among different records, we first construct new age models, using variable, model based estimates of reservoir ages for each record. Correlations are then estimated by shifting all records such, that the onset of deglaciation is concurrent. Networks are then constructed by mutual correlations between records. These networks show many known features of Atlantic ocean variability during the last deglaciation, including high synchronicity of oxygen isotope ratios during the transition and a bipolar pattern for carbon isotopes, illustrating the millennial scale changes in ocean circulation.

P-4408

Why and How to do Bayesian Palaeoclimate Reconstruction

Michael Salter-Townshend

University College Dublin, Dublin, Ireland

We compare and contrast climate reconstructions from proxy data in a range of settings using commonly used methods, both Bayesian and non-Bayesian. The key contribution of Bayesian methodology is the ability to combine multiple sources of uncertainty and propagate these through the model coherently to provide a final posterior probability distribution on unseen palaeoclimate conditional on observed proxy data. Such a distribution captures everything we know and don't know about unobserved palaeoclimate, conditional on the observed calibration and fossil datasets. The framework is applicable in a range of settings and we demonstrate the flexibility and usefulness of the approach for a range of climate-proxy models wherein a model for proxy given climate is fit to the data before being inverted to yield a model for climate given fossil proxy. Although the approach is demonstrated to be robust to some common climate reconstruction pitfalls, there are challenges to be overcome in it becoming widely used. Firstly, it is conceptually different from the more well known frequentist statistical paradigm. Computational overhead is often a concern as the models are typically sampled from using costly Markov Chain Monte Carlo algorithms. Efficiency and reliability of the algorithms is not always straightforward to check and tuning them in this regard may require technical expertise. However, some key advancements have been made generally in the field of Bayesian analysis with new tools available to perform model building, model comparison, and automatic algorithm creation and tuning. Furthermore, new flexible tools for Bayesian palaeoclimate reconstruction are now available. We discuss these challenges and point to solutions in the context of some motivating examples.

P-4409

Data assimilation of sea surface temperature reconstructions from various proxy types in the North Atlantic over the last two millennia

Gaëlle Gilson¹, Hugues Goosse¹, Michael Neil Evans², Anne de Vernal³, François Klein¹, Quentin Dalaiden¹, Casey Saenger⁴

¹Université catholique de Louvain, Louvain-la-Neuve, Belgium, ²University of Maryland College Park, College Park, USA, ³Université du Québec à Montréal, Montréal, Canada, ⁴University of Washington Seattle Campus, Seattle, USA

The assimilation of paleo-sea surface temperature (SST) reconstructions from proxies into climate models allows combining those two complementary sources of information to better estimate past climate variability. Up until now, its application has been limited due to the mismatch in model-data variance and to the spatio-temporal heterogeneity of SST proxy signals. This study aims at combining SST reconstructions from various proxy types with climate model results across the North Atlantic region via data assimilation experiments over the last two millennia. SST reconstructions used include: 1) cores from the Ocean2k synthesis database; 2) a dataset solely composed of dinoflagellate cysts, and 3) additional cores from the North Atlantic meeting the Ocean2k quality control criteria. As a first step, simulated and reconstructed SST time series are standardized in order to dismiss the mismatch in variances. The assimilation of those time series works well at the local scale even when combining proxies carrying contrasting seasonal and ocean depth signals. The best results are obtained with the summer SST reconstructions from the dinoflagellate cysts database. In a second step, a model-data scaling experiment based on satellite observations and on the change in variance with timescale is presented. Assimilating scaled time series leads to more robust results at the regional scale compared to the assimilation of simple standardized series. Regional reconstructions are then compared to higher-resolution terrestrial archives, and potential and limitations of the method are discussed.

P-4410

New monthly indices for the East Atlantic and the Scandinavian patterns beyond the 20th century

Laia Comas-Bru¹, [Armand Hernández](#)²

¹Centre for Past Climate Change and School of Archaeology, Geography & Environmental Sciences, Reading University, Reading, United Kingdom, ²Institute of Earth Sciences Jaume Almera, ICTJA-CSIC, Barcelona, Spain

Climate variability in the North Atlantic sector is commonly ascribed to the North Atlantic Oscillation. However, recent studies have shown that taking into account the second and third mode of variability (namely the East Atlantic – EA – and the Scandinavian – SCA – patterns) greatly improves our understanding of their controlling mechanisms, as well as their impact on climate. The most commonly used EA and SCA indices span the period from 1950 to present, which is too short, for example, to calibrate palaeoclimate records or assess their variability over multi-decadal scales. To tackle this, here, we create new EOF-based (empirical orthogonal function) monthly EA and SCA indices covering the period from 1851 to present, and compare them with their equivalent instrumental indices. We also review and discuss the value of these new records and provide insights into the reasons why different sources of data may give slightly different time series. Furthermore, we demonstrate that using these patterns to explain climate variability beyond the winter season needs to be done carefully due to their non-stationary behaviour. The datasets are available at <https://doi.org/10.1594/PANGAEA.892769>.

This research was partly funded through a Beatriu de Pinós–Marie Curie COFUND contract within the framework of the FLOODS2k (2016 BP 00023), PaleoModes (CGL2016-75281-C2), and HOLMODRIVE (PTDC/CTA-GEO/29029/2018) projects.

P-4411

What can we learn from Cladocera subfossil assemblages: a training set from Central Europe.

Izabela Zawiska¹, Monika Rzodkiewicz², Michał Woszczyk², Jarosław Jasiewicz²

¹Department of Geoecology and Climatology, Institute of Geography and Spatial Organization, Polish Academy of Sciences, Warsaw, Poland, ²Department of Quaternary Geology and Paleogeography, Institute of Geoecology and Geoinformation, Adam Mickiewicz University, Poznań, Poland

The main interest of presented study was to create the Cladocera based training set to be able to quantitatively reconstruct environmental changes that have occurred in the territory of Central Europe since last glaciation retreat. Firstly we evaluated the relationship between subfossil Cladocera community composition and environmental properties of lakes of different trophy status. We hypothesized that Cladocera species composition depends mainly on the trophic state of the lake and lake depth. Therefore we sampled 30 lakes of oligotrophic, mesotrophic and eutrophic character and sediment was taken from 3 different depths: deepest part, sublittoral (2-4m) and littoral (1-2m). The 61 sediment samples were collected. At each site important water quality parameters were measured: Secchi depth (m), Chlorophyll ($\mu\text{g/l}$), cyanobacteria (phycocyanin BGA, $\mu\text{g/l}$), dissolved oxygen (mg/l), total dissolved solids TDS (mg/l), pH, temperature using multiparameter measuring device YSI. Moreover water samples were taken and analysed in the laboratory to determine HCO_3^- , SO_4^{2-} , NO_3^- , NH_4^+ , P_{tot} and PO_4^{3-} . The field campaign took place in July 2018. The timing was chosen because earlier hydrochemical studies on the annual dynamics of water trophy indicators (TP, TN) from Lakes Żabińskie, Łazduny and Rzęśniki revealed that mid-summer values were best approximation of 8-year median of these parameters. The upper 4cm sediment layer was taken for the analysis as a representation of material sedimenting in Polish lakes annually (information obtained from project CLIMPOL and studies of Gościąż lake sediments dynamics).

The water properties measured in situ during the fieldworks in July 2018 using YSI device showed that studied lakes represent a wide gradient of values a particularly: Secchi depth (5,96-0,88 m), conductivity (152,4-479 μS), Chlorophyll (0,45-29,22 $\mu\text{g/l}$) and phycocyanin BGA (0-3,28 $\mu\text{g/l}$).

The preliminary results of the subfossil Cladocera analysis showed considerable changes in Cladocera distribution according to water parameters and depth of the site. The 34 Cladocera species were identified so far. In the pelagic samples species from Bosminidae family predominate, littoral species reaches higher abundance in near shore localities. Redundancy analysis (RDA) was applied to describe the relationship between the species composition and selected variables (depth, SECCHI depth, Chlorophyll, Conductivity, cyanobacteria, total dissolved solids, water temperature and pH). The results obtained so far indicate that Cladocera training set for reconstructing one of lake trophy parameters and water depth can be established. However, more lake need to be sampled which will be done in the current year.

This study is a contribution to project founded by National Science Centre 2016/23/D/ST10/03071.

P-4412

Diatom distributions in the north-eastern Poland lakes surface sediments and their relationship to modern environmental variables

Monika Rządkiwicz¹, Izabela Zawiska², Jarosław Jasiewicz¹, Michał Woszczyk¹

¹Department of Quaternary Geology and Paleogeography, Institute of Geoecology and Geoinformation, Adam Mickiewicz University in Poznan, Poznan, Poland, ²Department of Geoecology and Climatology, Institute of Geography and Spatial Organization, Polish Academy of Sciences Warsaw, Warsaw, Poland

Lakes ecosystems are very sensitive to climatic and environmental changes. In lake sediments, there are preserved remains of plant and animals that lived in the lake and its surroundings in the past. The species composition of past assemblages is a basis for the quantitative and qualitative reconstruction of the past environmental changes. Subfossil diatoms act as one of the most commonly used paleoenvironmental bio-proxies which enable reconstructions of lake water pH, nutrient status, salinity and temperature.

In this poster, we present preliminary results from ongoing research project aiming at quantifying the relationships between modern diatom assemblages and present-day environmental conditions. These relationships will be used to develop diatom-based training set that will be applied to future studies of environmental change in Polish lakes.

Surface sediments for diatom and chemical analyses were collected from 30 lakes located in Masuria and the Suwałki region (NE Poland). At each site, a suite of important water quality parameters was collected, including chemical (e.g. phosphorous, pH) and physical (e.g., SECCHI depth) variables. Diatom assemblages from each site were counted and identified to the most specific taxonomic level possible. Diatom data were compiled for comparison to corresponding environmental data and development of indicator models.

The first results of the analysis show changes in diatom distribution as well as the chemical and physical water properties. We found 146 taxa of diatoms with 40 species with minimum 2% abundance. Redundancy analysis (RDA) was used to describe the relationship between the species composition and selected variables (depth, SECCHI depth, Chlorophyll, Conductivity, phycocyanin (BGA), total dissolved solids (TDS), water temperature and pH). In the Monte Carlo test of selected variables, 1 out of 9 environmental parameters appeared significant, including SECCHI depth.

The most abundant species from the north-eastern training set were: *Stephanodiscus parvus*, *Pantocsekiella comensis*, *Stausosira construens*, *Stausosirella lapponica*, and *Aulacoseira ambigua*.

This study provides new insights to the ecology of lakes and provides the basis for the development of training sets for north-eastern Poland lakes, useful in environmental reconstructions with the transfer function.

This study is a contribution to project founded by National Science Centre 2016/23/D/ST10/03071.

On the validity of foraminifera-based ENSO reconstructions

Brett Metcalfe^{1,2}, Bryan Lougheed¹, Claire Waelbroeck¹, Didier Roche^{1,2}

¹Laboratoire des Sciences du Climat et de l'Environnement, LSCE/IPSL, CEA-CNRS-UVSQ, Université Paris-Saclay, Paris, France, ²VU University Amsterdam, Amsterdam, Netherlands

A complete understanding of past El Niño-Southern Oscillation (ENSO) fluctuations is important for the future predictions of regional climate using climate models. Reconstructions of past ENSO dynamics use oxygen isotope ratios ($\delta^{18}\text{O}_c$) and trace metal geochemistry (Mg/Ca) recorded by planktonic foraminifera to reconstruct past spatiotemporal changes in upper ocean conditions. We investigate whether planktonic foraminifera-based proxies offer sufficient spatiotemporal continuity with which to reconstruct past ENSO dynamics. Concentrating upon the period of the instrumental record, we use the *Foraminifera as Modelled Entities* (FAME) model to statistically test whether or not $\delta^{18}\text{O}_c$ and the Temperature signal (T_c) in planktonic foraminifera directly records the ENSO cycle. Our results show that it is possible to use $\delta^{18}\text{O}_c$ from foraminifera to disentangle the ENSO signal only in certain parts of the Pacific Ocean. Furthermore, a large proportion of these areas coincide with sea-floor regions exhibiting a low sedimentation rate and/or water depth below the carbonate compensation depth, thus precluding the extraction of a temporally valid palaeoclimate signal using long-standing palaeoceanographic methods.

P-4414

A new bias-correction method for precipitation over complex terrain suitable for different climate states

Patricio Velasquez^{1,2}, Martina Messmer^{1,2,3}, Christoph C. Raible^{1,2}

¹Climate and Environmental Physics Institute, University of Bern, Bern, Switzerland, ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ³School of Earth Sciences, University of Melbourne, Melbourne, Victoria, Australia

This work presents a new bias-correction method that considers orographic characteristics. The correction method provides a tool to improve the accuracy of the input data, e.g. precipitation and temperature, used by the hydrological and glacier models. To present the new bias correction, we carry out a simulation for present day conditions performed with the Weather Research and Forecasting model (WRF) at a resolution of 2 km that is driven by the coupled model Climate Community System Model version 4 (CCSM4). The domain simulated encompasses the Alps and its forelands. The bias correction consists of two main steps: (i) separation with respect to different orographic characteristics and (ii) Empirical Quantile Mapping method. Different orographic characteristics are tested in the first step; namely, height-intervals (400 m), the slope-orientation (north, east, south and west) and the combination of both. The Alpine region is separated in two regions, Switzerland and the rest of the Alps. Fitting the bias correction to one region and applying it to the other delivers an independent test of the quality of the method. Focusing on precipitation, the results show that all three settings of the orographic characteristics are able to correct the biases in both regions. Hence, the mean values of precipitation over the flatlands and the annual cycle are adequately adjusted; moreover, the biases related to mountain peaks are mostly corrected. However, the method slightly corrects the biases in very deep valleys. One reason for the moderate adjustment is that the observational dataset uncertainties, which may be more than 30% above 1500 m.a.s.l., make it impossible to obtain a fully adequate correction. The bias correction related to the height-intervals seems to be the optimal method because the other ones yield only a minimal gain with a high computational cost. Thus, the new bias correction provides a flexible tool which can be also used in studies where orography strongly changes, e.g. during glacial times.

P-4415

The PALEOLINK working project: The missing link in the Past – Downscaling paleoclimatic Earth System Models

Juan José Gómez-Navarro¹, Patrick Ludwig², Eduardo Zorita³

¹University of Murcia, Murcia, Spain, ²Institute of Meteorology and Climate Research, Karlsruhe Institute of Technology, Karlsruhe, Germany, ³Helmholtz-Zentrum Geesthacht, Geesthacht, Germany

The comparison of climate model simulations of past climates with proxy-based climate reconstructions allows assessing the validity of climate models under the impact of different boundary conditions (particularly when considering glacial climates). However, this comparison is burdened by the fact that most climate reconstructions are based on local or regional data, whereas the Earth System Models' paleoclimate simulations have a rather coarse spatial resolution that leads to large biases over extensive regions and inhibits a realistic representation of the small scale features that affect proxy records.

To overcome this scale gap, different techniques are applied, ranging from a 'naive' approach based on selecting the closest grid point of the climate model to complex approaches that refine the simulated large-scale fields with the help of statistical or dynamical methods, i.e. Regional Climate Models. Although the latter has proven to be a valuable tool, the computational resources involved in long climate simulations normally addressed by climate reconstructions are large. The associated cost has limited the number of studies based on this approach. Currently, few regions have been subject to dynamical downscaling efforts, with a negligible number of high-resolution simulations compared to the number of coarse, global-scale simulations.

The PALEOLINK working group, hosted within the PAGES 2k network, aims at evaluating and developing new downscaling strategies that allows linking coarse Earth System Model simulations with climate reconstructions. It promotes reviewing, coordinating and stimulating future efforts trying to bridge the scale gap between the coarse resolution of state-of-the-art Earth System Models used in paleoclimate simulations and local and regional climate reconstructions. Both dynamical and statistical approaches to downscaling are considered, as well as novel combinations of both, including the use of forward models driven by downscaled climate model data reproducing the local climate and its variability.

This contribution reviews the latest news within this group, such as the output of a workshop that is being organised in February 2019.

P-4416

Constructing synthetic analogues for Climate Field Reconstructions using Gaussian Processes

Eduardo Zorita, Marlene Klockmann
Helmholtz-Zentrum-Geesthacht, Geesthacht, Germany

The analogue method is a data-driven function between predictor and predictand that is based on a look-up library of previously available predictor-predictand data. This method has been applied to paleo-climate field reconstructions using a set of proxy records as predictors and climate fields from regional or global climate simulations as predictands.

Some questions remain not clearly solved, for instance, when no clear analogues are found for a particular value of the predictor or, in contrast, when several diverging analogues are potentially possible. These situations require an 'extrapolation' or 'interpolation' of the available analogues. Both operations are not straight forward, since the predictor analogues are in general defined in a high-dimensional space, for instance large-scale sea-level-pressure patterns defined over the Northern Hemisphere. In this contribution we explore the application of a Gaussian Process theory to achieve a meaningful extrapolation of analogues in situations in which extreme events (previously not observed in the look-up table), or interpolation of analogues in situations where several, but none of them optimal, analogues can be identified in the available look-up table. A Gaussian Process is then defined to locally approximate the empirical function defined by the look-up table in the vicinity of a particular instance of the predictor. The definition of a Gaussian Process requires the prescription of the functional form of a covariance kernel. In the case of multidimensional predictands, the covariance kernel takes the form of a vector kernel, which further complicates the interpolation or extrapolation of the Gaussian Process.

The contribution will show preliminary results of the application of this approach to the reconstruction of spatially resolved climate of the past millennium based on sparse information provided by point proxy data, e.g. dendroclimatological data.

We test the method in the virtual reality provided by paleoclimate simulations with Earth System Models, in which pseudo-proxies can be constructed by sampling from simulated data at the grid-cell level, and in which the 'true' solution - the past climate fields - is also provided by the climate model.

P-4417

Insolation Variations in Eurasian Subarctic for the Holocene

Eduard Kuznetsov¹, Konstantin Bezgodov¹, Aleksandr Borodin²

¹Ural Federal University, Yekaterinburg, Russian Federation, ²Institute of Plant and Animal Ecology of the Ural branch of the Russian Academy of Sciences, Yekaterinburg, Russian Federation

Variation of the insolation is one of the global factors which determine the Earth's climate. Multi-periodic variations of the insolation determine the cyclicity of the Earth's climate. Research of the insolation variation makes it possible to relate the known centers of the genetic and morphological diversity in the model species, and the changes in the taxonomic composition and structure of the regional fauna of the Northern Eurasia with the geological events and the insolation model. The aim of the investigation is the estimation of the insolation of the Subarctic latitudes of the Urals and West Siberia during the Holocene. The calculation of insolation in the Eurasian Subarctic for the Holocene is carried out based on the model long-period evolution of the Earth's orbit La2004. That model is a numerical solution for full Solar System with the Earth's precession model based on LLR observations, orbital solution valid from -50 to +20 Ma BP. We have estimated the insolation for the latitudes from 55 to 70 degrees N. We have considered the mean daily and mean monthly insolation over 12 ka BP. The correlation of insolation is estimated with the temperature sequence of the Yamal Peninsula over 12 ka BP and global temperature indices of oxygen isotopes to investigate the insolation influence on the climatogenic dynamics. The study is supported by RFBR, research project no. 19-04-00966.

Combining environmental archaeological and modern species distribution data for the conservation of insect biodiversity

Francesca Pilotto, Philip Buckland
Environmental Archaeology Lab, Umea University, Umea, Sweden

Global changes over the latest decades have triggered a biodiversity crisis, with decline in species abundance, changes in community composition and species range shifts in several taxonomic groups. Climate change, habitat loss and fragmentation, all resulting from human activities, have been identified as concurring main drivers of the current biodiversity crisis. Environmental archaeology provides unique tools to look back to previous periods of substantial environmental changes, which can help contextualizing the magnitude and dynamics of current trends. On the other hand, one of the challenges for archaeology is to make use of the existing large amount of information that is available in archives and to provide syntheses, which could inform conservation. For example, previous environmental archaeological studies found that species with declining distributional trends are the ones at highest risk of extinction. In this study, we combine existing databases of environmental archaeological and palaeoecological data with databases of current species distribution and status. Our focus is on beetles, a largely overlooked group in environmental archaeology. Beetles represent one of the most species-rich, abundant, environmentally sensitive and archaeologically preserved groups of terrestrial insects and are an excellent proxy of environmental changes. Using both modern and fossil biodiversity data, we test for patterns linking geographical distributional ranges with extinction risk for insects, and/or whether the species at strongest risk of extinction are associated to historically vulnerable habitats. For that, we analyzed the Strategic Environmental Archaeology Database (SEAD, www.sead.se) and Bugs dataset (www.bugscep.com). The SEAD database is an open access database that contains, among other proxies, data on the past distribution of beetles from over 1200 European archaeological and Quaternary geological sites. We studied the distributional dynamics of species in Quaternary fossil samples through time and compare them with present species distribution and conservation status. We obtained data of current species distribution from biodiversity data infrastructure, including Swedish LifeWatch and Artdatabanken, and data on conservation status from the IUCN red list. Understanding the mechanisms driving biodiversity fluctuations and species extinction risk will inform management and conservation.

P-4419

Holocene heterogeneous changes of aquatic ecosystems in ACA and the MASM indicated by subfossil *Pediastrum* in different lakes

Lixiong Xiang, Xiaozhong Huang

Key Laboratory of Western China's Environmental System (Ministry of Education); College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China

Subfossil *Pediastrum*, a genus of green algae (Chlorophyceae), which is sensitive to changes in the aquatic environment, can serve as a proxy for the evolution of the aquatic ecosystem and climate change. This study synthesizes subfossil *Pediastrum* records from arid central Asia (ACA) and the marginal areas of the Asian summer monsoon (MASM) to discuss the process of lacustrine ecosystem evolution during the Holocene. It was found that aquatic ecosystems performed differently in two areas influenced by different climate systems. In the early Holocene, the low concentration records of *Pediastrum* in ACA resulted from the higher salinity caused by dry climate or lower lake level, while, higher temperature or summer insolation promote growth of *Pediastrum* in relatively humid alpine lakes as there may have no limitation of salinity. In the same period, the concentration of *Pediastrum* was higher in the lakes located in the MASM. In the middle Holocene, *Pediastrum* began to appear in freshwater lake in ACA with a higher concentration, while alpine lakes in inland areas and the MASM have significantly reduced because either cooling or reduced rainfall. In the late Holocene, the concentration of *Pediastrum* in lakes of ACA had large fluctuations, indicating an unstable climate condition, while, in the MASM area, the *Pediastrum* was generally lower in abundance because higher salinity or alkalinity with weakened summer monsoon, and different lakes had large differences because of local environmental factors. The asynchronous change of *Pediastrum* in ACA and the MASM actually reflects the moisture or precipitation variation characteristics of the monsoon or westerly dominated climate modes. The change of *Pediastrum* is mainly controlled by salinity and/or alkalinity. There is a clear consistency between high concentration of *Pediastrum* and high precipitation in the MASM during the early-mid-Holocene, which indicates that the East Asian monsoon intensively increased with more precipitation and water level of the lakes. Varieties of *Pediastrum* in lake at middle-high latitudes, such as Lake Kanas in Altai Mountains and Lake Hulun in inner Mongolia, may be related to temperature fluctuation or nutrient input during the Holocene. The ecological processes and ecological limitations of *Pediastrum* are not clear enough, which leads to difficulties in explaining the paleo-ecological and paleoclimatic significance indicated by the changes in *Pediastrum* in the strata.

The European Pollen Database (EPD) – New opportunities as a constituent database of Neotoma

Thomas Giesecke^{1,2}, Simon Brewer³, Walter Finsinger⁴, Graciela Gil-Romera^{5,6}, Eric Grimm⁷, Oliver Heiri⁸, Pim van der Knaap⁹, Petr Kuneš¹⁰, Jacqueline van Leeuwen⁹, Michelle Leydet^{11,12,13}, Cesar Morales-Molino⁹, Alistair Seddon¹⁴, Martin Theuerkauf¹⁵, Steffen Wolters Wolters¹⁶

¹University of Utrecht, Utrecht, Netherlands, ²University of Göttingen, Göttingen, Germany, ³University of Utah, Salt Lake City, USA, ⁴Institute of Evolution Sciences of Montpellier, Montpellier, France, ⁵Aberystwyth University, Aberystwyth, United Kingdom, ⁶Pyrenean Institute of Ecology- CSIC, Zaragoza, Spain, ⁷University of Minnesota, Minneapolis, USA, ⁸University of Basel, Basel, Switzerland, ⁹University of Bern, Bern, Switzerland, ¹⁰Charles University, Prague, Czech Republic, ¹¹Aix-Marseille Université, Aix-en-Provence, France, ¹²IMBE-CNRS, Aix-en-Provence, France, ¹³Avignon Université, IRD, Aix-en-Provence, France, ¹⁴University of Bergen, Bergen, Norway, ¹⁵University of Greifswald, Greifswald, Germany, ¹⁶Lower Saxony Institute for Historical Coastal Research, Wilhelmshaven, Germany

The European Pollen Database (EPD) was created nearly 30 years ago, and its importance as a data repository and research tool has steadily increased over this time, in parallel with the increased need for greater transparency in science. The latest version hosts pollen data from 2570 different sedimentary archives from 1993 sites across the European continent. The database was originally created in Paradox on MS-DOS, which has become a limiting factor for maintaining, updating, and using the database. The Neotoma Palaeoecological Database (neotomadb.org) was built as a cyberinfrastructure to host palaeoecological databases, built on state-of-the-art database software, with tools and resources needing to be developed only once while they are available for all constituent databases. Thus, Neotoma provides an ideal solution for managing the EPD. Neotoma was initially populated with data from the Global Pollen Database (GPD), which contained an older version of the EPD (pre-2007). Recent work by the active EPD community has updated many of the existing datasets, so that the migration of EPD data to Neotoma had to account for both new data entries and updated EPD datasets in Neotoma. This migration of datasets was therefore carried out dataset by dataset, which provided an opportunity for correcting inconsistencies in the data and for updating and adding additional metadata. In addition to the data migration, the EPD taxonomy support group worked to preserve and update the pollen taxonomic hierarchy, for which we have developed a corresponding R-function for combining pollen taxa at different hierarchical levels based on pollen morphology. Here we present the challenges and results of this process, highlighting the changes made to the database as well as the new opportunities of interacting with the EPD through Neotoma. We also invite conference participants to our poster to discuss desirable future developments, current problems, and opportunities for future involvement in the community.

Distributing a huge volume of paleoclimate model data: the successful collaboration between PMIP and ESGF

Jean-Yves Peterschmitt¹, Sébastien Denvil², Guillaume Levvasseur², Mark Greenslade², Atef Ben Nasser²

¹LSCE/IPSL - CEA-CNRS-UVSQ, Gif-sur-Yvette, France, ²IPSL, Paris, France

The **Paleoclimate Modelling Intercomparison Project** (PMIP) is a long standing initiative that has provided an efficient mechanism for coordinating paleoclimate modelling activities. The resulting model output database is used not only by climate modellers, but also by multidisciplinary research dealing with environment and society, such as ecological niche modellers.

The amount of available PMIP model data has grown tremendously in each phase of PMIP, from almost 2 Gb in 1996 on a single server to a distributed 'unknown' number of Tb for PMIP4.

The fourth phase (PMIP4) has started in 2015 and the 20 modelling groups involved will run all or part of the following experiments: *Last Millennium, Mid-Holocene, Last Glacial Maximum, Last Interglacial, Mid Pliocene, transient simulations and sensitivity experiments.*

We will show how we have benefited from the standards and tools developed by the **Earth System Grid Federation** (ESGF) for maintaining the distributed **Coupled Model Intercomparison Project** (CMIP) database. Adopting and using strong community standards is a prerequisite to bring data from multiple data providers to multiple end users, and for making reproducible science. We also use ESGF tools for searching and downloading the available data, and then (re)processing the data to gain new insights. We will also give a few examples using PMIP data.

Large-scale vegetation history in China and its response to climate change since the Last Glacial Maximum

Qin Li^{1,2}, Haibin Wu^{1,3,4}, Yanyan Yu¹, Aizhi Sun⁴, Yunli Luo⁵

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, 北京, China, ²CAS Center for Excellence in Tibetan Plateau Earth Sciences, 北京, China, ³CAS Center for Excellence in Life and Paleoenvironment, 北京, China, ⁴University of Chinese Academy of Sciences, 北京, China, ⁵Institute of Botany, Chinese Academy of Sciences, 北京, China

Large-scale palaeovegetation reconstruction plays a critical role in improving our understanding of the response of vegetation to climate change and in reducing the uncertainty in predictions of vegetation change under global warming scenarios. Here, we present quantitative vegetation reconstructions for China since the Last Glacial Maximum (LGM), using 286 selected fossil pollen records analyzed using the biomization method. The results show that from 23-19 ka (1 ka = 1000 cal yr BP), steppe and desert expanded southeastwards, dominating northern China, whereas forest in eastern China shrank southwards to near the middle and lower reaches of the Yangtze River; the percentage of forested sites at this time was the lowest during the studied interval. Forest then developed gradually during 18-12 ka. During the early and middle Holocene, tropical seasonal forest, broad-leaved evergreen/warm mixed forest, and temperate deciduous forest shifted northwards by 2°, 4° and 5° in latitude, respectively, relative to today, and then declined in the late Holocene. In detail, forest flourished in the middle Holocene (9-4 ka) in semi-arid and semi-humid northern China, whereas it reached a maximum in the early and middle Holocene (11.5-6 ka) in humid southern China. Our results suggest that although forest throughout China exhibited the expected response to the evolution of the East Asian summer monsoon, precipitation exerted a more significant effect on vegetation change in northern China, whereas temperature and precipitation played a more important role in southern China. Our results are a potentially useful reference for assessing future vegetation dynamics under global warming scenarios.

The PAGES 2k Network: Understanding the climate of the past 2,000 years

Steven Phipps¹, Nerilie Abram², Oliver Bothe³, Sarah Eggleston⁴, Hans Linderholm⁵, Belen Martrat⁶, Helen McGregor⁷, Raphael Neukom⁸, Scott St George⁹

¹University of Tasmania, Hobart, Australia, ²The Australian National University, Canberra, Australia, ³Helmholtz-Zentrum Geesthacht Centre for Materials and Coastal Research, Geesthacht, Germany, ⁴PAGES International Project Office, Bern, Switzerland, ⁵University of Gothenburg, Gothenburg, Sweden, ⁶Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, ⁷University of Wollongong, Wollongong, Australia, ⁸University of Bern, Bern, Switzerland, ⁹Univ of Minnesota, Minneapolis, USA

The past 2,000 years (2k) provide critical context for the recent anthropogenic forcing of the Earth's climate. The PAGES 2k Network was created with the aim of using data from natural archives to reconstruct and understand changes in regional and global surface climate over this period.

During Phases 1 (2008-2013) and 2 (2014-2016), regional and trans-regional groupings focused on building reconstructions for terrestrial regions and the oceans. The conclusion of Phase 2 coincided with the release of an open and transparent global database of temperature-sensitive proxies spanning the Common Era (PAGES 2k Consortium, 2017). This database is primarily encoded using the Linked Paleo Data format, which ensures that the data is both structured and machine readable (McKay et al., 2016).

Phase 3 aims to use open data to address questions articulated around the themes "Climate Variability, Modes and Mechanisms", "Methods and Uncertainties" and "Proxy and Model Understanding". Research is organised as a network of projects, identified and led by 2k community members. We present the ten current projects that have been established by the PAGES 2k Network community, and summarise their key outputs to date:

- ARAMATE investigates the mechanisms of ecosystem variability in the North Atlantic region using annually resolved marine and terrestrial climate archives.
- CLIM-ARCH-DATE combines new absolutely-dated marine proxy archives with other dating techniques to determine the relative and absolute timing of cultural and environmental events in the past.
- MULTICHRON investigates multidecadal climatic signals in North Atlantic sclerochronological records.
- CLIVASH2k studies large scale modes of climate variability and the mechanisms and drivers of climate change in Antarctica, the sub-Antarctic and the wider Southern Hemisphere.
- CORALHYDRO2k investigates tropical ocean hydroclimate and temperature from coral archives.
- ISO2k is building a water isotope database to study hydroclimate at decadal to centennial-scales, as well as possible secular trends.
- PALEOLINK is developing new downscaling strategies that allow the linking of coarse Earth System Model simulations with local climate reconstructions (Ludwig et al., 2018).
- PSR2k studies ocean modes by combining marine proxy records and the output from isotope-enabled and traditional GCM simulations.
- "GMST (Global Mean Surface Temperature Reconstructions)" and "Global Temperature Climate Field Reconstruction" are estimating global temperatures by using the PAGES 2k database and an ensemble of different reconstruction techniques.

Overview of the Palaeoclimate Modelling Intercomparison Project and first PMIP4 results

Masa KAGEYAMA¹, Pascale Braconnot¹, Sandy Harrison²

¹LSCE/IPSL, Gif-sur-Yvette, France, ²University of Reading, Reading, United Kingdom

The Palaeoclimate Modelling Intercomparison Project is a long-standing initiative set up to understand the response of the climate system to different climate forcings for documented climatic states very different from the present and historical climates. Through comparison with observations of the environmental impact of these climate changes, or with climate reconstructions based on physical, chemical, or biological records, PMIP also addresses the issue of how well state-of-the-art numerical models, used for climate projections, simulate climate change. Climate models are usually developed using the present and historical climates as references, but climate projections show that future climates will lie well outside these conditions. Palaeo-climates very different from these reference states therefore provide stringent tests for state-of-the-art models and a way to assess whether their sensitivity to forcings is compatible with palaeoclimatic evidence. PMIP, now starting its fourth phase, is therefore contributing to the Coupled Modelling Intercomparison Project (CMIP) and using the same model versions as those used to simulate future climates.

Simulations of five different periods have been designed to address the objectives of the sixth phase of the Coupled Model Intercomparison Project (CMIP6): the millennium prior to the industrial epoch; the mid-Holocene, 6000 years ago; the Last Glacial Maximum, 21 000 years ago; the Last Interglacial, 127 000 years ago; and the mid-Pliocene Warm Period, 3.2 million years ago. In this poster, we will give an overview of the motivation and the protocols for each of these periods and will show a first evaluation of the PMIP4 models for the mid-Holocene and the Last Glacial Maximum climates, which have been modelled since the beginning of PMIP. This will give us the opportunity to discuss about the models, the experimental protocols to run them, paleodata syntheses and methods to compare models and paleoclimatic reconstructions.

We acknowledge all PMIP participants for their contribution to simulations and data used in this work.

P-4425

Integrating tephrochronology with environmental and historical data: Tephabase and dataARC

Anthony Newton¹, Andrew Dugmore¹, Oana Huminyik¹, Rachel Opitz², Gísli Pálsson³, Richard Streeter⁴

¹School of GeoSciences, University of Edinburgh, Edinburgh, United Kingdom, ²Archaeology, School of Humanities, University of Glasgow, Glasgow, United Kingdom, ³ Department of Historical, Philosophical and Religious Studies, University of Umeå, Umeå, Sweden, ⁴School of Geography and Sustainable Development, University of St Andrews, St Andrews, United Kingdom

Tephrochronology is a well-established technique employed by Quaternary scientists and archaeologists across the globe to build interconnected dating frameworks of unrivalled precision, linking the key environmental archives formed by ice cores, ocean sediments, lacustrine deposits, peats and terrestrial soils. Since the 1990s databases have provided rigorous, effective and pragmatic ways of accessing tephra-related data and new information technologies are allowing more sophisticated integration of tephra-data. Until now, these databases have not been linked to other environmental and historical databases. This linkage could provide new insights into understanding socio-environmental change.

The National Science Foundation-funded “dataARC” project aims to bring together a wide range of disparate palaeoenvironmental, historical, literary and archaeological datasets from across the North Atlantic to help us better understand socio-environmental change in the region. Initially the effort has been focussed on Iceland and the North Atlantic, with the ambition of crafting a system that is applicable to other geographic areas as well. Rather than producing one large complicated database, dataARC uses concept mapping and combinatorics to provide the framework through which a wide variety of datasets can be connected and accessed. Tephra data is being incorporated into the system through Tephabase, a tephrochronological database. As well as Tephabase, other data sources being incorporated into the dataARC discovery portal include the NABONE zooarchaeological database, the Orkney Faunal Database, the Strategic Environmental Archaeology Database (SEAD), the Icelandic Sagas Database and the Iceland Farm Histories Database.

Over the past 24 years, Tephabase has been continually developed and now contains details of over 4,500 tephra layers at over 1100 sites. A new stage of this process is its integration into the dataARC portal, allowing tephrochronological data to directly link archaeological and palaeoenvironmental records. The number of Icelandic tephra records stored in Tephabase is being greatly expanded to provide the wider environmental context for the new archaeological tephra data. In particular, data from the areas around Mývatn in northern Iceland, and Eyjafjallajökull and Mýrdalsjökull in southern Iceland are being targeted. At the same time, Tephabase’s capability for automated stratigraphic profile construction and sediment accumulation rate (SeAR) calculations has been expanded to all relevant Icelandic profiles. This will facilitate rapid comparison of SeARs and profiles within and between regions.

P-4426

Rising Novelty in Ecosystems and Climates: looking to the past to address the challenges of a human dominated world

Alejandro Ordonez

Aarhus University , Aarhus, Denmark

We live in a world of where humans are the dominant driver of biological and environmental change. Already, many communities have been transformed by human action and the legacies of past actions, and now comprise mixtures of species with no historical or evolutionary counterpart. This has resulted in many contemporary ecosystems already differ substantively from all historical counterparts (i.e., novel ecosystem). The emerge of novel ecosystems, and climates pose both opportunities and challenges for ecologists. In our efforts to predict, understand, and prepare for the behaviour of ecosystems in a strange new world, geological and historical data are essential sources of information about processes governing species and ecosystems for timescales and states of the earth system that are inaccessible to direct observation. In this talk I will address several critical questions regarding mechanisms do novel climates give rise to novel ecosystems, what metrics best represent the exposure of communities to climate-driven reorganisation, and how *Open Big Data* can help us address the challenge of a no-analog future.

P-4427

Late Pleistocene Isoscapes: Taking the big picture approach to faunal isotope studies

Hazel Reade, Andrew Bevan, Rhiannon Stevens
UCL Institute of Archaeology, London, United Kingdom

A wealth of faunal stable isotope data exists in the published literature, largely produced during site-specific archaeological and palaeontological research. Large-herbivore stable isotope signatures track that of their diets, thus providing a valuable proxy for the isotopic composition of past vegetation, and in turn climate and environment. Faunal isotope data therefore present a unique opportunity to examine past climates, ecosystems, and the landscapes of human activity. The approach has several advantages. First, because some species have home ranges similar in size to past human groups, their isotopic signatures can provide a homogenised environmental signature at a spatial scale relevant to understand the human experience of the landscape. Likewise, because an animal's signature reflects no greater time period than its lifespan, it provides a proxy record at an annual to decadal resolution. And finally, because analysed faunal remains often bear the marks of human hunting and butchery, and because they can most often be directly dated through radiocarbon methodologies, they provide a direct means to tie together palaeoenvironmental and archaeological information. Thus, by taking a big data approach to examine spatial patterns in the isotope data (creating 'isoscapes'), big picture questions related to the influence of climate change on biogeochemical systems and human utilisation of different ecosystems during these periods can be addressed.

However, despite this potential, large-scale analysis of this type data is rarely undertaken. Two main barriers currently exist; access to data is restrictive and requires scouring individual publications; and reporting of the data is inconsistent, often lacking vital information that allows for thorough assessment of the data quality. Furthermore, many data lack specific information on sample geographic origin and age. In this study, we have undertaken a large-scale data collation project, building a near complete quality-checked and geo-referenced database of published faunal stable isotope data from Eurasia spanning the Late Pleistocene and Early Holocene. We present time-sliced spatial analysis that show gradients in isotopic compositions across the Eurasian continent and discuss the impact that this approach has on climate change and archaeological research.

P-4428

Open Science by Design: a Vision for 21st Century Research

Ester Sztein, Thomas Arrison National Academy of Sciences, Washington, DC, USA

In July 2018, the National Academies of Sciences, Engineering, and Medicine released the report *Open Science by Design: Realizing a Vision for 21st Century Research* (DOI: <https://doi.org/10.17226/25116>). This consensus study describes the current state of open science, defined as “the free availability and usability of scholarly publications, the data that result from research, and the methodologies, including code or algorithms, that were used to generate those data.” The authoring committee developed the concept of “open science by design” as a future state of affairs in which researchers possess the knowledge, tools, and incentives necessary to pursue and support open science practices throughout the full research lifecycle of a given project. The report states that the research enterprise is already realizing benefits of open science including rigor and reliability; ability to address new questions; faster and more inclusive dissemination of knowledge; broader participation in research; effective use of resources; improved performance of research tasks; and open publication for public benefits. The report also explores the barriers and limitations that still exist, including costs and infrastructure; structure of scholarly communications; lack of supportive culture, incentives, and training; privacy, security, and proprietary barriers to sharing; and disciplinary differences. The authoring committee developed key findings and recommendations with specific implementation actions for specific stakeholder communities around five areas: (1) building a supportive culture, (2) training for open science by design, (3) ensuring long-term preservation and stewardship, (4) facilitating data discovery, reuse, and reproducibility, and (5) developing new approaches to fostering open science by design. A central focus of the study and its recommendations is to ensure that research data are made openly available under FAIR (findable - accessible - interoperable - reusable) principles. The importance of scientific collections and sample preservation was also discussed. This paper will review the key challenges and opportunities for open data identified in the consensus study, and draw implications for geoscientists and the wider geosciences community.

Explosive Volcanism Triggers Chinese Dynastic Collapse

Francis Ludlow

Trinity College, Dublin, Ireland

The need to understand human vulnerability to future climate change is driving research into the influence of climate on past societies. Capitalizing upon advances in palaeoclimatic reconstruction, prominent coincidences have been noted between climatic changes and the sudden “collapses” known or inferred from historical, archaeological and palaeoecological records. These are often associated with a reduction in socioeconomic complexity and/or political discontinuity, with climate deemed to play a role mainly through the disruption of a society’s agro-ecological base. China is unique in experiencing 68 well-defined dynastic collapses during the first two millennia CE. Their frequency and precise dating affords an unparalleled opportunity to test whether climate played a role amongst the debated suite of possible causes offered to date. Here we use a state-of-the-art multi-ice-core reconstruction of volcanism to show a repeated and statistically significant association between explosive eruptions and Chinese dynastic collapses, whether of long-lived dynasties controlling large territories or shorter-lived regional dynasties in periods of instability. Collapse often occurred amidst warfare: both a contributor to and consequence of collapse. Using a 1,062 year reconstruction of warfare intensity spanning China’s northernmost to southernmost extent, we further show that warfare during and following collapse scaled in intensity with the magnitude of volcanic forcing. This result is suggestive of the pathways by which explosive eruptions may trigger collapse, including intensified resource competition under climate-induced scarcity, and opportunistic rivals exploiting reduced social cohesion alongside the material weakness and unpopularity of ruling families (associated with a perceived loss of the “mandate of heaven”) during times of socioeconomic stress. These results for the first time identify a systematic role for volcanic eruptions as historical actors in the political collapse of one of the world’s most populous, sophisticated, and long-lasting civilizations.

P-4430

Global temperature change induced by Samalas mega volcanic eruption based on CESM simulation

Bin Liu

Nanjing Normal University, Nanjing, China

Global warming is more and more severe, and the rise in Arctic surface air temperature has almost doubled the global average in recent decades. As a natural factor, volcanic eruption plays an important role in suppressing global warming. The 1257AD Samalas mega volcanic eruption on Indonesia is the largest eruption of the Common Era. How does the global temperature especially the polar region temperature response to this mega eruption that requires more discussion. We address this issue by using the Community Earth System Model to perform control experiment and volcanic sensitivity experiment. The result shows that global surface air temperature decreases obviously after the Samalas mega volcanic eruption. The temperature anomaly amplitude over high latitude is much larger than mid-low latitude. The significant cooling effect on mid-low latitude (40S-60N) lasts for five years, while the effect on high latitude could last for a decade. Besides, inter-hemispheric differences are apparent. The NH cooling (maximum is -3.97°C) is more pronounced than SH (-2.47°C). The Arctic experiences a stronger cooling with its maximum (-7.92°C) is almost twice of Antarctic (-4.26°C), and the cooling is significant and continued over a decade, whereas the Antarctic experiences a pronounced cooling for just 2 years, and followed by weak regional scale warming anomalies. The sea ice extent of Arctic and Antarctic increase simultaneously in first two post-eruption years, and there is a persistent expansion for Arctic sea ice and a retreat for Antarctic sea ice subsequently. This long-term asymmetry is mainly due to different geographical characteristic of Arctic and Antarctic, and it has an impact on the change of albedo and ocean-atmosphere heat transport over polar region. After the eruption, the first stage of temperature changes over polar region is year 0 to year 1, in which the Arctic and Antarctic basically cool, and temperature mainly reduces in local summer. This is due to the direct weakening of solar radiation induced by volcanic aerosol in polar local summer and the enhancement of solar radiation reflection caused by the increase of albedo. The second stage is the period from year 2 onwards, the temperature change over polar region is mainly in local winter, which is characterized by continuous cooling in Arctic winter and a slight warming in Antarctic winter. This is the result of ocean-atmosphere heat transport change caused by the asymmetric change of polar sea ice. In boreal winter, the expansion of Arctic sea ice hinders ocean transfers heat to atmosphere, resulting in less heat is added to atmosphere, which makes temperature drop more obvious. Whereas in Austral winter, the retreat of Antarctic sea ice promotes heat transfer from upper ocean to atmosphere, which gives more heat to atmosphere and leads to warm anomaly over the Antarctic.

P-4431

Simulation of drought persistency responses to volcanic eruptions at divergent drought phases basing on Community Earth System Model

Kefan Chen, Liang Ning, Jian Liu
Nanjing Normal University, Nanjing, China

Drought is a complex phenomenon that influenced by both internal variability as well as external forcing. Explosive volcanism is known to be a leading natural cause of aridity in monsoon regions.

The Ming dynasty drought (AD 1637-1643), which is the most severe extreme drought event in Eastern China in the past millennium, was initially triggered by internal variability and amplified by a volcanic eruption (Mt. Parker) in AD 1641 in south Philippines, according to our spectrum analysis as well as volcanic sensitivity experiments,

Subsequently, to identify whether the volcanic eruption took place in the prophase, metaphase nor anaphase of this drought, three kinds of volcanic sensitivity experiments were carried out on the basis of CESM. We selected 15 drought cases from a 500-year control run, and then added the volcano in AD 1641 to the last year, middle year and second year of each drought cases respectively.

The composited results show that, when volcano erupted in the last and middle year of the aridity, drought prolonged nearly five years, but the results in metaphase is not significant. When volcano erupted in the second year of the aridity, drought persisted merely three years, which is insignificant as well. That is to say, if the eruption time approaches the end of a drought, the duration of aridity may be longer and the magnitude may be larger. Conversely, if the eruption time is close to the beginning of a drought, the volcano is likely to weaken the initial drought trend.

The circulation field and spatial pattern of precipitation show that after explosive volcanism, drought mainly distributed in North China and the Yangtze-Huaihe region where summer monsoon decayed significantly. By comparing the sea surface temperature (SST) in both control runs and volcanic sensitivity tests, it was found that, the SST in Northwest Pacific, which is highly correlated with the variation of precipitation in eastern China, decreased significantly after volcanic eruption. In the initial stage of the drought, the low SST lasted shorter while in last stage persisted longer. The persistency of drought after volcanism is determined primitively by the persisting time of low SST in the Northwest Pacific, which is related to the SST in Northwest Pacific before eruption.

Furthermore, in the middle and early drought-stages, anticyclone occurred in the coastal area of Southeast China in the first and second year of the eruption, explaining why precipitation increased more rapidly when volcanic eruption occurred in earlier drought stages. To some extent, these findings indicated that during the Ming Dynasty drought, volcanic eruption is more likely to occur at the anaphase of the drought.

P-4432

Climatic and Human Impacts of Catastrophic Volcanic Events during the late Holocene

Kenneth Tankersley

University of Cincinnati, Cincinnati, USA

This paper uses a variety of elemental analyses including high-magnification microscopy, inductively coupled plasma mass spectrometry (ICP-MS), scanning electron microscopy, energy-dispersive X-ray, energy dispersive X-ray fluorescence, and X-ray diffractometry to identify changes in the global atmospheric budget of volcanogenic elements and minerals, which correspond to explosive late Holocene volcanic eruptions in and Guatemala, Iceland, Mexico, the United States, and Vanuatu.

Pt anomalies occur in four widely separated regions across the Western Hemisphere (Caribbean, Maya Lowland, Southwestern and Midwestern United States), which date to three climate changing late Holocene high magnitude volcanic events: Laki, Iceland (CE 1783–1784), Kuwae, Vanuatu (CE 1452–1453), and Eldgjá, Iceland (CE 934). These anomalies indicate distinctive time-correlative atmospheric deposition rates of platinum-rich volcanic ash. Kuwae produced $\sim 32\text{--}39 \text{ km}^3$ of magma and a stratospheric injection of $\sim 175\text{--}700 \text{ Mt}$ of H_2SO_4 and is considered one of the most explosive volcanic events of the Holocene. Laki produced a convective column of $\sim 120 \text{ Mt}$ of SO_2 , volcanic ash, and water vapor into the stratosphere, which reflected solar radiation, absorbed terrestrial radiation, and resulted in one the longest and coldest drops in historically recorded global temperatures. The Eldgjá eruption is the largest volcanic eruption historically recorded. It produced $\sim 219 \text{ Mt}$ of SO_2 and a $\sim 6 \text{ km}^3$ terrestrial ash fall, resulted in global cooling, famine, and epidemics for almost 10 years following the eruption.

In the Maya Lowland, volcanic ash fell in the southern Yucatan Peninsula from late Holocene catastrophic eruptions in Guatemala and Mexico. Volcanic ash was crucial in the development and maintenance of ancient Maya agricultural soils. Ash fall in this regional is controlled by wind patterns and seasonal rainfall, which are linked to changes in the Intertropical Convergence Zone (ITCZ). Changes in the ITCZ likely cause changes in the deposition of volcanic ash, increased aridity, and drought frequency and severity, which likely disrupted the Maya economy.

In the southwestern United States, volcanic ash from the late Holocene eruptions of the Sunset Crater volcano in Arizona fell in Chaco Canyon, New Mexico and likely throughout the four-corners region during the Pueblo II cultural period. Volcanogenic mineral phenocrysts and anomalously high levels of Ni, Cr, and Pt anomalies occur in Ancestral Puebloan hydraulic features including a large suite of canals and reservoirs, which retain volcanogenic mineral phenocrysts from ash falls, which date to $\sim 1085 \text{ CE}$. These volcanic eruptions likely had a profound impact on Ancestral Puebloan culture.

Elemental and mineralogical anomalies provide new chronostratigraphic markers for late Holocene high magnitude volcanic eruptions, which are especially valuable in the Western Hemisphere in strata with limited chronometric control. These anomalies provide important tracers for the age of these volcanic events and ultimately a new chronostratigraphic marker in archaeological sediments.

Socio-environmental dynamics and volcanic eruptions in the 500-1250 CE period deciphered from Lake Ljøgottjern sediment sequence (SE Norway)

Manon Bajard¹, Jostein Bakke², Eirik Ballo¹, Eivind Støren², Helge Høeg³, Frode Iversen³, Henrik Svensen¹, Kirstin Krüger⁴

¹Centre for Earth Evolution and Dynamics, University of Oslo, Oslo, Norway, ²Department of Earth Science and Bjercknes Centre for Climate Research, University of Bergen, Bergen, Norway, ³Department of Archaeology, Museum of Cultural History, University of Oslo, Oslo, Norway, ⁴Department of Geosciences, University of Oslo, Oslo, Norway

Large volcanic eruptions are the major drivers of climate variability in the pre-industrial era of the last two millennia. Understanding their impacts on societies is necessary to consider future climate and socio-environmental interactions. Lake sediments can record these dynamics on a continuous time scale and include at the same time footprints from volcanic eruptions, climate changes and human activities associated to vegetation changes. Lake Ljøgottjern is located in southeastern Norway and is of glacial origin. The lake is 18 m depth, groundwater-fed and provide a sediment sequence covering the last 8000 years. The largest burial mound of Norway was built in the mid-6th century on the shore of this lake for King Rakni and makes this place an ideal site to study human-environmental interactions throughout the last millennia, confronting them to archaeological evidences.

Using a high-resolution multi-proxy analysis of this record, including ¹⁴C dating, sedimentological and both mineral and organic geochemical analyses as well as palynological data, this study will allow reconstructing climate and socio-environmental changes in this area, with a focus on the 500-1250 CE (Common Era) period.

A previous palynological study evidenced the first openings of the environment linked to the development of agriculture between 3000 and 3500 yrs cal. BP. This change in land use was associated with changes in the geochemistry of the sediment. Maximum anthropogenic impacts were recorded in ca. 600 CE, when the mound was raised, and in the Little Ice Age, between the 13th and 17th centuries. The pollen diagram of Lake Ljøgottjern presents also three substantial decreases in charcoal particles between 500 and 1250 CE. An updated and high resolution dating of the new sequence will allow to associate or not these changes in fire regimes to major volcanic events (i.e., 536-540 unknown, 939 Eldgjà and 1257 Samalas).

The comparison of this record with other environmental archives from Norway, as well as climate reconstructions from ice cores and tree rings will allow us to discuss resilience times and adaptation of the Viking society in a changing Scandinavian environment.

P-4434

Influence of volcanic forcing on climate variability in transient simulations of the Holocene

Johann Jungclauss¹, Stephan Lorenz¹, Matthew Toohey², Claudia Timmreck¹, Jürgen Bader¹, Michael Sigl³

¹Max Planck Institute for Meteorology, Hamburg, Germany, ²GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany, ³Climate and Environmental Physics, University of Bern, Bern, Switzerland

Radiative forcing induced by variations of stratospheric sulfate aerosol from volcanic eruptions is one of the strongest natural drivers of climate variability. The primary effect of major eruptions is a short-term but substantial decrease in global mean surface temperature. In addition, volcanic forcing can influence oceanic and atmospheric circulation as well as sea ice, which may lead to long-lasting (decadal to centennial) climatic effects and spatially complex regional impacts.

Here we present results from two transient simulations covering the Holocene from 8kyr BP to 1850 CE using the comprehensive Earth system model MPI-ESM1.1. MPI-ESM is run at relatively high resolution for long-term paleo-applications. The ECHAM6 atmosphere includes the stratosphere up to 0.01 hPa and is run at T63 spectral horizontal resolution (1.9 degr.) and the MPIOM ocean model grid features variable resolution between 20 km and 180 km.

While one of our simulations is forced only by the slowly varying orbital parameters and changes in greenhouse-gas concentrations, the other includes additional, comparatively fast forcing agents including volcanic aerosols and variations in solar irradiance. In particular, we present the first application of a newly derived volcanic forcing data set for the Holocene.

Comparing the two simulations highlights in particular the effects of strong volcanic eruptions. In addition to the direct cooling effects by volcanic eruptions, we diagnose sustained changes in ocean and atmosphere circulation, and sea-ice cover. Feedbacks between these components introduce long-lasting variations in Northern Hemisphere climate. Over the Holocene, including the “fast” forcing agents introduces not only distinct climate anomalies in terms of occurrence and magnitude, but also changes the spectral characteristics of climate variability modes. This could potentially explain discrepancies between reconstructions and prior climate model simulations of the Holocene that have traditionally only included forcing associated with orbital changes.

P-4435

High-resolution lacustrine records of environmental changes in Scandinavia with a focus on the Migration period and the Viking age

Eirik Ballo¹, Manon Bajard¹, Eivind Støren², Jostein Bakke², Henrik Svensen¹

¹Centre for Earth Evolution and Dynamics (CEED), University of Oslo, Oslo, Norway, ²Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway

The middle of the 6th century marked the beginning of a decadal-scale cooling period in Northern Europe due to the 536/540 CE volcanic eruptions. This period has been linked to crop failures, famines and to a number of other major societal crises in the Northern Hemisphere, such as the European outbreak of the plague of Justinian (541 CE). A comparable volcanic event, Eldgjá 939 CE, was so powerful that it must have had a severe effect on climate, environment and society during the Norse expansion of the Vikings in Scandinavia. Although published sediment records from Scandinavia give information about the general climatic evolution of the past 2000 years, they do not have the needed resolution to provide yearly or decadal information which is necessary to obtain a sufficient chronology for the studied period. In this study, we target varved lake sediments in order to construct a high-resolution timeline of geochemical information, vital to discuss and understand the environmental and climatic response to these volcanic eruptions.

We have cored two lakes in southeastern Norway in order to obtain high-resolution records from the time period of interest: Lake Sagtjernet and Lake Nordbytjern. Lake Sagtjernet (c. 12 m depth) provided a sediment sequence of 5 m. A previous study from this nonglacial lake highlighted varved sediments throughout the Holocene. Lake Nordbytjern has a depth of 24 m and is categorized as an endogenic meromictic lake of glacial origin with hydraulic influx about evenly divided between groundwater seepage and two small streams. It is located roughly 1.5 km northeast of the largest burial mound in Norway (mid-6th century). The first short gravity core retrieved from this lake is 1.80 m and displays finely laminated sediments. Based on high resolution geochemical and radiographical analyses including short lived radionuclides, AMS ¹⁴C and CT scanning, we will discuss the varved potential of this lake sediment sequence. Mineral and organic geochemical methods are used to reconstruct climate variations.

By comparing our sedimentary records with other natural archives in Scandinavia this study will allow us to discuss the dynamics between climate and environmental changes and their role in facilitating societal changes of the Viking society in Scandinavia.

P-4437

The impact of the double volcanic eruption event 536/540 CE on the climate in southern Scandinavia

Evelien van Dijk¹, Matthew Toohey², Claudia Timmreck³, Michael Sigl^{1,4}, Kirstin Krüger¹

¹Department of Geosciences, University of Oslo, Oslo, Norway, ²GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany, ³Max Planck Institute for Meteorology, Hamburg, Germany, ⁴Climate and Environmental Physics, University of Bern, Bern, Switzerland

Here we present analyses of the impact of a double volcanic eruption event in 536/540 CE on the atmospheric circulation and surface climate, with a focus on southern Scandinavia, using climate model simulations, new and available paleo proxies.

The middle of the 6th century is an outstanding period marked by an unusual cold period that lasted several years to decades, due to the 536/540 CE double eruption event. Evidence from multiple tree ring records from the Alps to the Altai Mountains in Central Asia demonstrate a centennial cooling lasting from 536 up to 660 CE (Büntgen et al., 2016). In this period, glaciers advanced strongly throughout Eurasia which has motivated researchers to refer to the period as the “Late Antique Little Ice Age (LALIA)”.

Ensemble simulations with the Max Planck Institute Earth System Model (MPI-ESM) have been used to show that the double eruption led to a global decrease in temperature and an increase in Arctic sea-ice for at least a decade (Toohey et al., 2016), possibly initiating the long lasting cold period until ~660 CE. This study analyzes the model output from the MPI-ESM simulations for the effects on the polar vortex, stratospheric-tropospheric circulation, North Atlantic Oscillation/Northern Annular Mode variations, and the hydrological cycle, in particular for southern Scandinavia. As part of the VIKINGS project, new proxy data such as lake sediments and tree rings will be compared with the model output for the 536-550 CE period. The extent of agreement between available and new proxies and the simulations will be assessed and possibilities for further improvements discussed.

Palaeolimnological analysis of sulphate deposition events following large volcanic eruptions in historical times

Dan Hammarlund¹, Ethan Silvester¹, Richard Bindler², Erik Björn³, Karl Ljung¹, Antti Ojala⁴, Per Persson⁵, Gill Plunkett⁶, Ulf Skyllberg⁷

¹Department of Geology, Lund University, Lund, Sweden, ²Department of Ecology and Environmental Sciences, Umeå University, Umeå, Sweden, ³Department of Chemistry, Umeå University, Umeå, Sweden, ⁴Geological Survey of Finland, Espoo, Finland, ⁵Department of Biology, Lund University, Lund, Sweden, ⁶School of Natural and Built Environment, Queen's University, Belfast, United Kingdom, ⁷Department of Forest Ecology and Management, Swedish University of Agricultural Sciences, Umeå, Sweden

Major volcanic eruptions may have severe societal impacts as shown by ash dispersal and sulphur emissions from recent Icelandic eruptions. However, ice-core sulphur records in combination with written accounts demonstrate that these events were minor as compared to historical events of much larger magnitude. For example, the eight month-long fissure eruption of Laki in Iceland in AD 1783-84 is estimated to have produced over 200 megatons of sulphur. Within weeks of the start of the eruption in June 1783, a dry fog extended across Europe, which persisted until autumn. Following an unusually warm summer, the subsequent winter was one of the coldest on record in Europe and North America. Acid precipitation caused harvests to fail in large parts of Europe, and these effects combined led to many thousands of casualties in Iceland and beyond. We still lack a sufficient understanding of the environmental impacts of such colossal eruptions, which take place on average once per century and can be expected to recur at any time in the future. As part of a newly initiated project, we aim at estimating the extent of such sulphate deposition events in northern and central Europe, their typical duration and effects on aquatic biota, catchment vegetation and soils, including the potential release of highly toxic methyl mercury to lake waters. By freeze-core sampling of varved lake sediments at well-documented sites, we will target some selected volcanic events of known origin during the last millennium, such as Askja 1875, Tambora 1815, Laki 1783, Veidivötn 1477 and Samalas 1257. Their physical, chemical and biological impacts on the local ecosystems will be analysed at annual resolution, if possible aided by the identification of tephra particles from the respective eruptions. Established geochemical and palaeolimnological methods will be applied, including diatom analysis of biogenic varve sequences, and comparisons will be made with historical accounts when available. As part of ongoing efforts to establish instrumentation for synchrotron-based analysis of chemically unaltered, frozen sediment records at the MAX IV facility at Lund University, we will also perform high-resolution S, Fe and Hg speciation analyses of the varve records, using X-ray absorption spectroscopy. Apart from deeper insight into ecosystem responses to massive volcanic sulphur deposition and associated ashfall events, the project will pave the way for future applications of synchrotron-based techniques within palaeolimnology. Here we present the approach and the targeted archives, as well as some preliminary results based on diatom analysis of varved sediment records from Sweden.

High-resolution sulfur isotopes from ice cores: insights into climatic impacts of double eruptions over the past 2000 years

Andrea Burke¹, Michael Sigl^{2,3}, Kathryn Moore¹, Joe McConnell³, Jess Adkins⁴

¹University of St Andrews, St Andrews, United Kingdom, ²University of Bern, Bern, Switzerland, ³Desert Research Institute, Reno, USA, ⁴Caltech, Pasadena, USA

The record of the volcanic forcing of climate over the past 2500 years is reconstructed primarily from sulfate concentrations in ice cores. Of particular interest are stratospheric eruptions, as these afford sulfate aerosols the longest residence time and largest dispersion in the atmosphere, and thus the greatest impact on radiative forcing. Identification of stratospheric eruptions currently relies on the successful matching of the same volcanic sulfate peak in ice cores from both the Northern and Southern hemispheres (a “bipolar event”). These are interpreted to reflect the global distribution of sulfur aerosols by the stratospheric winds. Despite its recent success, this method relies on precise and accurate dating of ice cores, in order to distinguish between a true ‘bipolar event’ and two separate eruptions that occurred in close temporal succession.

Sulfur isotopes can be used to distinguish between these two scenarios since stratospheric sulfur aerosols are exposed to UV radiation which imparts a mass independent fractionation (Baroni et al., 2007). Mass independent fractionation of sulfate in ice cores thus offers a novel method of fingerprinting stratospheric eruptions, and thus refining the historic record of explosive volcanism and its forcing of climate. Here we present new high-resolution (sub-annual) sulfur isotope data from the Tunu Ice core in Greenland and B40 ice cores from Antarctica over several eruptions, with a focus on major double eruptions that occurred within a few years of each other, and their climatic impact.

Baroni, M., Thiemens, M. H., Delmas, R. J., & Savarino, J. (2007). Mass-independent sulfur isotopic compositions in stratospheric volcanic eruptions. *Science*, 315(5808), 84–87. <http://doi.org/10.1126/science.1131754>

P-4440

Blue-stained rings in ancient bristlecone pine as a volcanic proxy

Matthew Salzer¹, Charlotte Pearson¹, Jacques Tardif², Andrew Bunn³, France Conciatori², Liliana Siekacz⁴, Malcolm Hughes¹

¹University of Arizona, Tucson, USA, ²University of Winnipeg, Winnipeg, Canada, ³Western Washington University, Bellingham, USA, ⁴Nicolaus Copernicus University, Torun, Poland

Blue-stained rings, subannual ring features visible in some temperature-sensitive trees, including upper treeline bristlecone pine (*Pinus longaeva*), provide evidence for the timing of past rapid cooling often associated with large-scale volcanic eruptions. Blue-stained rings are discovered by cutting 15–20 μm thin transverse sections from a wood sample and double staining. Cell walls that did not sufficiently lignify during the growing season take on the blue color, a result that has been linked to abrupt temperature reduction. Large-scale volcanic eruptions cause rapid cooling of surface temperatures. The climatic effects associated with these eruptions can have wide-ranging disruptive impacts on plant and animal communities including human societies. We examined upper treeline bristlecone pine samples from three different mountain ranges in western North America across both the 20th century AD and three ‘volcanically interesting’ time periods: the 6th century AD, 1700–1400 BCE, and 2300–2100 BCE. Blue-stained rings tend to co-occur but with frost rings, but are a more common and perhaps more sensitive indicator of cooling than these features. Blue-stained rings occurred during all time periods and can be associated with trees growing in the coldest topoclimatic positions on the landscape and with abrupt cold snaps in both the beginning and end of the growing season.

P-4441

The role of volcanism and solar irradiance on sea-ice conditions in Baffin Bay/Labrador Sea over the last 2000 years

Kaarina Weckström^{1,2}, Steve Juggins³, François Klein⁴, Hugues Goosse⁴, Guillaume Massé⁵, Marit-Solveig Seidenkrantz⁶, Jesper Olsen⁶, Antoon Kuijpers²

¹University of Helsinki, Helsinki, Finland, ²GEUS, Copenhagen, Denmark, ³Newcastle University, Newcastle, United Kingdom, ⁴Université Catholique de Louvain, Leuven, Belgium, ⁵University of Laval, Laval, Canada, ⁶Aarhus University, Aarhus, Denmark

Volcanic eruptions and variability in solar activity are important physical drivers of climate change. Large eruptions and grand solar minima have the potential to decrease air temperatures, affect patterns of atmospheric circulation and precipitation, and increase sea-ice extent and transport to lower latitudes (with climate feedbacks). Elucidating the impacts of these drivers via proxy records and climate model simulations provides essential knowledge of their importance in natural climate variability. In this study we reconstructed sea-ice conditions in the Baffin Bay/Labrador Sea system over the last 2000 years by analysing the sea-ice biomarker IP₂₅ from a well-dated core collected in Bonavista Bay, NE Newfoundland, a site that records sea-ice variability in and export from Baffin Bay. Marked step changes were identified in the IP₂₅ flux data, and the correlation between solar irradiance and the IP₂₅ record was assessed. March-May sea-ice concentrations for the Hudson and Baffin Bays were modelled using LOVECLIM, resulting in 10 ensemble simulations (and the mean of these) over the last two millennia. Based on the proxy records and long-term data on volcanic eruptions and solar irradiance, it appears that clear (step-wise) increases in sea-ice concentrations can be observed at times when repeated explosive volcanism and centuries of lower solar irradiance (grand minima) coincide, whereas either driver alone does not markedly change sea-ice conditions in the system. While there are quite large differences between the different LOVECLIM simulations, highlighting the chaotic property of the climate system, these step-wise increases in IP₂₅ can also be observed in the modelling results: there seems to be a transition around 500-600 AD in most simulations, which is when sea-ice export to the study site began based on proxy data. Further two transitions, although not detectable in all simulations, can be seen around 1200-1300 AD and 1600-1700 AD, when repeated volcanism and grand solar minima are recorded. These time periods coincide with the Dark Ages and the beginning and the height of the Little Ice Age – both cold climate periods, which had severe impacts on societies of the time.

P-4442

Timing of the initial Mediterranean response to major climate reorganization during the last interglacial-glacial transition

Martin-Puertas Celia¹, Lauterbach Stefan², Allen Judy, R.M.³, Perez Marta¹, Blockley Simon¹, Wulf Sabine⁴, Huntley Brian³, Brauer Achim⁵

¹Royal Holloway University of London, Egham, United Kingdom, ²Christian-Albrechts-University of Kiel, Kiel, Germany, ³University of Durham, Durham, United Kingdom, ⁴University of Portsmouth, Portsmouth, United Kingdom, ⁵GFZ-German Research Centre for Geosciences, Potsdam, Germany

Millennial-scale Dansgaard-Oeschger (DO) variability in northern high latitudes has influenced climatic and environmental conditions in the Mediterranean during the last glacial period. There is evidence that the global transmission of the DO variability occurred at the end of DO 25; however, the exact timing and the trigger that activated the Mediterranean response remains incompletely understood. Here, we provide evidence that the rapid teleconnection between both regions started at ~111.44 ka forced by a sub-millennial scale cooling in Greenland (GI-25b) with immediate impact in the Mediterranean. High-resolution sediment proxies and the pollen record of the renowned Lago Grande di Monticchio (MON), Italy, reveal climatic instability during the last millennium of interglacial conditions, which was characterised by a first and short cooling episode MON 1 at 111.44 ka which coincides with the Greenland cold sub-event 'GI-25 b' in timing and duration. Monticchio and Greenland also agree in describing a subsequent rebound phase that culminated in an abrupt stadial oscillation MON 2/ GS-25 marking the transition into the last glacial period. Our results show an early response at Monticchio to centennial scale climate change in Greenland as a prelude to the millennial-scale global climate variability that was maintained during the glacial period.

P-4443

Millennial-scale climate variability in arid Central Asia: evidence from the Ili Basin loess

Kathryn Fitzsimmons¹, Alexandra Engström Johansson¹, Charlotte Prud'homme¹, Pierre Antoine², Tobias Sprafke³, Aditi Dave¹, Zoran Peric¹, Laurent Marquer¹, Giancarlo Scardia⁴, Yue Li⁵, Saida Nigmatova⁶

¹Max Planck Institute for Chemistry, Mainz, Germany, ²LGP-CNRS, Paris, France, ³University of Bern, Bern, Switzerland, ⁴UNESP, Rio Claro, Brazil, ⁵Chinese Academy of Sciences, Xi'an, China, ⁶Institute of Geology K Satpaeva, Almaty, Kazakhstan

Central Asia lies at the core of the largest and most populous continent on Earth – Eurasia – however we know little about its role in global climate dynamics past and present. We know that the region lies at a critical transition zone between the major northern hemisphere climate subsystems, the intensity and scale of which waxed and waned throughout the climatic oscillations of the Quaternary. As yet, however, the history of climate dynamics in arid Central Asia, and its teleconnections with the better understood extremities of the continent, remains effectively unexplored. This is largely because we have yet to recognise the full potential of Eurasia's most widespread archives for past climates: loess.

Traditionally, the hypothesised link between loess and climate is relatively straightforward: loess accumulation intensifies during cold glacial phases, and decreases and is overprinted by soil formation under relatively milder climates. For the loess deposits draping the mountain piedmonts of arid Central Asia, however, the climatic link is more complex. The glaciers of the Asian high mountains respond more to changes in precipitation rather than temperature, resulting in an increase in loess accumulation rates both during glacial advance under warmer, wetter interstadials and during cold stadials. Extracting the climatic signal from loess, and what it means for climate dynamics, therefore represents a complex challenge requiring the reconstruction of quantitative palaeoclimate parameters, and at sufficiently high resolution to identify millennial-scale variability.

Here we provide the first quantitative record of last full glacial cycle climate from loess in arid Central Asia, at sufficiently high resolution to identify millennial-scale changes. Our dataset from the Remizovka profile in the northern Tien Shan foothills integrates centimetre-scale chronostratigraphies with estimates of past temperature, precipitation, and seasonality based on organic and stable isotope geochemistry, alongside established grain-size, palaeoecological and magnetic susceptibility analyses. Our results suggest that during warmer climate phases such as MIS3, northward expansion of monsoonal precipitation regimes and glacial advance impeded teleconnections with the temperate zone westerlies to the north. The resulting compression of synoptic-scale systems against the piedmont intensified wind strength and loess flux, particularly during short-term Heinrich Events which saw increased eastward penetration of westerly dust-storms. By contrast, the last glacial maximum was colder and drier, with reduced but sustained glacial ice volume providing fine-grained material for transport via persistent northerly and westerly wind regimes onto the piedmont. Our study provides a useful first glimpse into millennial-scale climate dynamics in the heart of the world's largest continent, and the first meaningful possibility to interrogate hypothesised climate teleconnections across Eurasia.

Identifying cryptotephra in the ICDP Dead Sea deep core to synchronise past hydroclimate changes in the eastern Mediterranean

Ina Neugebauer¹, Markus J. Schwab¹, Christine S. Lane², Birgit Plessen¹, Rik Tjallingii¹, Sabine Wulf³, Achim Brauer¹
¹GFZ German Research Centre for Geosciences, Section Climate Dynamics and Landscape Evolution, Potsdam, Germany, ²University of Cambridge, Department of Geography, Cambridge, United Kingdom, ³University of Portsmouth, Department of Geography, Portsmouth, United Kingdom

In the drought-affected eastern Mediterranean region, a better understanding of the past hydroclimate variability is a prerequisite to improve our capability for estimating future changes of the water balance. In this respect, palaeoclimate records from marine or lake sediments provide invaluable information about natural hydroclimate changes. The hypersaline Dead Sea is a key palaeoclimate archive in the south-eastern Mediterranean region, situated at a critical position between more humid Mediterranean climate and the hyper-arid Saharo-Arabian desert belt. The ca. 450 m long ICDP drill core 5017-1, from the deepest part of the Dead Sea, covers the last ~220,000 years, as constrained by radiocarbon, U-Th dating and floating $\delta^{18}\text{O}$ stratigraphy methods. Nevertheless, an independent dating method is much needed because (i) radiocarbon dating is limited to the last ~40,000 years, (ii) U-Th dating of authigenic carbonates requires a comprehensive correction procedure leading to large age uncertainties, and (iii) wiggle matching of oxygen isotope data is not independent and, hence, does not allow the identification of lead- and lag-phase relationships of changing hydroclimate in comparison to other palaeoclimate records.

Tephrochronology has been demonstrated a powerful tool for dating and synchronisation of palaeoclimate records for regional and global comparison. Due to a lack of visible tephra layers in the Dead Sea sediment record, however, direct links with the eastern Mediterranean tephrostratigraphical lattice are still absent. The recent discovery of the first cryptotephra ever identified in Dead Sea sediments (the early Holocene S1-tephra from central Anatolia) encouraged the systematic search for tephra time-markers in the ICDP deep-basin core 5017-1, with the aim of improving the chronology of the deep record significantly. Here we present preliminary results of a new project focusing on the identification of widespread and well-dated Mediterranean tephra time-markers in the ICDP sediment cores from the deep Dead Sea basin.

Tracking environmental changes at the time of modern human dispersal within Europe during Marine Isotope Stages (MIS) 3 and 2 when past climate conditions varied rapidly, often on decadal to millennial timescales, is still challenging. The emergence of palaeoclimate records including lake sediments, speleothems and loess for central-eastern Europe, and the significant progress recently achieved in studying the Late Quaternary environments provide crucial insights (i) for understanding past human-environment interactions in the light of INTIMATE chronostratigraphy and (ii) the cultural development during the Upper Palaeolithic in central-eastern Europe.

Here we discuss latest results arising from an archaeological-chronological investigation of Upper Palaeolithic habitation contexts within the Bistrita valley, Eastern Carpathians. Bistrita valley hosts the largest inventory of Upper Palaeolithic sites in Romania with condensed loess and colluvium sequences and settlements located on river terraces, and largely assigned to the Late Aurignacian/Gravettian and Epigravettian technocomplexes. Notwithstanding their unusual density, very few of these pluristratified settlements rely on reliable numerical chronologies or on accurate palaeoenvironmental contextualization.

In order to augment the cultural considerations we applied a multi-method chronological research. This includes optically stimulated luminescence dating of sediment and direct thermoluminescence dating of burned flints, whereas charcoal remains were dated via multi-protocol radiocarbon dating. The contextualization of the sedimentary environments and integration of numerical dating results (e.g. luminescence, radiocarbon, tephrochronology) has been achieved via detailed sedimentological and environmental magnetic proxies that indicate a loess depositional setting, modulated by slope processes and possibly by anthropogenic activities such as periodic large-scale vegetation burning. We show that the Bistrita valley provides reference records from multi-disciplinary research into the interaction between humans and their environment during late Quaternary, more closely integrating archaeological and paleoclimate. In exploring the contextual basis for understanding human dynamics in close connection to biodiversity changes during MIS 2-3 in the Eastern Carpathians as possibly modulated by past climate and environmental conditions, a review of available regional palaeoclimate records (palaeovegetation, stable isotopes, palaeodust dynamics) is also presented.

P-4446

Investigating timing of rapid climate shifts in northern Europe during the LGIT using a new tephra study from southernmost Sweden

Simon Larsson^{1,2}, Stefan Wastegård^{1,2}

¹Department of Physical Geography, Stockholm University, Stockholm, Sweden, ²The Bolin Centre for Climate Research, Stockholm, Sweden

This work in progress employs the method of tephrochronology to establish linkages between the previously published palaeoclimate record of the Körslättamossen fen in southernmost Sweden (Hammarlund & Lemdahl 1994) and other reconstructions of climate change in northern Europe during the Last Glacial–Interglacial Transition (c. 15–8 ka b2k). The identifications of four cryptotephra horizons (distinct concentrations of volcanic ashes not visible to the naked eye, extracted from the sediments and geochemically analysed by electron probe microanalyser) at this site has enabled correlations to a multitude of palaeoclimatic investigations in the region, including linkages based on the Laacher See Tephra as it is one of the tephras identified at Körslättamossen—the first discovery of the Laacher See Tephra on Swedish mainland (Larsson & Wastegård 2018). The other identified tephras are the Hässeldalen Tephra, the Vedde Ash, and the Borrobol or Penifiler Tephra.

By examining the palaeoclimate records of sites geographically distant from each other through the correlations enabled by tephrochronological synchronisation, the issues of temporal and spatial evolution of rapid climate changes are assessed. These event, including abrupt, large-scale events such as the Younger Dryas stadial, are as of yet not entirely understood in terms of causes or behaviour—though such knowledge is crucial to understand the climate system and its development in the past. Tephrochronology is a highly useful method for this purpose due to its precision and geographical coverage (as volcanic ashes tend to spread far and wide over, geologically speaking, short periods of time before settling) and this study represents one of several recent opportunities to gain new, detailed knowledge on past climate change.

Environmental change at Esthwaite Water, English Lake District: re-visiting lacustrine sediments with new chronological and proxy techniques.

Charlotte Slaymark¹, Antonio García-Alix², Adrian Palmer³, Alison MacLeod⁴, Derek Fabel¹, Jaime Toney¹

¹University of Glasgow, Glasgow, United Kingdom, ²University of Granada, Granada, Spain, ³Royal Holloway University of London, Egham, United Kingdom, ⁴University of Reading, Reading, United Kingdom

This study presents a new geochronological, lithological and organic geochemical analysis of the Late Pleistocene and Holocene sediments from an 8.45-m long sediment core from Esthwaite Water in the English Lake District. Due to the limitations of dating techniques when the first lithological and palynological studies were carried out (e.g. Franks and Pennington, 1961) uncertainty remains regarding the timing of the Dimlington Stadial ice retreat in the Southern Lake District and the (a)synchronicity of climate records from the Late Glacial and Holocene with other Northern Hemisphere records. We present an independent age model for the entire core using short-lived radionuclides ²¹⁰Pb and ¹³⁷Cs, radiocarbon (n = 11), tephra (n=2) and varve counting across the 1.83-m section of varved basal sediments. We show the geochemistry of two tephra horizons in the Pleistocene – Holocene transition, which will allow this record to be independently linked with others in the North Atlantic region and for the first time; North America. The new age model for Esthwaite Water is constructed using Bayesian statistics and provides constraints on events inferred from the lithostratigraphic description and magnetic susceptibility, organic content and grain size analysis. Organic proxies; C/N, algal lipids and plant leaf waxes are used to reconstruct environmental change across the last glacial – interglacial transition. The age model and varve counts show the site could have been contact with ice during the Dimlington Stadial as late as 15 919 cal BP. Lithology and climate proxies show stadial climate conditions ended, at latest 15 204- 14 542 cal BP. We see a response in lithology and environmental proxies to Bølling/Allerød interstadial climate change and the Younger Dryas climate deterioration. Lithology and proxy data show a delayed response to the onset of the Holocene when compared to temperature data from Greenland oxygen isotope records.

The high-precision chronology of varved sediment from Lake Suigetsu, combined with its high-resolution climate reconstruction based on pollen, has the potential to enable robust assessments of climatic leads and lags with other key palaeoclimatic archives. Indeed, the lead author presented our preliminary results at a plenary session of Nagoya INQUA (2015), where we concluded that two abrupt warming episodes at the onsets of the Holocene and the Lateglacial interstadial have different spatio-temporal structures (i.e. the Holocene onset was synchronous between Japan and the North Atlantic, whereas the onset of the Lateglacial interstadial was earlier in Japan by about two centuries). However, those interim conclusions in 2015 were essentially hypothetical because the site-specific age scales of Lake Suigetsu (SG06₂₀₁₂yr BP) and Greenland (GICC05 yr BP) were not precisely synchronised with each other.

Recently, the GICC05 and IntCal13 chronologies were synchronised by wiggle matching cosmogenic isotopes (¹⁰Be in ice and ¹⁴C in tree rings; Muscheler et al. 2014; Adolphi et al. 2018). Similarly, we performed Bayesian modelling of Suigetsu's ¹⁴C dataset onto the IntCal13 radiocarbon calibration model, by which we could put the Suigetsu proxy record onto the IntCal13 age scale. This enables robust assessment of the relative timing of climatic events at Suigetsu and Greenland, as well as in other archives that have been synchronised to either GICC05 or IntCal13. In our presentation, we report whether our 2015 Nagoya hypotheses of synchrony and asynchrony are accepted or rejected.

Geological Science, Warsaw, Poland, ⁶University of Portsmouth, Department of Geography, Buckingham Building, Lion Terrace, Portsmouth, United Kingdom

Annually laminated (varved) lake sediments are suitable high-resolution climate archives. However, local factors including lake bathymetry and catchment morphology may influence lacustrine sedimentation processes and modify the sediment response to climate change. Therefore, differentiation between local factors and regional climate signals is crucial for using lake sediments as robust climate archives.

Here, we compare three partly varved sediment records within a lake cascade for their response to the Younger Dryas (YD) climate change by using a multiproxy approach (varve-microfacies, stable isotopes, XRF element scanning). The YD is an appropriate time window to study lake response to large-scale and abrupt climate change.

The basins of Lake Głębobczek (JG), palaeolake Trzechowskie (TRZ) and Lake Czechowskie (JC) were formed by glacial hydrodynamic processes and form a cascade chain. Their catchment is mainly composed of outwash plain deposits and subordinated by glacial till. We investigate the time interval from 13100 to 11200 BP to compare lake specific sediment responses to rapid climate change. The sediment records are synchronized through well-defined biostratigraphic boundaries (Allerød/YD and YD/ Preboreal) as well as the Askja-S cryptotephra.

All three records show a cessation of varve formation and an increase of detrital influx at the onset of the YD, reflecting increased windiness and catchment erosion. However, the timing of varve disappearance at the onset of the YD is delayed by 160 varve years in JG compared to TRZ and JC, where varve cessation is synchronous with the most prominent vegetation change. More stable conditions in JG with respect to varve formation is explained by the small surface area and the wind sheltered position of JG. At the YD/ Holocene transition, varve preservation in JG starts earliest for the same reason, while varves in JC recurred with an offset of 60 years. In TRZ, varve preservation did not start again.

Bulk carbonate $\delta^{18}\text{O}_{\text{carb}}$ values reflect distinct differences in the amplitude of change. The general shift to lighter $\delta^{18}\text{O}_{\text{carb}}$ at the onset of the YD reflecting colder temperatures is biased in JG by the occurrence of rhodochrosite. The return to more positive $\delta^{18}\text{O}_{\text{carb}}$ at the onset of the Holocene is visible in all records whereas the JC shows a significant increase of 4‰, likely caused by evaporation processes. Despite local differences, our data shows that changes in the catchment area are consistently recorded in the all three bulk $\delta^{13}\text{C}_{\text{org}}$ records. A significant shift of approximately 4‰ towards more positive values may reflect the regional vegetation change from forest to grassland at the YD onset.

This study is a contribution to the BaltRap project "WP2: Holocene annually laminated lake records", funded by the Leibniz Association.

P-4450

Abrupt climate changes during the early last glacial period recorded in French speleothems

Ellen Corrick^{1,2}, Russell Drysdale^{1,2}, John Hellstrom³, Isabelle Couchoud^{1,2}, Didier Cailhol², Stéphane Tocino⁴

¹School of Geography, The University of Melbourne, Melbourne, Australia, ²EDYTEM, UMR5204 CNRS, Université Savoie Mont Blanc, Le Bourget-du-Lac, France, ³School of Earth Sciences, The University of Melbourne, Melbourne, Australia, ⁴Grand site de l'Aven d'Ornac, Ornac-l'Aven, France

The early last glacial period marks a transition interval from interglacial to glacial climate conditions and is accompanied by the onset of abrupt stadial-interstadial changes known as Dansgaard-Oeschger (DO) events. These early DO events are clearly represented in the NGRIP ice-core record, but their expression in many other terrestrial records remains more equivocal than later DO events. High-resolution and chronologically well-constrained records of the early last glacial are needed to improve our understanding of the geographical extent and timing of these first DO events. Here we present speleothem stable oxygen and carbon isotope records from two neighbouring caves in Ardèche, southern France; l'Aven d'Ornac and the cave of Saint-Marcel d'Ardeche. The speleothem records span the period 125 – 87 ka and are tied to a uranium-thorium based chronology. These records show millennial-scale variability that is structurally very similar to the NGRIP ice-core record and sea-surface temperature records from the Iberian margin, suggesting a strong climatic teleconnection between southern France and the North Atlantic during these early DO events. The Ardèche speleothems, with up to decadal resolution, also preserve evidence of shorter-lived, precursor or rebound type interstadials including GI 25a, 24.c and 23.2. This provides some of the first clear evidence of these events outside of Greenland and suggests that these features were widespread climate variations that also occurred in this region of Europe. Both isotope profiles record evidence of millennial-scale climate variations, interpreted to reflect wetter and more vegetated conditions above the cave, which is in contrast to some other stalagmites from France and the Iberian Peninsula where $\delta^{18}\text{O}$ does not respond as strongly to such changes. The timing of interstadial events in the speleothems agrees within the uncertainty of the GICC05 and GICC05modelext chronologies, but provides much greater chronological control. Together, the Ardèche stalagmite records provide high-resolution and precisely constrained information on the expression of abrupt climate changes in southern France during the early last glacial.

P-4451

Timing and abrupt oscillations during last deglaciation in stalagmites from Ostolo Cave, Western Pyrenees, Spain

Juan Luis Bernal Wormull^{1,2}, Ana Moreno¹, Carlos Sancho², Miguel Bartolome^{1,3}, Carlos Pérez-Mejías^{1,2}, Arantza Aranburu^{4,5}, Eneko Iriarte^{5,6}, Martin Arriolabengoa^{4,5}, Christoph Spötl⁷, Hai Cheng^{10,8,9}

¹Pyrenean Institute of Ecology-CSIC, Zaragoza, Spain, ²Earth Sciences Department, University of Zaragoza, Zaragoza, Spain, ³National Museum of Natural Sciences-CSIC, Madrid, Spain, ⁴Department of Mineralogy and Petrology, Faculty of Science and Technology, University of the Basque Country (UPV-EHU), Leioa, Spain, ⁵ARANZADI Geo-Q Zentroa, Leioa, Spain, ⁶Department of Historical Science and Geography, University of Burgos (UBU), Burgos, Spain, ⁷Institute of Geology, University of Innsbruck, Innsbruck, Austria, ⁸Institute of Global Environmental Change, Xian Jiaotong University, Xian, China, ⁹Department of Earth Sciences, University of Minnesota, Minneapolis, USA, ¹⁰State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Xian, China

The last deglaciation (from ≈ 19 kyr BP to the onset of the Holocene) is an interesting time interval when all the components of the climate system underwent large-scale changes associated with global warming. This trend was punctuated by several warming and cooling events that took place abruptly. It is very important to know when precisely these events occurred and what their amplitude was in order to better understand their causes and impacts on the regional environment.

The northern Iberian Peninsula, due to its location with respect to the polar front at that time, is a sensitive place to determine climatic changes in Southern Europe during the last deglaciation. The climatic events mentioned above are recorded in lake and marine sediments denoting the importance of these records in the transitional zone between the Atlantic and the Mediterranean climatic realms. The glacial-interglacial transition was also identified in speleothems from northern Spain and southern France, where possible differences with the patterns identified in the Greenland record during GI-1 were analysed. In addition, a high-resolution analysis of a stalagmite suggests that the GS-1 response in the central Pyrenees was divided in two distinct phases.

In this new study, three stalagmites from Ostolo cave in the Western Pyrenees were analysed to identify and characterize the timing and climate variability along the abrupt changes that punctuated the last deglaciation. The samples were dated at high precision and cover almost continuously the same period (18-10 kyr BP) with a high degree of replication. The $\delta^{18}\text{O}$ record follows closely the well-known changes from high latitudes showing more negative values during GS-1 and H1 (-8‰), related to colder climates, while more positive values were reached during GI-1 and the Early Holocene (-2‰), pointing towards warmer temperatures. The $\delta^{13}\text{C}$ record is usually interpreted in this region as a proxy of vegetation cover density. However, $\delta^{13}\text{C}$ variations in the Ostolo stalagmites suggest better hydrological conditions for vegetation development from 16 to 14 kyr BP, a period previously characterized by cold temperatures. Trace-element data together with monitoring are in progress to help clarifying this aspect.

P-4452

Is there a climatic imprint of the 8.2kyr event in Antarctica?

Florian Adolphi^{1,2}, Michael Sigl¹, Tobias Erhardt¹, Jürg Beer³, Hubertus Fischer¹

¹Climate and Environmental Physics, Physics Institute & Oeschger Centre for Climate Change Research, Bern University, Bern, Switzerland, ²Quaternary Sciences, Department of Geology, Lund University, Lund, Sweden, ³Swiss Federal Institute of Aquatic Science and Technology Eawag, Dübendorf, Switzerland

The 8.2kyr event is the most recent episode of abrupt cooling prominently recorded in the Greenland ice cores. It is widely believed that this climatic oscillation has been triggered by a freshwater pulse into the North Atlantic perturbing the Atlantic Meridional Overturning Circulation. By analogy to similarly forced glacial climate swings, we can thus expect a bipolar see-saw response in the Southern Hemisphere albeit under early Holocene interglacial conditions. This is supported by some (sub-) tropical speleothem and marine records implying a southward shift of the ITCZ during the event. However, the efforts to reliably test whether a climate response can be detected in Antarctica has so far been hampered by the short duration of the event, the relatively small expected amplitude of the climatic response (signal to noise), and timescale uncertainties.

Here we synchronize Greenland and Antarctic ice core timescales by means of cosmogenic radionuclides and volcanic tie-points, eliminating phasing uncertainties between climate records from both regions, and employ a suite of high-resolution water isotope and impurity records from Greenland and Antarctic ice cores to increase the signal to noise ratio of the climate records. We test whether an imprint of the 8.2kyr event can be detected in Antarctica and whether its timing is consistent with the proposed response time of the bipolar see-saw mechanism seen during the last glacial.

P-4453

Enhanced Bayesian statistical modelling of radiocarbon datasets obtained from three British sediment sequences spanning the Last Glacial-Interglacial Transition

Richard Staff¹, John Lowe², Michael Walker^{3,4}

¹SUERC, University of Glasgow, East Kilbride, United Kingdom, ²Department of Geography, Royal Holloway University of London, Egham, United Kingdom, ³School of Archaeology, History and Anthropology, Trinity St. David University of Wales, Lampeter, United Kingdom, ⁴Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom

We apply revised Bayesian statistical modelling to radiocarbon datasets obtained from three sediment sequences from the British Isles: Llanilid (SW Wales); Sluggan Bog (N. Ireland); and St. Bees (NW England); each spanning the Last Glacial-Interglacial Transition (LGIT). The existing chronologies for each of these sites is based upon radiocarbon (¹⁴C) dating of different material types, including both base-insoluble ('humin') and base-soluble ('humic') bulk sediment fractions. Previously, subjective choices were adopted when accepting or rejecting individual dates for inclusion in the finalised, published age-depth models, which is not ideal. Here, we account for the 'maximum' and 'minimum' ages that may be assumed to apply to the humin and humic sediment fractions through application of 'After' and 'Before' functions (more commonly employed for archaeological contexts) in the OxCal Bayesian statistical software (Bronk Ramsey, 2019). In this way, we seek to maximise the chronological information nevertheless attainable from such 'bulk' sediment samples, while minimising the need for the potentially subjective removal of data during age-depth model construction.

Bronk Ramsey, C. (2019) OxCal ver.4.3, <https://c14.arch.ox.ac.uk/oxcal/OxCal.html>.

P-4454

Reconstructing abrupt climate changes of the last deglaciation & Holocene: Pollen and biomarker analyses from the Portuguese Margin

Anna Cutmore¹, Blanca Ausin², Timothy Eglinton², Mark Maslin¹, Chronis Tzedakis¹

¹University College London, London, United Kingdom, ²ETH, Zurich, Switzerland

In light of the current rate of anthropogenic climate change, it is becoming increasingly critical to enhance knowledge of past abrupt climate events and subsequent responses of the Earth system. One period that can provide such insight is the last ~30 kyr, with several abrupt changes occurring over the course of the deglaciation. The Portuguese Margin has been an ideal location to study the impacts of these abrupt climate events on marine and terrestrial environments. The combined effect of the narrow continental shelf and close proximity to the Tagus and Sado rivers, lead to the rapid delivery of a high quantity of sediment, including pollen and biomarker proxies, to the Tagus Abyssal Plain. Joint terrestrial and palaeoceanographic analyses from the same sediment samples enable an *in situ* assessment of the relative timing of changes in palaeoceanographic and terrestrial proxies.

Here we document the response of western Iberian vegetation to millennial and centennial-scale changes, particularly changes in moisture availability, over the deglaciation and Holocene, by combining (for the first time at a Portuguese Margin site) pollen and leaf-wax isotopic biomarker records ($\delta^{13}\text{C}$ and δD) from core SHAK06-5K. A high-resolution pollen record (every 2cm) and lower-resolution *n*-alkane $\delta^{13}\text{C}$ and δD records spanning 28kya are compared with high-resolution XRF sediment and planktonic foraminiferal $\delta^{18}\text{O}$ analyses from the same core. The sequence is supported by high-resolution age control, based on 38 Accelerator mass spectrometry (AMS)¹⁴C dates from monospecific samples of the planktonic foraminifera, *Globigerina bulloides*.

Our pollen record indicates the rapid response of regional vegetation to centennial changes and millennial-scale climate events, with forest expansion during the warm interglacial/ interstadial Bølling-Allerød and Holocene, and forest contraction and steppe expansion during cold glacial/ stadial conditions of the Last Glacial Maximum and Younger Dryas. Comparing our pollen and *n*-alkane biomarker data with the XRF Zr:Sr ratio and planktonic foraminiferal $\delta^{18}\text{O}$ records, a clear synchronicity can be seen in the timing of millennial-scale changes in all records. The millennial-scale changes in our leaf wax *n*-alkane δD and $\delta^{13}\text{C}$ records can be explained by both vegetation composition and growing season water availability.

P-4455

A first annual-layer-counted chronology for the EastGRIP ice core and the search for a precise dating for the Thera eruption.

Giulia Sinnl¹, Sune Olander Rasmussen¹, Eliza Cook¹, Anders Svensson¹, Mathias Skov Jensen¹, Tobias Erhardt², Camilla Marie Jensen², Seyedhamidreza Mojtabavi³, Frank Wilhelms³, Mai Winstrup⁴

¹Centre for Ice and Climate, University of Copenhagen, Copenhagen, Denmark, ²Climate and Environmental Physics, University of Bern, Bern, Switzerland, ³Alfred-Wegener Institute, Bremerhaven, Germany, ⁴Danish Meteorological Institute, Copenhagen, Denmark

The development of paleoclimatic timescales is of vital importance for the understanding of climate. Ice cores are optimal tools for the construction of a timescale because they record the signal of multiple annually resolved proxies with well preserved stratigraphy. In 2018, the East Greenland Ice Coring Project (EastGRIP) reached a depth of 1760 m, corresponding to an age of approximately 21000 years BP. The newly drilled core has been matched to other Greenland ice cores to adapt the GICC05 ice-core timescale. This provides a chronological basis for the study of the core that is consistent with other Greenland cores.

The techniques adopted for matching of the ice cores rely on the assumed synchronicity of deposits from volcanic eruptions, biomass burning events, and solar events [1]. These time markers are essential for the synchronization of different time records as well as for the determination of regional leads and lags occurring at the onset of climatic transitions. The measurements used for volcanic matching are electrical conductivity measurements (ECM) and dielectric profiling (DEP), which were performed directly in the field and then processed to a high precision in depth assignment. Independent matching of DEP and ECM matching was performed to assess the precision of the synchronization before the two records were merged.

The strength of the volcanic matching between Greenland ice cores is increased by locating the same Northern Hemisphere volcanic ash deposits (tephra), which possess unique geochemical

'fingerprints'. This challenging search is conducted along the length of each core and is particularly useful in the Last Glacial Maximum, where the presence of acidic spikes is scarce both in ECM and DEP data. The transferred timescale is complemented by automated counting of annual layers between the observed tie-points, using annually resolved proxy data measured by chemical Continuous Flow Analysis (CFA). Ultimately, these new results will feed into the revision of the GICC05 time scale and hopefully reconcile the differences between GICC05 and the timescale proposed by Sigl et al [2].

In this framework, we are trying to narrow down the dating of the Thera eruption on Santorini (around 3500 BP). The timing of this event is still debated, because of an apparent discrepancy of about 100 years between carbon-14 dating and historical dating [3].

The nature and expression of climate change in the Eastern Mediterranean, the Levant and North Africa is of considerable interest across a range of disciplines. This is, in part, due to the need to understand the potential for future climate forcing of environments in the region, but also as it is key locale for multiple phases of human dispersal out of Africa, with the potential for climate drivers to be implicated as a stimulus for these dispersals. The last glacial to interglacial period (c. 130-8 ka BP) is a critical window to examine such processes as a range of climatic signals are recorded. As with all such questions, however, absolute dating of abrupt climatic transitions with sufficient resolution to allow meaningful comparison is difficult, especially in the period where radiocarbon dating becomes challenging and other techniques are required.

To address such issues the INTegration of Ice core, MARine and TERrestrial (INTIMATE) community has proposed the INTIMATE event stratigraphy, which couples the stratigraphic framework of the Greenland Ice cores as a regional framework with a series of tephra horizons identifiable in the North Atlantic and Europe, to aid the process of independent correlation of records. The last INTIMATE event stratigraphy coupled the extended GICC05 timescale for Greenland back to 128 b2k with an allied tephra record (Blockley et al., 2014). This included a limited number of tephra known to originate or be located across the Eastern Mediterranean region, however, in many instances their distribution and origin was poorly understood. This work aims to improve and extend this provisional framework by integrating important Levantine archaeological records, and long marine and terrestrial palaeoclimate archives in the Eastern Mediterranean. These results are compared with data from known volcanic centres in Turkey and the Aegean Islands, as well as tephra from archaeological and palaeoclimate archives from the RESET project (Lowe et al., 2015) to assess the current potential and limitations for building a tephrostratigraphic framework for the correlation of archives in this region.

Cryogenic cave carbonates suggest changing winter conditions in the European Alps during the mid-Younger Dryas

Gabriella Koltaj¹, Hai Cheng², Christoph Spötl¹

¹University of Innsbruck, Innsbruck, Austria, ²Xi'an Jiaotong University, Xi'an, China

Coarsely crystalline cryogenic cave carbonates (CCC_{coarse}) are secondary carbonate deposits that form via slow freezing-induced supersaturation of small water bodies in cave ice at temperatures very close to 0°C. CCC_{coarse} are also receiving increasing attention as a quantitative indicator of palaeo-permafrost thawing, because they can be precisely dated using U-series disequilibrium methods.

CCC_{coarse} formed during the Younger Dryas (GS-1) cold period were found in two caves in the Eastern Alps that are located approximately 170 km apart from each other. The entrance of Cioccherloch cave is located at 2245 m a.s.l. in the Dolomites; the second cave (Großes Almbergloch) is situated in Totes Gebirge at an elevation of 1475 m a.s.l. Both caves act as cold traps, i.e. their microclimate is mainly governed by dense cold air incursions in winter, while being insulated from the outside atmosphere during summer. Modern cave air temperatures at the CCC_{coarse} sites are 2.5°C and 1.9°C in Cioccherloch and Großes Almbergloch, respectively.

²³⁰Th dating of fourteen samples from Cioccherloch and four from Großes Almbergloch indicates a mid-Younger Dryas age for CCC_{coarse} formation with a weighted mean of 12.20 ±0.09 and 12.32±0.09 ka BP, respectively. These data demonstrate that perennial (thawing) ice due was present in these caves during the mid-Younger Dryas, whereby cave temperatures were very close to the melting point.

As the thermal regime of these caves is controlled by the outside air temperature during winter only, the transient warming in these subsurface environments at 12.3 ±0.1 ka BP recorded a shift from very cold and dry to milder and more humid winter conditions in the Alps. The timing of this change agrees with proxy data from other terrestrial archives in Europe (e.g., Meerfelder Maar, El Soplao cave) and corroborates the hypothesis of a northward shift of the polar front during the mid-Younger Dryas in central and northern Europe.

First results from the Lateglacial and Early Holocene fill of Lac Retournemer (Vosges, France): another INTIMATE Example

Wim Hoek¹, Arjan van Eijk¹, Stan Schouten¹, Stefan Engels², Christine Lane³, Nathalie van der Putten⁴, Didier Roche^{4,5}
¹Department of Physical Geography, Faculty of Geosciences, Utrecht University, Utrecht, Netherlands, ²Department of Geography, Birkbeck University of London, London, United Kingdom, ³Department of Geography, University of Cambridge, Cambridge, United Kingdom, ⁴Department of Earth Sciences, Faculty of Science, VU University Amsterdam, Amsterdam, Netherlands, ⁵Laboratoire des Sciences du Climat et de l'Environnement, Gif sur Yvette, France

One of the current activities of the INTIMATE Network is the organization of bi-annual research training schools for Early Career Scientists. During these INTIMATE Example summer schools, fieldwork, lectures and lab-based activities are executed focusing on a central theme or specific site. The fourth INTIMATE Example Research Training school centered around the coring of Lac Retournemer in July 2018, and aimed at collecting a Lateglacial-Holocene record of past environmental change. Retournemer is located in the High Vosges mountains, and is a nice example of a cirque lake that was formed during the Weichselian. Lac Retournemer is located at 776m above sea level in the head-waters of the Vologne Valley and is currently a 11m deep lake behind a glacial threshold consisting of igneous rock. This area is one of the wettest areas in France with high precipitation values and might therefore be a good site to record Icelandic tephra. Previous investigations show that at least 15m of partially laminated sediments are present in this basin with also a possible occurrence of Laacher See Tephra.

During the summer school we obtained a 18m sediment record before we reached the basal glaciolacustrine sediments at 29 m below water level. In the top part of the sequence, clear sediment fluxes can be observed which might be linked to human impact or increased precipitation events in the catchment. The first results from the basal part of the sequence show a clear Lateglacial and Early Holocene record with Laacher See Tephra in a laminated sequence and a possible occurrence of Vedde Ash in the more siliciclastic Younger Dryas sediments. The Loss on Ignition profile shows multiple fluctuations in the Lateglacial Interstadial and Early Holocene which might be linked to the oscillations in the INTIMATE event stratigraphy for this time period. Preliminary palynological results support the Lateglacial and Early Holocene age of the sequence and will be further explored to investigate the differences in response with other proxies such as chironomids, geochemistry etc. The occurrence of Laacher See and Icelandic tephra in the core will add to the existing tephra lattice for the Lateglacial and Early Holocene in Central and NW Europe.

Last glacial tephra markers recorded in the western North Atlantic and the Nordic Seas

Sunniva Rutledal^{1,2}, Sarah M.P. Berben^{1,2}, Trond M. Dokken^{2,3}, Eystein Jansen^{1,2,3}

¹Department of Earth Science, University of Bergen, Bergen, Norway, ²The Bjerknes Centre for Climate Research, Bergen, Norway, ³NORCE Climate, Bergen, Norway

Tephrochronology is an important geochronological tool for the synchronization of disparate paleoclimate archives. With the increased development of cryptotephra analysis, regional tephra frameworks are growing into important datasets. Marine tephra frameworks describe both distal and proximal tephra horizons and compile information on the spatial and temporal distribution of different volcanic eruptions. Furthermore, they provide an essential source to aid in the correlation of marine paleorecords across oceanic basins.

Here, we present new data from two well-known, distinct and broadly deposited tephra horizons: the basaltic Faroe Marine Ash Zone II (FMAZ II) and the rhyolitic component of the North Atlantic Ash Zone II (NAAZ II). A visible tephra layer (ca. 5 cm) recorded in a marine sediment core from the Nordic Seas (MD99-2284) stratigraphically fits the timing of the FMAZ II. The geochemical compositions of several tephra shards from different size fractions were analyzed using an electron microprobe. The major elements correlate graphically and statistically with previously published data. Thereby, it confirms a Hekla source and the identification of the FMAZ II. The visible layer is distinctly deposited, shows no signs of bioturbation and has a homogenous geochemistry, which all argues for a primary airfall deposition. Additionally, tephra horizons from two marine sediment cores from the Irminger Sea (GS16-204-18CC and GS16-204-22CC) stratigraphically also fit the timing of the FMAZ II. IRD records of both cores show no increased concentration coinciding with the observed tephra horizons. Within GS16-204-18CC, the tephra concentration profiles for different size fractions indicate a first appearance of increased tephra shards in the cryptotephra (25-80 μm) approximately 2-3 cm prior to the increased concentrations in the larger size fractions (80-125 μm and >125 μm). Within GS16-204-22CC, a general background of tephra shards is recorded within the two largest size fractions (>125 μm and 80-125 μm), while the cryptotephra shows one tephra concentration peak. For both cores, the major elements of the cryptotephra show a homogenous population, which graphically and statistically correlates well with previously published data and thus, confirms the identification of the FMAZ II. The more heterogenous geochemistry from the larger size fractions indicates multiple tephra populations. The different geochemistry of the three size fractions is likely due to diverse transport mechanisms. Further, the geochemical compositions of identified rhyolitic tephra horizons from the two Irminger Sea cores correspond to the NAAZ II horizon. The homogenous geochemistry and low IRD argues for a primary air-fall deposition, although deposition on seasonal/short-lived sea ice drifting past the site cannot be excluded.

Overall, the identified FMAZ II and NAAZ II horizons within different cores contribute to the North Atlantic marine tephra framework, which allows for a better marine-marine cross-correlation of paleorecords across the basin.

P-4460

Tephra and abrupt climate changes in the North Atlantic: key achievements and future directions

Siwan Davies¹, Peter Abbott^{2,3}, Anna Bourne⁴, Mark Chapman⁵, Nick Pearce⁶, Anders Svensson⁷, Eliza Cook⁷, Bill Austin⁸

¹Swansea University, Swansea, United Kingdom, ²Cardiff University, Cardiff, United Kingdom, ³University of Bern, Bern, Switzerland, ⁴Queen Mary University of London, London, United Kingdom, ⁵University of East Anglia, Norwich, United Kingdom, ⁶Aberystwyth University, Aberystwyth, United Kingdom, ⁷University of Copenhagen, Copenhagen, Denmark, ⁸University of St Andrews, St Andrews, United Kingdom

Without a full spatiotemporal synthesis of climate variability, the causal mechanisms of abrupt climate events during the last glacial period remain unknown. Unravelling the lead/lag responses (hence cause and effect) between the Earth's climate components is limited by the challenges of synchronising palaeoclimate records on a common timescale. Tephra deposits have long been hailed as powerful independent marker horizons for precisely correlating palaeorecords, but their full potential has yet to be realised. Here we present a summary of work undertaken during the TRACE project (Tephra constraints on RAPid Climate Events) whereby tephra deposits are targeted to precisely correlate the Greenland ice-cores with North Atlantic marine records. A series of new tephra deposits have been identified in both archives, including those originating from ultra-distal sources beyond the North Atlantic region. These discoveries increase the scope of identifying coeval isochrons, but also bring new challenges in the search for unique and robust geochemical fingerprints for unequivocal tephra correlations. As such, we categorize some tephra as being more valuable than others for underpinning key snapshots in time during the last glacial period. The North Atlantic Ash Zone II, for instance, represents the most widespread isochron and constrains the cooling of GI-15. NGRIP1895.24 m and NEEM 1669.25 m provide constraints for the GS-5-GI-4 interval and the FMAZ II offer a fix-point for GS-3. We present climatic snapshots related to these tie-points and explore possible future directions for optimising the application of tephrochronology to scrutinise abrupt climate changes.

P-4461

Late Quaternary vegetation, climate and ocean dynamics in southeastern South America and the adjacent Atlantic inferred from marine sediment cores

Fang Gu¹, Karin Zonneveld², Cristiano Mazur Chiessi³, Hermann Behling¹

¹University of Göttingen, Department of Palynology and Climate Dynamics, Göttingen, Germany, ²University of Bremen, MARUM – Center for Marine Environmental Sciences, Bremen, Germany, ³University of São Paulo, School of Arts, Sciences and Humanities, São Paulo, Brazil

Southeastern South America harbours highly diverse ecosystems, such as the Atlantic rainforest, *Araucaria* forest and grasslands. These ecosystems are highly sensitive to changes in climate which in turn is influenced by a complex interaction between atmospheric and oceanographic features. In the study area, different climatic features, such as the South Atlantic Convergence Zone, cold polar fronts and El Niño Southern Oscillation can play a role.

Furthermore, the Brazil Current from the north as well as the Malvinas Current (MC) and Brazilian Coastal Current (BCC) from the south not only control the major hydrological patterns in the western South Atlantic, but also influence the climate on land.

To reconstruct vegetation, climate and ocean dynamics over long time periods, three marine sediment cores located on a 1400 km-long latitudinal transect (Figure 1) from ca. 27 to 38°S off southeastern South America have been studied for its pollen, spore, dinoflagellate cysts and freshwater algae content.

The northernmost core GeoB2107-3 (27.18°S) indicates cool but wet climatic conditions that probably produced an extensive coverage of *Araucaria* forest from 73.5 to 65 cal kyr BP. Colder and drier climatic conditions prevailed between 38.5 and 13.0 cal kyr BP, and were probably related to an enhanced transport of cold water masses from the south, evidenced by the occurrence of long distance transport of *Nothofagus* pollen. Multiple proxy records indicate that orbital obliquity is one of the most important factors controlling marine and continental environmental changes during the last 73.5 cal kyr BP.

Core GeoB6211-2 (32.50°S) recorded environmental changes since the Last Glacial Maximum (LGM). The results indicate cold and dry climate during the LGM when grasslands dominated the landscape over the studied area. Gallery forests expanded slightly during Heinrich Stadial 1. The Atlantic rainforest expansion to the south was only recorded after 5.5 cal kyr BP. The MC and BCC had a stronger influence to the coring site during the LGM and HS1.

The southernmost core GeoB13862-1 (38.01°S) provides ocean dynamics of the upper water column in the Brazil Malvinas Confluence region since 12.6 cal kyr BP. The palynological records suggest an increase in precipitation since 5.7 cal kyr BP, which probably related to higher frequency and stronger El Niño events. The highest eutrophication of the ocean surface occurred during the last ca. 100 years, which was most probably due to stronger human impact in the drainage basin of the Rio de la Plata.

Our transect records contributes to a better understanding of past vegetation and climate dynamics in southeastern South America, and ocean conditions in the western South Atlantic over long time periods. It also provides an insight into how long-term sea level changes affect coastal ecosystems in southeastern South America.

Figure 1: Coring sites and schematic surface oceanic currents in the study area. Colour shading shows mean annual sea-surface temperatures (°C). BCC: Brazilian Coastal Current, BMC: Brazil-Malvinas Confluence.

P-4462

North-south gradients of $\delta^{18}\text{O}$ in precipitation between Greenland and Gibraltar during the Last Glacial

Tim Atkinson¹, Meighan Boyd², Dirk Hoffmann³, Wolfgang Mueller⁴, David Matthey²

¹University College London, London, United Kingdom, ²Royal Holloway, University of London, Egham, United Kingdom, ³Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany, ⁴Goethe-Universität Frankfurt, Frankfurt am Main, Germany

We describe a methodology for reconstructing $\delta^{18}\text{O}$ in palaeo-precipitation from speleothem records in Gibraltar and examine the implied north-south gradients of $\delta^{18}\text{O}$ during the mid-Last Glacial.

A merged record obtained from flowstone and stalagmite (Gib10d/10e) from the same chamber of Ragged Staff Cave has a resolution of 5-20 years spanning 30 – 110 ka. $\delta^{18}\text{O}$ variations between 40 and 62 ka align closely with NGRIP's GICC05modelext timescale but there is some divergence before and after this. We therefore restrict our reconstruction to 40-62 ka.

Three factors determine the $\delta^{18}\text{O}$ of dripstone calcite: the seepage water's $\delta^{18}\text{O}$, the cave temperature (that determines the equilibrium fractionation factor between water and calcite), and non-equilibrium fractionation caused by CO_2 degassing and/or surface reactions. Reconstructing the seepage's $\delta^{18}\text{O}$ requires independent constraints on the second and third factors. It is also necessary that the relationship between $\delta^{18}\text{O}$ in seepage and rainfall be well-constrained.

We constrain cave temperature using UK'37 data for annual average sea surface temperatures (SSTs) in core ODP-977A in the Alboran Sea, with its timescale converted to NGRIP from original tuning against the GRIP ice core. We assume that in coastal Gibraltar SSTs equalled Mean Annual Air Temperatures (MAATs). Cave temperatures would have tracked MAATs with a lag due to the thermal capacity of the bedrock. To deal with the uncertainty this imposes, we use two bounding scenarios for the evolution of cave temperatures. One computes the effects of heat storage and conduction using a 1-D model whereas in the other the lag is zero. The cave temperature scenarios are used to determine fractionation factors from which time-series of 'equilibrium' values for $\delta^{18}\text{O}$ in water are calculated.

The effects of non-equilibrium factors are difficult to assess. The $\delta^{18}\text{O}$ records for the two speleothems overlay almost exactly despite different morphologies. We take a similar approach to 'disequilibrium' as for cave temperature, defining one bounding scenario of 'no disequilibrium', and a second using the published 'Tremaine curve' that takes disequilibrium into account.

This approach gives rise to a 2 x 2 set of scenarios that define an 'envelope' for $\delta^{18}\text{O}$ in palaeo-seepage. Cave monitoring shows that average seepage $\delta^{18}\text{O}$ is currently 0.6 to 0.75 ‰ less than rainfall because of complete evaporation of summer rains. A similar loss probably occurred during interstadials but was less during stadials. We adjust the reconstructed envelope for seepage water by amounts related to prevailing SST, to obtain estimates and uncertainties for the average $\delta^{18}\text{O}$ of palaeo-precipitation in Gibraltar that can be compared directly with NGRIP (see Figure). $\delta^{18}\text{O}$ shows some similarities in the two records but the variation in Gibraltar is much smaller and partly

decoupled from NGRIP. Abrupt changes in Gibraltar may lead those in Greenland.

P-4463

Exploring the evidence for abrupt reorganisations in atmospheric circulation across NW Europe during the Last Glacial to Interglacial transition.

Ian Matthews

Royal Holloway, University of London, Egham, Surrey, United Kingdom

The Last Glacial to Interglacial transition (16 – 8 ka BP) is defined by a series of millennial-scale oscillations in climate where the transitions between warm (interstadial) and cold (stadial) states seemingly occurred abruptly. Shifts to stadial conditions appear to be forced by meltwater influx weakening in the Atlantic meridional overturning circulation (AMOC) amplified by feedbacks, while subsequent strengthening of AMOC leads to climatic amelioration. These changes are recorded across NW Europe in proxies for temperature, however, temperature change is unlikely to be the sole responding variable to this forcing. For instance, recent studies between 42 - 65°N have proposed variable timing and expression of the onset, progression, and termination of stadial conditions across the North Atlantic region. This research proposes that the offsets are likely to be driven by changes in sea ice and/or terrestrial glacier extent closely associated with abrupt shifts in the westerly wind patterns and consequently precipitation bearing weather systems. Therefore changes in hydroclimate may be as important to environmental change as temperature. These models also suggest that northerly and southerly latitudes are potentially less sensitive to these changes. However, testing these hypotheses is currently difficult as many of the available palaeoclimate records have one or more of the following challenges: (1) insufficient sampling density; (2) qualitative proxy data; (3) uneven spacing in time; (3) stratigraphic breaks in the records; (4) poorly constrained chronologies; and/or (4) poorly defined transitions.

This research identifies new and existing records which have sufficiently precise chronological control and quantitative proxy data to identify leads and lags in climatic variables and environmental responses. These records are then subjected to change-point analyses to constrain the timing of the onset, duration and termination and variability within each event. This presentation focuses on results from the onset of the Lateglacial interstadial (c. 14.7 ka BP) and the Younger Dryas period (c. 12.9-11.7 ka BP) and demonstrates that: (1) temperature and hydrological changes are asynchronous during periods of warming; (2) during cold intervals more variability occurs in hydroclimate than temperature; and (3) there are variable temperature and hydroclimatic responses across Europe.

P-4464

A lunar role in long-term climate variability

Alison Kelsey

The University of Queensland, St. Lucia, Australia

Essential characteristics of climate variability include cycles at various time scales, such as the ~209-yr Suess de Vries cycle of warm-cool temperatures and the Bond and Dansgaard-Oeschger quasi-periodicities of ice-rafted debris associated with abrupt climate change. Evidence also exists of a ~133-yr periodicity in precipitation, about which little is known, influencing water levels, sedimentation records, fire and drought cycles, and extreme weather events such as cyclones. A ~60-yr cycle has also been found in records of precipitation, atmospheric pressure, sea-level, global air temperature, and length of day. The global nature of these events suggests external forcing but these periodicities are poorly understood and have produced strong debates, particularly in relation to the Bond 'cycle'. Despite radioisotopic records suggesting a potential solar role at decadal, centennial and millennial scales, the longest known solar cycle is the ~11-yr variability in solar luminosity, with an inferred association with the sunspot cycle. Long-term solar cycles beyond the range of historical records are inferred from radioisotopic records, such as ^{14}C and ^{10}Be . The Moon's role in these events has only been partially considered. Keele (1910) linked a non-stationary 57-yr precipitation in Australia, Britain, and Egypt to southern lunar declinations. Keeling and Whorf (2000) linked lunar-forced tidal oceanic forcing to an 1800-yr cycle but were not able explain the mechanism that produced the Bond quasi-periodicity.

Based on 5.5 ky of astronomical data and dependent physical models, I provide evidence of a quasi-periodic, millennial-scale, lunar forcing associated with reduced Earth-Moon distance and maximum gravitation. A 133-yr cycle is a harmonic of the millennial-scale cycle, also resulting from variations in Earth-Sun and Earth-Moon distances. This 133-yr cycle consists of 57-yr and 76-yr components. The millennial-scale, quasi-periodic patterns in Earth-Moon distances and gravitation are strongly pronounced, with peak forcing coincident with the occurrence of Bond events during the term of the astronomical data. Patterns in insolation, total solar irradiance, and gravitation are not independent, influenced by distance. These results offer a mechanism for abrupt climate change, where concurrent tidal forcing of the atmosphere and ocean is accompanied by variations in radioisotopic records, thereby suggesting a solar influence. This mechanism has the capacity to produce regional variations through latitudinal variations that influence both oceanic tides and insolation.

P-4465

New insights into vegetation disturbance and Māori agricultural practices on an active tectonic coastline, eastern North Island, New Zealand

Matthew Ryan¹, Bruce Bruce McFadgen¹, John Carter¹, Aline Holmes¹, Lara Shepherd², Ben Hines¹

¹Victoria University of Wellington, Wellington, New Zealand, ²Museum of New Zealand Te Papa Tongarewa, Wellington, New Zealand

Recent radiocarbon dating suggests Polynesians likely settled on the New Zealand archipelago less than 750 years ago, making New Zealand the last major land mass colonized by humans. Two hundred and fifty years ago this year, Captain James Cook's ship, HMS Endeavour, arrived off the eastern coast of New Zealand. At that time, Māori gardening of introduced Polynesian cultivars was taking place in the north-eastern North Island (subtropical climate), while similar sites had been abandoned in the south-eastern North Island (temperate climate). Here, we present research on stone rows from a coastal site in the south-eastern North Island, in order to shed light on early Māori agricultural practices. Dating of these long stone mounds placed in shallow trenches is constrained to ~600 years ago. We have used an integrative approach incorporating analyses of microfossils, such as pollen and phytoliths, macrofossils and DNA from sediment samples taken at different depths to determine the plant remains present on and around the rows.

One of our aims is to determine whether crops were planted directly on the stone rows, which would have provided warmth and extended the growing season, or between the rows, with the stones providing shelter. Our data indicates the presence of both kumara (*Ipomoea batatas*) and gourd (*Lagenaria siceraria*) remains, making this site one of the most southerly records of gourd cultivation documented so far. Produce from this region may have been traded with South Island iwi across the ~25 km Cook Strait. A combination of dating and analysis of plant remains should provide insights into; a) the timing of when New Zealand's indigenous vegetation was initially and dramatically transformed by burning; b) the subsequent replacement by cultivars; and c) the cessation of Māori occupation at the site and continued degradation of New Zealand's indigenous flora upon European arrival. Hypotheses that have been proposed for the abandonment of stone row gardening from this region include tsunami inundation along this tectonically active coastline; and pronounced climate deterioration at this more southerly site. Both could have been devastating for the growth of these cultivars.

P-4466

When was the South Pacific colonised? A lake sediment approach to understanding palaeoecosystem change on remote Pacific islands

Nichola Strandberg¹, Sandra Nogué-Bosch^{1,2}, David Sear¹, Pete Langdon¹, Mary Edwards¹

¹University of Southampton, Southampton, United Kingdom, ²University of Oxford, Oxford, United Kingdom

The islands of the South Pacific were amongst the last places on Earth to be colonised. However, the timing and associated impacts of colonisation are still much debated. The human colonisation of oceanic islands allows for the study of biological invasions of pristine environments. The isolation of these islands and their relative small size allow us to investigate processes and rates of invasions of exotic flora and fauna. The islands also act as microcosms in which we can observe the impacts of agriculture and altered burning regime. The relative recentness (late-Holocene) of the colonisation means that evidence (archaeological and palaeoecological) is well preserved. The aim of this poster is to summarise and describe the palaeoecological research project that we started in 2018. We will use sediment cores from locations across the South Pacific and will apply different methods to investigate palaeoecological changes and human impacts. These methods will include the analysis of pollen, non-pollen palynomorphs, charcoal, sediment DNA, biomarkers (coprostanol) and radiocarbon dating. These proxies will indicate the timing of colonisation and the drivers of landscape change (burning, agriculture and exotic species introductions). We will investigate the rate of change from pre-colonisation through to the establishment of settlements and post-European contact.

P-4467

Stress in paradise: Understanding and quantifying drought in South Pacific islands.

Charlotte Hipkiss¹, David Sear¹, Justin Sheffield¹, Peter Langdon¹, Ian Croudace²

¹University of Southampton, Southampton, United Kingdom, ²National Oceanography Centre, Southampton, United Kingdom

The South Pacific is the home of 13 island nations and 8 overseas territories that accommodates a population of over 10 million people across 1779 islands (Nunn et al, 2016). The small size and remoteness of these islands means that their natural resources are particularly susceptible to both natural and human hazards and are very limited. The availability of drinking water in Pacific Island Nations (PINs) is highly dependent upon rainfall but this region is also drought-prone. The risk to this vital resource is increasing due to human pressures, higher variability in rainfall, an increase in extreme El Niño events and stronger and more frequent storm events (IPCC, 2014).

The tropical Pacific Islands were the final frontier of the human colonisation of Earth and there is still uncertainty surrounding what drove migration across the region. It has been suggested that the climate – specifically drought - may have put pressure on the resources of certain islands and this may have forced the Polynesians to migrate eastwards (Nunn and Kumar, 2016). The Pacific region is a notoriously data poor region and there are still significant gaps in our knowledge around the past and present climate dynamics. It is important to understand the frequency, intensity and duration of droughts that have occurred and how they impacted these islands. Palaeoenvironmental records can provide key insights into the long-term variability of rainfall over millennial timescales so that it is potentially possible to understand the patterns of drought frequency, intensity and duration. From this we can infer whether the patterns we have observed in the past 50-100 years are typical or part of a larger scale of variability driven by Global Warming.

We hope to develop a better understanding of the role and definition of drought in this part of the world both past and present. This research intends to provide an applied palaeoenvironmental study using palaeodata to provide useful insights into the historical drought records and its impacts upon water security. The aim of this poster will be to provide a brief overview and review of the current water security issues in the Pacific and how we can use this to inform our understanding of the environmental pressures on historical Polynesian communities.

New high-resolution Holocene ENSO records from tropical Pacific lakes: a varve-based chronology approach

Marjorie Fis¹, David Sear², Justin Sheffield², Peter Langdon², Ian Croudace³

¹School of Geography and Environmental Science, University of Southampton, SOUTHAMPTON, United Kingdom,

²School of Geography and Environmental Science, University of Southampton, Southampton, United Kingdom,

³School of Ocean and Earth Science, National Oceanography Centre Southampton, Southampton, United Kingdom

The South Pacific Convergence Zone (SPCZ) is the most extensive convective cloud band in the Southern Hemisphere, which generates a strong rainfall gradient in the South Pacific basin (SP). On inter-annual to inter-decadal timescales, Pacific climate phenomena, such as the El Niño-Southern Oscillation (ENSO) cause the SPCZ to shift position (Figure 1). Indeed, El Niño events cause the SPCZ to move north-eastwards and extreme El Niños, make the SPCZ join the Intertropical Convergence Zone (ITCZ). Polynesian islands experience severe droughts during such events, while SPCZ Zonal phenomenon is predicted to become more frequent under a warming world. Moreover, a major shift in the position of the SPCZ and ITCZ has occurred around the time of Polynesian migration (850-1150 BCE), resulting in a prolonged north-eastwards shift of the SPCZ that has strongly modified climate conditions on the islands. Nevertheless, the relationship between ENSO and the hydrological pattern of individual Pacific Islands is still poorly constrained. Thus, the SP is considered to be one of the most vulnerable areas to extreme climate events on Earth. However, only few instrumental data records are available from this critical region and these are often partial and short (<50 years). Therefore, high-resolution quantitative palaeoclimate data are a research priority to fully understand major SP climate dynamics (SPCZ, ENSO). This information is vital for the population of 13 million inhabiting the 1395 SP islands, who especially rely on rainfall for freshwater and food security. New high-resolution climate records from laminated lake sediment cores, collected at two key sites located across the SPCZ contraction axis (Atiu, Cook Islands and Efate, Vanuatu), will be presented. Thanks to a promising method based on varve chronology (thin section analysis), detailed intra-annual records covering main climatic transitions for the last 8000 years have been generated. These records allow to extend our understanding of hydroclimatological change in the SP, linked to SPCZ and ENSO dynamics and thus, to the colonisation of Eastern Polynesia.

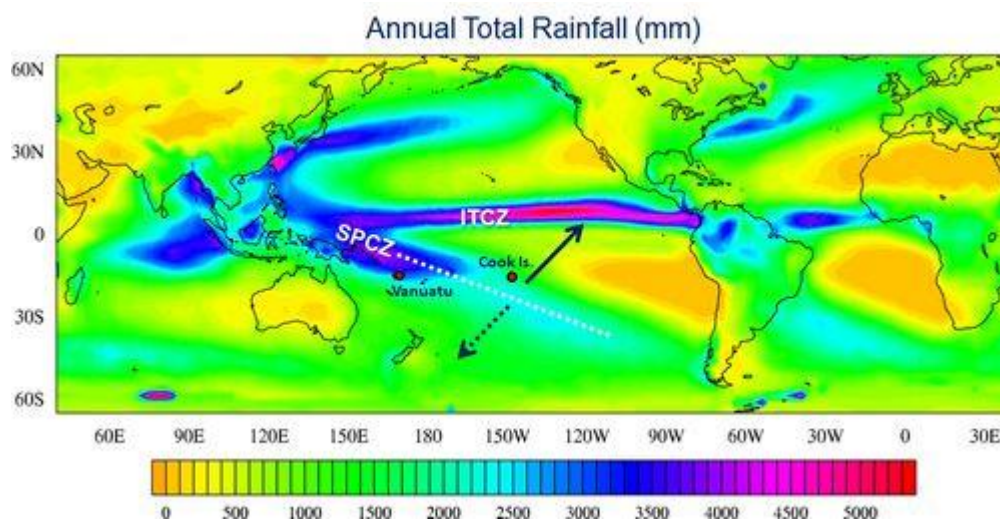

Figure 1: Position of the tropical sediment archives along the diagonal contraction axis of the SPCZ (dashed white line): sites mentioned are highlighted (red circles). El Niño phenomenon causes the SPCZ to move north-eastwards

toward the ITCZ (solid black arrow), whereas La Niña causes it to move south-westwards (dashed black arrow).
Basemap generated from NOAA annual precipitation 1990-2015.

Lake sediment hydroclimate proxies from the tropical South Pacific reveal large scale changes in the SPCZ over the Holocene

Peter Langdon¹, David Sear¹, Jon Hassall¹, Ian Croudace¹, Julian Sachs², Ashley Maloney³, Axel Timmerman⁴

¹University of Southampton, Southampton, United Kingdom, ²University of Washington, Seattle, USA, ³Princeton, Princeton, USA, ⁴Pusan National University, Busan, Korea, Republic of

The South Pacific Convergence Zone (SPCZ) is one of the largest rain bands on our planet. Its interannual to decadal swings are largely governed by tropical Pacific sea surface temperature anomalies. The dynamics of this important climate feature and its response to external forcings have not been fully understood. Here we present the first continuous, Holocene record of SPCZ variability from Vanuatu, Samoa and the Cook Islands, southwest Pacific. Covering the past 9,500 years, this record reveals large scale shifts in the strength and / or position of the SPCZ and corresponding changes in hydroclimate across the South Pacific. The results document a large and rapid transition to pluvial conditions beginning at ca. 5,400 cal yr BP and lasting until 2,800 cal yr BP in Samoa, with a corresponding dry period in the Cook Islands. After 3000 BP, records from different lakes show how the SPCZ moved NE, creating drying in Vanuatu and Samoa, wetter conditions in the Society Islands and Cook Islands, before switching back around the Little Ice Age. Published records from Easter Island confirm existing conceptual models for the role that the SE Pacific High (Anticyclone) plays in strengthening moisture transport into the SPCZ. The Holocene hydroclimate proxies demonstrates how recent climate records provide only a partial understanding of the dynamics of the SPCZ.

P-4470

Reconstructing the geochronological context of the former Patagonian Ice Sheet in understudied northern Patagonian valleys (43°S) using cosmogenic radionuclides

Tanocrède Leger, Andrew S., Hein

The University of Edinburgh, School of Geosciences, Edinburgh, United Kingdom

The former Patagonian Ice Sheet (PIS) was the most extensive Quaternary ice sheet of the southern hemisphere outside of Antarctica, with a latitudinal extent of approximately 2000 km stretching along the Patagonian Andes (Davies *et al.*, 2018). Against the background of global, Northern Hemisphere-dominated ice volumes, it is essential to document how the PIS and its sensitive outlet glaciers fluctuated throughout the Quaternary. This information can help us investigate the climate forcing mechanisms responsible for ice sheet fluctuations and provide insight on the causes of Quaternary glacial cycles at the southern mid-latitudes. Although the PIS has been subject to an increasing number of geochronological glacial reconstructions, there is a general lack of published data for glacial deposits from the north-eastern part of the former PIS, between latitudes 41 and 46° S. Glacier reconstructions in this region are required to better understand the latitudinal variation in the timing of glacial advance and retreat throughout Patagonia, and the complex atmospheric and oceanic circulation systems responsible for millennial-scale interhemispheric coupling of climate change throughout the last glacial cycle. This study presents an effort to reconstruct the glacial geomorphology and geochronology in a valley of northern Patagonia previously occupied by the *Rio Huemul* and *Rio Corcovado* (43°S, 71°W) outlet glaciers. Several field-based techniques, with an emphasis on geomorphological mapping and cosmogenic radionuclide dating, will be used to establish a chronology from the oldest preserved deposits, to the Holocene. This geochronological reconstruction also aims at understanding the past evolution of the drainage system of those valleys throughout the last deglaciation, and to reconstruct the magnitude and timing of past local climate variations. By comparing our findings with results from other palaeoclimate studies, this research aims at improving our understanding of atmospheric systems and energy redistribution mechanisms responsible for climate variability in northern Patagonia. Such palaeoclimatic information is vital to parameterize climate models and better assess the significance of current and predicted global environmental change in the southern mid-latitudes.

The Patagonian Ice Sheet from the last glacial cycle to the Present Day

Bethan Davies¹, Christopher Darvill², Harold Lovell³, Varyl Thorndycraft¹, Julian Martin¹, Neil Glasser⁴, Andy Hein⁵
¹Royal Holloway University of London, Egham, United Kingdom, ²Manchester University, Manchester, United Kingdom, ³Portsmouth University, Portsmouth, United Kingdom, ⁴Aberystwyth University, Aberystwyth, United Kingdom, ⁵Edinburgh University, Edinburgh, United Kingdom

We present a new state-of-the art compilation of published Patagonian glacial and glaciolacustrine geomorphology and recalculated, recalibrated, compilation of published chronostratigraphy. These data are used to generate a new, updated reconstruction of the Patagonian Ice Sheet extent, volume and dynamics at the Last Glacial Maximum and at 5 ka timeslice to the present day, illustrating changes in the dynamics of the ice mass and the ice-dammed proglacial lakes through time. We compile published geomorphological mapping and combine this with our own new remotely sensed mapping to create a detailed GIS database of the geomorphological imprint of past Patagonian ice-sheet fluctuations. We also compiled published ages from the literature that give insights into the lateral and vertical extents of the Patagonian Ice Sheet and later ice fields. The literature was scoured for data pertaining to the geographical position of the ages, which was checked in ArcGIS using the maps and datasets provided in the published literature. The final ages were mapped in ArcGIS as ESRI point shapefiles (*.shp). Each age contains attribute information including the publication reference, location (latitude, longitude, description), altitude (m asl), sample site, dating method, comments regarding sample characteristics, material dated, stratigraphical context or setting, reliability of the age and any other applicable information. Each sample has a unique ID in the table that can be cross-referenced to the maps in this paper. These data are used to generate isochrones of ice extent at 5 ka timeslices across the ice sheet. Using these isochrones, we generate palaeo ice-sheet reconstructions from 30 ka until the present day.

P-4472

Patagonian Ice Sheet deglaciation and palaeolake evolution in the Cisnes-Aysén basins, Chile

Emma Cooper, Varyl Thorndycraft, Bethan Davies, Adrian Palmer
Royal Holloway University of London, Egham, United Kingdom

The structure, timing, and rate of Patagonian Ice Sheet (PIS) retreat since the Last Glacial Maximum are widely debated. Recently published geomorphological and chronological data (10Be, OSL, 14C) obtained from the Rio Cisnes Glacier catchment (44°S) suggests an earlier PIS deglaciation may have occurred in this region in comparison to more southerly latitudes. However, there is still scope for the development of more robust chronologies to test regional differences in the timing of deglaciation, for example through Bayesian age modelling underpinned by varve- and tephrochronologies. The formation of large proglacial lake systems as ice-lobes receded in the Cisnes-Aysén basins provides significant potential for the use of laminated lake sediments to improve our understanding of the timing, and processes associated with ice sheet retreat during the last glacial-interglacial transition (LGIT).

This project will apply a number of methods to constrain the rate and timing of PIS deglaciation and associated palaeolake formation in the Cisnes-Aysén basins (44- 45°S). This will be achieved by undertaking: (1) detailed geomorphological mapping using close and near range remote sensing methods (GIS, UAV mapping); (2) analysis of the timing of lake formation, duration and drainage by developing a deglacial varve chronology for the Rio Cisnes catchment, (3) dating the timing of glacial retreat using cosmogenic nuclide surface exposure ages (10Be) from Aysén Basin moraine crest boulders, and (4) examining visible tephra horizons found in glaciolacustrine sediments.

The aim of this poster is to present new geomorphological mapping, as well as a review of the regional geomorphology for the Cisnes-Aysén catchment, including dates on early-human occupation of the basin. We present data on topographic cross-sections to examine relationships between landforms and retrograde slopes at these sites. This research will have a number of broader scientific implications including insights into: (1) PIS deglaciation and wider late-Quaternary Ice Sheet responses to the LGIT, (2) regional palaeoclimate associated with the prevailing winds (southern hemisphere westerlies), and (3) early human occupation of Patagonia.

P-4473

Extending the speleothem record from Madre de Dios Archipelago, Patagonia, beyond the Holocene

Charlotte Honiat¹, Richard Maire², Christoph Mayr³, Gina Moseley¹, Christoph Spötl¹, Stéphane Jaillet⁴, Phillipp Bartmann³, Larry Edwards⁵, Hai Cheng⁶, Bernard Tourte⁷, Natalia Morata⁷

¹University of Innsbruck, Innsbruck, Austria, ²UMR 5319 PASSAGES CNRS-Univ. Bordeaux-Montaignes, Bordeaux, France, ³Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany, ⁴Laboratoire EDYTEM, Univ. Savoie Mont Blanc, CNRS, Le bourget du Lac, France, ⁵University of Minnesota, Minneapolis, USA, ⁶Xi'an Jiaotong University, Xi'an, China, ⁷CENTRE-TERRE, Toulouse, France

Located at 50° S, Madre de Dios Archipelago is the southernmost karst region on Earth. Carved by Pleistocene glaciers, this exceptional maritime landscape has experienced extreme rates of karst denudation in a temperate oceanic climate characterized by extreme rainfall (up to 7-8 m/yr) and strong westerly winds. Little is known about how orbital- to millennial-scale climate change has affected this region. Speleothems in caves provide one of the best terrestrial environmental archives, with respect to chronology. Due to the remoteness of this area, however, very few speleothem records have been published so far (Schimpf et al., 2011) which span the Holocene only.

Here we present a set of speleothems from the islands of Madre de Dios and Guarello which for the first time extend into the Pleistocene. Dating these speleothems using U-Th is challenging given the abundance of non-carbonate constituents and the low Uranium concentrations. The resulting ages, however, provide robust chronological anchor points. The specimens comprise inactive flowstones and stalagmites which cover short growth intervals only, typically a few thousand years. The majority of the samples date from the Holocene, but some cover the Late Glacial, MIS 3, MIS 5e and MIS 7a. This demonstrates that subsurface environments on these islands at least locally preserve a record of climate and environmental conditions which survived the pervasive glacial and meltwater erosion during the Last Glacial Maximum, which obliterated coeval sediment archives on the surface.

Stable isotope data provide snapshots of local paleoclimate variability. Carbon isotopes show large excursions (up to 12‰ in the entire data set and up to 7‰ in a given sample) with values as low as -11‰ and as high as +1‰. In contrast, oxygen isotopes show a much smaller amplitude (less than 3‰) and most values are between -5‰ and -4‰. In several samples both isotopes co-vary, pointing towards kinetic isotope effects.

This new dataset highlights the potential of speleothems as recorders of environmental change even in an extreme setting such as the Madre de Dios Archipelago and opens the door to explore the impact of climate change on this unique landscape and vegetation beyond the Holocene.

P-4474

High-resolution glacial geomorphological mapping of the Cordillera Darwin Icefield, Tierra del Fuego, Chile

Eñaut Izagirre^{1,2}, Iñaki Antigüedad¹, Sérgio H. Faria^{3,4}, Neil F. Glasser⁵

¹Hydrology and Environment Group, Science and Technology Faculty, University of the Basque Country UPV/EHU, Leioa, Spain, ²Cryosphere Group, Basque Centre for Climate Change (BC3), Leioa, Spain, ³Cryosphere Group, Basque Centre for Climate Change BC3, Leioa, Spain, ⁴IKERBASQUE, Basque Foundation of Science, Bilbao, Spain, ⁵Dept. of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom

The Cordillera Darwin Icefield (CDI) is the third largest icefield in South America. Recent publications have focused on the extensive recession of its glaciers during the last termination as well as the marked frontal retreat of its outlet glaciers (e.g. Marinelli Glacier) since the Little Ice Age. Few studies have focused on Neoglacial advances of the CDI and the differences between the evolution of its marine-terminating and land-terminating glaciers.

In this poster, we present new mapping of the CDI. We combine high-resolution satellite imagery interpretation (mainly 3-5 m resolution PlanetScope/RapidEye and 1-m resolution DigitalGlobe/GeoEye-1 images available through the QGIS 'QuickMapServices' service) largely validated by fieldwork to improve the glacial geomorphological mapping of the CDI. The map is designed as a basis for future chronological campaigns and to enable a refined reconstruction of the glacial history of the icefield.

Our results emphasize the importance of local topographic and glaciological conditions, such as the presence or absence of marine-terminating or land-terminating glaciers, in determining glacier behaviour and response to climate change. We also consider the importance of these local topographic and glaciological conditions for a correct understanding of the glacier dynamics and glacial history reconstruction.

Dynamic shifts in the forest/steppe boundary, Southernmost South America (~53°S) during the Late-glacial and the Holocene: climatic inferences.

Claudia A. Mansilla¹, Robert D. McCulloch², Flavia Morello³, Pamela Soto-Rogel⁴, James Blaikie⁵, Frank Schäbitz⁶

¹Centro de Investigación Gaia Antártica (CIGA), Universidad de Magallanes, Punta Arenas, Chile, ²Centro de Investigación en Ecosistemas de la Patagonia, Coyhaique, Chile, ³Instituto de la Patagonia, Universidad de Magallanes, Punta Arenas, Chile, ⁴Institut für Geographie Friedrich-Alexander Universität Erlangen-Nürnberg, Germany, Erlangen, Germany, ⁵Biological Environmental Sciences, University of Stirling, Stirling, United Kingdom, ⁶University of Cologne, Institute of Geography Education, Cologne, Germany

The ecotones from forest to steppe are one of the most sensitive ecosystems of the world and where the impact of global climate changes becomes most evident. Therefore, the changes in the distribution and abundance of the vegetation in the ecotone can be linked to large-scale regional and global climate controls and can be used as indicators of climatic change. The Andes in Southernmost South America form a topographic obstacle to the Southern Westerlies Winds leading to an abrupt change of climate across short distances that produce a dramatic west-east precipitation gradient, which is reflected in the vegetation pattern in Fuego-Patagonia. Hunter-gatherer populations were the first inhabitants after the end of the last glaciation and persisted until the beginning of the twentieth century. They were nomads with a low population density and without agricultural development. These features permit the reconstruction of palaeoenvironments under low human impacts.

We present a synthesis of ten palynological records (peatlands) from Fuego-Patagonia. The synthesis was constructed using continuous well-dated records, new and previously published, which cover the Last Glacial-Interglacial Transition and the Holocene to produce an enhanced regional record of environmental changes. The records were taken from different locations along the west-east precipitation gradient. Tephrochronology was used to link palaeoenvironmental records from across the region and to view vegetation changes along the tephra isochrones. Comparison using methods for climate regime shift of the records of *Nothofagus* forest demonstrates that they differ in their response to regional climatic changes depending on the location along the west-east precipitation gradient. The palaeoenvironmental evidence provides a rare insight into the local site-specific environmental changes and more regional perspective of movements in the forest-steppe ecotone driven by longitudinal shifts in the west-east precipitation gradient across Fuego-Patagonia.

Our synthesis based on CONNIS cluster analysis suggests across the region a first pulse of establishment of *Nothofagus* forest between c.13.5-12.5 ka cal yr BP. An early Holocene dry period at c.10.5-9.5 ka cal yr BP and a major arid phase during the mid-Holocene at c.8.5-6.5 ka cal yr BP. Between c.6.5-2.0 ka cal yr BP, there was a gradual expansion of the forest which suggests an increase in the levels of effective moisture. From c.2.0 ka cal yr BP to present, the forest appears to have undergone repeated phases of wetting and drying probably in response to significant variability in the effective moisture levels. There were two marked contractions of the forest at c.2.0 and c.1.0 ka cal yr BP, likely due to short periods of reduced effective moisture.

This study provides a regional perspective of the movements in the forest-steppe ecotone and the lag in the response of vegetation to climate change. This shows that *Nothofagus* forest is highly vulnerable to future climate change.

The Última Esperanza piedmont lobe is one of the outlet glaciers fed by the Patagonian Ice Sheet in the southern part of Chile in South America during the Last Glacial Maximum (LGM). The Andes Range in the study area reaches ca. 1500-2000 m a.s.l. of elevations and contains deeply dissected glacial valleys and extensive moraine ridges and glacial lakes developed further east of the present-day ice field. The objective of this study is to understand the deglaciation timing of Cerro Benitez area (51°33' S, 72°34' W; 120 m a.s.l.) to the north of Puerto Natales, where several caves and rock shelters, including the famous Mylodon Cave, are located. To that end, 16 erratic blocks were dated by cosmogenic ¹⁰Be surface exposure method on top and around the caves. The age results clearly indicate that the maximum glacial advance was ca. 40.0 ± 6.0 ka ago during the local Last Glacial Maximum (lLGM). Indeed, several glacier records around the globe suggest that the southern and northern hemisphere ice sheets may have fluctuated out-of-phase during the last glacial period. The second maximum glacial advance is also clearly dated to ca. 20.0 ± 3.0 ka indicating that the global LGM (gLGM) was less extensive in Patagonia, as previously reported by other studies. We conclude that the Mylodon Cave and other caves and rockshelters of Cerro Benitez area were ice-free and opened up to be inhabited by the megafauna including, now extinct but well-preserved large mammals such Mylodon darwini, and then, later, by the first Palaeoindians. This work was supported by the French CNRS PICS GEOCEBE, the Chilean FONDECYT 1150845 and 1180272, and the İstanbul Technical University Research Funds (Project No: TGA-2017-40610).

P-4477

Late Holocene glacial chronology at Mount Tenerife, southern Patagonia Andes, using image analysis, geomorphologic mapping, tree rings, and lichens.

Juan-Carlos Aravena¹, Gonzalo Amigo¹, Paulina Ruiz¹, Michael Kaplan²

¹Universidad de Magallanes, Punta Arenas, Chile, ²Lamont-Doherty Earth Observatory, Columbia University, New York, USA

Glacier fluctuations have been used to reconstruct past climate variability to understand mechanisms underlying past climate changes at different time and spatial scales. For the Southern Andes, although important advances have been obtained refining glacier changes chronologies during the last glacial cycle, the timing, patterns and causes of glacial fluctuations, remain elusive. Besides, small mountain glaciers may be a useful approach to estimate glacier fluctuations during the Late Holocene, avoiding the complexities associated with large icefields and calving glacier fluctuations.

This work aims to reconstruct the history of glacial fluctuations for a small climate-sensitive mountain glacier in Mount Tenerife (51°20'S, 72°51'W, 1,600 m asl), during the Late Holocene, a period within recent earthy history for which there remain large discrepancies in our interpretation of the geological records.

We combined image analysis, glacial geomorphology mapping, dendrochronology, and lichenometry to document the spatial and temporal structure of Late Holocene glacial changes in Mount Tenerife, southern Patagonia. By combining these approaches, we expect to establish high-resolution glacial chronologies that allow us not only to decipher the timing and structure of fluctuations of the study glaciers, but also to test mechanisms involved in the initiation and modulation of the magnitude of glacial events in this study site during the Late Holocene.

Tree-ring series show significant positive correlation with summer temperature records from Punta Arenas and negative correlations with the SAM index. No significant correlations were found between tree-growth patterns and precipitation. Taking advantage of the correlation between tree-growth and climate variability, we compared the relationship between variations on the length of the Mount Tenerife glacier, a climate index mimicking glacier mass balance, and tree-growth trends. Our results show for the last few decades a constant negative mass balance, a marked decrease in glacier lengths and a decreasing trend in tree growth. Dating control for these processes was obtained from contemporaneous time series provided by tree-ring counting, lichen growth and image analyses.

Results exposed here contribute to our understanding of natural climate variability under interglacial conditions, providing a baseline to assess present-day glacier fluctuations, and to look for new insights regarding the mechanisms underlying glacial fluctuations.

P-4478

Glacial geomorphic map of patagonian islands and peninsulas between the Gran Campo Nevado and Estrecho de Magallanes, Chile.

Paulo C Rodríguez¹, Alessa J Geiger^{2,3}, Gastón Herrera⁴, Lidia Ferri⁵, Juan L García², Rachel K Smedley⁶

¹Centro de Investigación GAIA-Antártica (CIGA), Universidad de Magallanes, Punta Arenas, Chile, ²Institute of Geography, Pontificia Universidad Católica de Chile, Santiago, Chile, ³School of Geographical & Earth Sciences, University of Glasgow, Glasgow, United Kingdom, ⁴Escuela de Arquitectura, Universidad de Santiago, Santiago, Chile, ⁵IANIGLA-CONICET, Mendoza, Argentina, ⁶School of Environmental Sciences, University of Liverpool, Liverpool, United Kingdom

We present the first extensive glacial geomorphic map of peninsulas and islands located between the Gran Campo Nevado and the Estrecho de Magallanes, south-western Patagonia (52.8-53.1°S, 73.0-73.9°W). The map covers an area of 1.200 km² and is based on remote-sensing data analysis in a GIS environment and corroborated by field observations at Isla Tamar, Isla Zanelli and Peninsula Muñoz Gamero. High-resolution Planet satellite images (Imagery © 2019 Planet Labs Inc) from 2017 to 2018 and aerial photographs taken between 1978 and 1982 by the Servicio Aerofotogramétrico Chileno (SAF) were used to map at scales of 1:5000 and 1:8000. The ALOS PALSAR Digital Elevation Model was used as the topographic base data, while the 3D Google Earth viewer platform helped to improve landform limit determination. Selected remotely mapped sites were visited during the #ChileFjords18 science cruise in November 2018 to corroborate mapped features using direct field measurements, photography & drone footage. The research area is dominated by glacial erosional landforms that include horns, cirques, u-shaped valleys, roche moutonnees, whalebacks and truncated spurs. Glacial related depositional features principally correspond to fluvio-glacial terraces, outwash plains and erratic boulders on scoured bedrock. Frontal and lateral moraines were mapped on land, most of them are located close to cirques. This map is the first high-resolution geomorphic map in the area and one of the few at the western flank of the Andean Cordillera in south-western Chile. The methods developed here could be used as a guide to develop future studies that aim at understanding and comparing ice sheet behavior on both sides of the Andean massif during the last glacial period and subsequent deglaciation.

P-4479

The local Last Glacial Maximum along the Patagonian Andes, southern South America: inferences from new ^{10}Be , Luminescence and ^{14}C chronologies

Juan-Luis Garcia¹, Andrew S Hein², Christopher Lüthgens³, Maria-Paz Lira⁴, Angel Rodés⁵, Rodrigo M Vega⁶, Steven A Binnie⁷, Michael J Bentley⁴

¹Instituto de Geografía, Facultad de Historia, Geografía y Ciencia Política, Universidad Católica de Chile, Santiago, Chile, ²School of GeoSciences, University of Edinburgh, Edinburgh, United Kingdom, ³Institute for Applied Geology, University of Natural Resources and Life Sciences (BOKU, Vienna, Austria, ⁴Department of Geography, University of Durham, Durham, United Kingdom, ⁵Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom, ⁶Instituto de Ciencias de la Tierra, Universidad Austral de Chile, Valdivia, Chile, ⁷Institut für Geologie und Mineralogie, Universität zu Köln, Köln, Germany

The Patagonian ice sheet developed along the southern Andes between 38-55°S during the last glacial period. The ubiquitous imprint of this former glaciation is preserved in the landscape and is suitable for reconstructing how glaciers and climate fluctuated during this time, including Marine Isotope Stages 4-3-2. To present, most evidence has pointed out that Patagonian outlet glaciers reached their maximum extents during, or slightly earlier than, the global Last Glacial Maximum (gLGM) between ~26 and 18 ka (e.g., Kaplan et al., 2008). However, more recent evidence from southernmost Patagonia has unraveled that the local LGM (lLGM) occurred earlier during mid-MIS 3 at c. 48 ka (Darvill et al., 2015; García et al., 2018). The goal of this work is to unravel the lLGM along the Patagonian Andes and determine possible glacial asymmetries that may have punctuated the late Pleistocene glacial history in southern South America. Here, we discuss new paleoglacier ^{10}Be , ^{14}C and single grain feldspar luminescence records obtained from the Chilean Lake District (40°S), Isla Grande de Chiloé (42°S), Río Cisnes Valley (44°S) and Seno Skyring (53°S). Our data shows that the timing of the local LGM varied depending on site/latitude. The geochronometers (^{10}Be , ^{14}C and luminescence) used to date outwash sediments in Chiloé indicate a pre-gLGM glacier maximum there, on the western Andes side. Here, a ^{10}Be depth profile from the highest Cucao I terrace linked to the outer ice marginal position yielded a preliminary exposure age of 70 ± 15 ka. At the same site, multiple luminescence ages indicate deposition at about ~50-70 ka. The lower Cucao II outwash terrace yielded preliminary luminescence ages in correspondence with the gLGM. Altogether, these ages indicate that maximum glaciation in Chiloé occurred during the MIS 4, which is consistent with MIS 3 ^{14}C dated wood overlying the Cucao I outwash sediments. A later ice advance reaching an inboard ice marginal position occurred during MIS 2 during the gLGM. In contrast, a gLGM timing has been dated at Río Cisnes, on the eastern side of the Andes, as based on >15 ^{10}Be exposure dates from boulders resting on the outer CIS I and CIS II moraine ridges. CIS I moraine yielded a mean age of 25.1 ± 0.9 ka and CIS II an age of 22.3 ± 1.6 ka. Exposure ^{10}Be samples collected from outer Laguna Blanca moraines at the Skyring site (eastern southern Andes) will be presented during the conference, with their paleoglacial and paleoclimatic significance discussed in relation to the causes underlying the lLGM in Patagonia.

P-4480

Deglacial and postglacial forest history and climate changes on the eastern slopes of the central Patagonian Andes

Rodrigo Villa-Martínez^{1,2}, Patricio Moneno^{3,4}, Isabel Vilanova⁵

¹GAIA-Antártica, Universidad de Magallanes, Santiago, Chile, ²Millennium Nucleus for Paleoclimate, Punta Arenas, Chile, ³Departamento Ciencias Ecológicas, Universidad de Chile, Santiago, Chile, ⁴Millennium Nucleus for Paleoclimate, Santiago, Chile, ⁵Museo Argentino de Ciencias Naturales BR, Buenos Aires, Argentina

We report a high-resolution pollen and charcoal records from lake sediments obtained from Lago Mellizas to reconstruct the history of vegetation, fire and climate changes on the eastern slopes of the central Patagonian Andes over the last 17 ka (ka=1000 cal yr BP). These data allow examination of the timing and direction of arboreal colonization through the increasingly ice-free Patagonian landscapes and the timing and structure of the southern westerly winds (SWW) changes during and since the last glacial termination. Lago Mellizas (45°32' S; 71°48' W, 760 masl) is a small closed-basin lake located along the eastern slopes of the Andes near to the climate-modulated forest-steppe ecotone in central Patagonia. Central Patagonia (44°-49°S) is an area in which the SWW are the only source of precipitation, generating a strong west-east precipitation gradient across the Patagonian Andes that induces a zonation of the regional vegetation, which can be used for inferring past changes in precipitation regimes based on fossil pollen records. Furthermore, the Chilean-European colonization process in central west Patagonia started early in the 20th century, allowing characterization of natural vegetation and climate.

The pollen record shows an open landscape dominated by herbs (Poaceae, *Gunnera*, *Acaena*, Apiaceae) and shrubs (*Empetrum*) suggesting an open landscape under cold conditions between 17 and 16.7 ka. An increasing trend of *Nothofagus* started at 16.7 ka, along with hygrophilous and cold-tolerant conifers (*Pilgerodendron*, *Podocarpus*). The latter reached maximum abundance between 15-11.7 ka, indicating a rise of the precipitation, followed by the establishment of dense *Nothofagus* forests and declines in hygrophilous and cold-resistant trees, herbs, shrubs and increases of fire activity under warm and dry climate conditions until 9.5 ka. *Nothofagus* forests have persisted with little variation since 9.5 ka, despite of the occurrence of the increase of fire activity at multicentennial timescales and subtle increases of conifers. We detect a major change in the pollen stratigraphy at 0.06 ka when started a sustained decreasing trend in *Nothofagus*, along with increases of Poaceae and the aquatic Cyperaceae and *Myriophyllum*. We interpret these changes as a forest opening and centripetal expansion of littoral environments toward the lake center driven by lake-level lowering in response to lowered precipitation. *Rumex* and *Plantago*, which are indicative of human perturbation, increase at 1900 AD. Our results suggest an early expansion of cold-resistant hygrophilous conifers and rainforest trees sourced from the eastern flanks of the Andes in central Patagonia and the precipitation variations related to changes in the influence of the SWW during and since the last termination.

P-4481

Late glacial and Holocene mean annual temperature changes in the south-central Chile using a chironomid-based inference model

Alejandra Martel-Cea^{1,2}, Marjorie Hernández¹, Julieta Massaferro³, Ana María Abarzúa¹

¹Instituto Ciencias de la Tierra, Universidad Austral de Chile, Valdivia, Chile, ²PhD program, Fac. Cs. Naturales y Recursos Naturales, Universidad Austral de Chile, Valdivia, Chile, ³CONICET, CENAC/APN, Bariloche, Argentina

The use of non-biting midges as a tool for inferring past environmental conditions in south America has grown in the recent years. However, the lack of modern ecological and taxonomic information at spatial scale difficult to state if the main forcing factor that control chironomid assemblages are the same across the continent. Here we present a chironomid training set from 24 lakes located in the south-central Chile between 37°S and 41°S. Multivariate analyses indicate that mean annual temperature (MAT) is the main driver that controls the chironomid distribution (12,8% of total variance and MAT gradient 7-13°C). Based on these results, a temperature inference model is developed using the weighted average partial least square technique, achieving a performance of $R^2_{\text{jack}}=0.64$, $\text{RMSEP}_{\text{jack}}=1.15^\circ\text{C}$, $\text{Max.Bias}_{\text{jack}}=1.38^\circ\text{C}$. A transfer function was applied to infer quantitative MAT changes in the fossil record from Laguna Las Ranas (39.2°S, 72.1°W, 389m asl, modern MAT=10.2°C) spanning the last 18,6 ka BP. The results suggest the major MAT increment occurred during the late glacial between 18,6 and 13,5 cal ka BP, from 7.6°C to 9.5°C, and then, the rising temperature trend stopped and fluctuated around 10.5°C until 10.8 cal ka BP. From the early to mid-Holocene (10.8 and 6.5 cal ka BP) an increase and high variability of MAT values are recorded (peak MAT=12.3°C around 9 cal ka BP), and associated to important changes in the chironomid assemblages suggest environmental instability around Laguna Las Ranas. Less extent MAT fluctuations are observed in the last 7 cal ka BP, however, comparing to modern values, relative cold periods are inferred around 7-4.2 cal ka BP and 0.25 cal ka BP (ca. 9.7°C), whereas warm periods occurred around 4.2-3.6 cal ka BP and 0.8-0.25 cal ka BP (10.6°C). Despite to relative low coefficient of determination of the inference model and the short environmental gradient of sampled lakes, the chironomid-based MAT reconstruction follows the main climatological patterns occurred in the southern South America during the late Quaternary.

Direct constraints on the timing of Neoglacial glacier advances remain sparse in the South American mid-latitudes. Classical schemes – based on limiting ¹⁴C ages – indicate several steps of Neoglaciation with the most extensive reached during the mid-Holocene, around 5 ka (Porter, 2000). Here we investigate the timing of Neoglacial extent of two contrasting east-flowing outlet glaciers of the Southern Patagonian Icefield (SPI) through ¹⁰Be exposure dating of moraine boulders. The studied glaciers show different size, slope and tongue grounding environment. Viedma glacier is one of the largest SPI outlets (~900 km²) whose tongue calved into lake Viedma during most of the Holocene, whereas Marconi glacier (~50 km²) – whose tongue was grounded during the intervening period – merged with another major SPI outlet (Chico glacier; ~300 km²) during Holocene highstands. We show that the Viedma and Marconi glacier experienced their Neoglacial maxima around 7 ka and that at least two other advances quite similar in size occurred before 4 ka. Then, two other Neoglacial stadials of decreasing magnitude occurred around 2 ka and during the Little Ice Age, from 0.5 ka. Our chronology is consistent with growing evidence of a prominent change in the regime of the Southern Westerly Winds (SWW) at 7 ka, as indicated by proxy records (Moreno et al, 2018).

A 17,500-year record of environmental change based on pollen and charcoal in a lake sediment in northwestern Patagonia

Carla Henriquez, Patricio Moreno
Universidad de Chile, Santiago, Chile

Patagonia is a key region to study the climate evolution of the southern mid-latitudes and the behavior of the Southern Westerly Winds (SWW) since the Last Glacial Maximum (LGM). Here we present results from sediment cores collected from Lago Fonk, a small closed-basin lake located in the Chilean Lake District sector of northwestern Patagonia (41°S). The record provides continuous information to reconstruct the vegetation, climate and fire disturbance history since Last Glacial Termination (LGT) to the present.

During LGT the record shows abundant presence of arboreal pollen, mainly elements characteristic of North Patagonian rainforests, such as *Nothofagus*, until 15,600 cal. yr BP, after that occur a rapid increase of Myrtaceae and *Podocarpus nubigena* until 12,300 cal. yr BP. And the end of LGT is coincident with the expansion of *Weinmannia trichosperma* between ~12,300–10,000 cal yr BP, and concurrent with the start of fire activity, suggesting the start of disturbance events. A total of 55 local fire events were detected in the record. The element characteristic of Valdivian forest, *Eucryphia/Caldcluvia*, show two pulses of increase at 10,000 cal yr BP and 6,700 cal yr BP, this results suggest warming condition during this epoch. After 6,700 cal yr BP vegetation alternate between *Nothofagus* and *Eucryphia/Caldcluvia*. We interpret this alternations in dominance between North Patagonian (e.g. *Nothofagus*) and Valdivian rainforests (e.g. *Eucryphia/Caldcluvia*) driven by changes in temperature and precipitation of westerly origin at millennial timescales.

Finally, we observed in the record that vegetation composition and heterogeneity declined in response to Chilean/European disturbance around 350 years cal. BP, with the rapid deforestation and increase of artificial grasslands and introduced species of the genus *Plantago* and *Rumex*.

Dysoxic conditions through the Holocene at the Churruca I site, Strait of Magellan, Chile (53°S)

Maria A. Godoi Millan^{1,2}, Philip L. Gibbard², Michael A. Kaminski³

¹Centro de Investigación Gaia-Antártica (CIGA), Universidad de Magallanes, Punta Arenas, Chile, ²Cambridge Quaternary, Department of Geography, University of Cambridge, Cambridge, United Kingdom, ³Earth Sciences Department, King Fahd University of Petroleum & Minerals, Dhahran, Saudi Arabia

Multiproxy records from three overlapping sediment cores from the marginal site Churruca I (53° 03.460'S, 73° 55.543'W; ca. 75 m water depth), inner region of the Western/Pacific entrance of the Strait of Magellan, reveal two major changes in the marine environment and dysoxic conditions that prevailed throughout the Holocene.

The compound sequence span from deglaciation to fully marine conditions at present, with the transgression occurring by ca. 10400 a BP. Different opportunistic species dominated benthic foraminiferal records in small test sizes (mainly below 200µm), indicating the prevalence of stressed conditions.

During the early Holocene assemblages were strongly dominated by the infaunal genera *Buliminella* and *Stainforthia*, both associated with fine substrates, dysoxia, and denitrification capabilities. The earlier stages of foraminiferal colonization occurred in a probably tidally controlled proglacial environment.

Higher species diversity and the dominance of the genus *Stainforthia* changing to the detritivore *Epistominella* characterizes the mid-Holocene, a stage of known higher stand in relative sea levels in the region. The onset of this period was marked by a strong pulse of taxa from deeper and more open marine settings (genus *Uvigerina*, planktonic taxa), occurring between the date at ca. 9200 a BP and deposition of tephra linked to the Hudson volcano (H1 eruption previously dated at ca. 7700 a BP). This suggests the incursion of a strong tsunami-type of wave that broke apart the barrier restricting the site, allowing stronger exchange with outer waters while stagnation remained at the sea floor. This agrees well with the 8.2 ka BP event, common in the Holocene records around the world.

The late Holocene also started with a pulse in planktonic taxa followed by deposition of volcanic products arguably linked to the Reclus volcano. Regional relative sea levels dropped and organic flux increased, leading to a more restricted water exchange that limited species diversity. The genus *Buliminella* strongly dominates through this stage to present, conditions established by 3200 a BP.

This sequence records global and regional signals, including the southward migration of the Sub-Antarctic Front, which approaches the latitude of the Western entrance of the Strait of Magellan not earlier than the onset of the mid-Holocene.

Two major changes in the hydraulic regime are clearly identified, in agreement with the formal subdivisions of the Holocene series. Their occurrence at depths close to those of volcanic horizons, also highlights the need to explore the role of volcanic and seismic activity on deglaciation and their subsequent effect on the marine environment in this region.

Preliminary results of this work were presented at the Foraminifera and nannofossils groups joint meeting of The Micropaleontological Society in 2012.

Palaeohydrology of lowland rivers in the Murray-Darling Basin, Australia

Paul Hesse, Rory Williams, Timothy Ralph, Kirstie Fryirs, Zacchary Larkin, Kira Westaway, Will Farebrother
Macquarie University, Sydney, Australia

This study derives a new function describing the relationship of channel bankfull discharge (Q_{bf}) to channel width in modern rivers of the Murray-Darling Basin (MDB) of southeastern Australia and applies this to dated palaeochannels of seven rivers to quantify late Quaternary discharge history in this important basin. All rivers show high MIS3 and MIS2 Q_{bf} , declining in the Holocene. The Q_{bf} of modern MDB rivers is correlated with total catchment precipitation but comparison with palaeochannel Q_{bf} estimates shows that while enhanced runoff efficiency is necessary to account for much larger late Pleistocene palaeochannels, either lower or higher precipitation rates could have prevailed. A strong association between relative palaeo- Q_{bf} enhancement and temperature suggests a temperature-mediated mechanism controlling river discharge, such as the fraction of precipitation stored as snow and thawing in spring, the enhancement of orographic rainfall, or CO_2 feedbacks with vegetation cover. Significantly enhanced MIS3 Q_{bf} requires an additional mechanism, such as increased rainfall. These findings are consistent with others that increased moisture availability was associated with past colder climates, although this was not necessarily the result of enhanced precipitation.

Speleothem records of Late Pleistocene abrupt climate change in the southern mid latitudes

Claire MacGregor, John Hellstrom, Russell Drysdale, Jon Woodhead, Petra Bajo
University of Melbourne, Melbourne, Australia

Precise radiometric dating of palaeoclimate archives, such as speleothems, provides an avenue for deciphering interhemispheric teleconnections and understanding the mechanisms behind abrupt climate change. In this context, the terrestrial southern mid latitudes remain relatively unexplored in comparison to the Northern Hemisphere; radiometrically dated records from this region are even rarer. Tasmania, Australia, is situated between 40-43 degrees south and is one of just three major land masses intercepted by the Southern Westerly Winds. It has experienced extensive glaciation during cold stages of the Quaternary. As such it presents an ideal location in which to study both glacial terminations and millennial scale events in the southern mid latitudes. After an extensive U-Th reconnaissance survey to identify suitable materials using low-impact sampling protocols, a number of stalagmites were selected for the construction of detailed proxy records. Here we present preliminary speleothem records of abrupt climate change occurring between MIS 8 and 2 using high-resolution chronologies. This data will help to document the southern mid latitude expression of abrupt changes in climate throughout the Quaternary and allow comparison with their much more thoroughly studied counterparts in the Northern Hemisphere.

P-4487

Late Quaternary palaeoenvironmental records of tropical Australasia

Alexander F. Wall

University of Wollongong, Wollongong, Australia

The palaeoenvironments of tropical Australasia were extremely dynamic during the late Quaternary. Changing regional geology (e.g. ongoing subduction, uplift, and associated volcanism) and global climate interacted to create complex and localized environmental changes. For example, because the Sunda shelf includes large areas near sea level, changes in sea level dramatically affect the land area, the exchange between the Indian and Pacific Oceans, and the volume of the Indo Pacific Warm Pool. These dynamics are important for understanding the past and future of climate change in the region. The environment of the late Quaternary also paints the setting for the diversity of hominins in the area, including the intrepid ancestors of the first Australians.

This talk synthesizes a variety of data from published sediment records marine and terrestrial settings in tropical Australasia. Data drawn from stable isotopes, pollen, trace elements, and sedimentological features describe different aspects and different resolutions of the palaeoenvironmental story. It also provides an overview of current interpretations and highlights informational gaps. Finally, the talk describes preliminary results from new records from several tropical Australasian sites and incorporates them into the broader understanding of the region's past.

Comparison of $\delta^{18}\text{O}$ in groundwater and a cave flowstone: improving the interpretation of the speleothem $\delta^{18}\text{O}$ paleoclimate proxy

Lewis Adler¹, Stacey Priestley², Pauline Treble^{2,3}, Andy Baker³, John Hellstrom⁴, Alan Griffiths², Karina Meredith²
¹Bioanalytical Mass Spectrometry Facility, UNSW, Sydney, Australia, ²ANSTO, Lucas Heights, Australia, ³Connected Waters Initiative Research Centre, UNSW, Sydney, Australia, ⁴Department of Earth Sciences, University of Melbourne, Melbourne, Australia

Speleothems are high-resolution records that can be used for terrestrial paleoclimate reconstruction from their oxygen and carbon isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$), and whose deposition is directly related to the groundwater recharge process. Groundwater $\delta^{18}\text{O}$ records have the potential to provide an important long-term record of past climate, but they are low-resolution records as the isotope signal can be altered during flow within the aquifer. In this study we compare measured $\delta^{18}\text{O}$ values from both a groundwater record and speleothem record from a flowstone over the past 12,000 years for the first time from south west Western Australia.

Flowstones normally form from cave streams or fast dripping seepages and their oxygen isotope composition is sensitive to the extent of kinetic fractionation, determined by water flow rate, as well as, streams or seepages water $\delta^{18}\text{O}$ composition. In this study comparison of $\delta^{18}\text{O}$ values from a groundwater record and flowstone enables the source water oxygen isotopic composition to be constrained in order for a more complete interpretation of the higher resolution speleothem record, including the site specific kinetic processes and climatic changes.

The flowstone $\delta^{18}\text{O}$ values appear consistent with millennial variability in recharge $\delta^{18}\text{O}$ predicted using the groundwater values, although the flowstone oxygen isotopes are generally enriched in ^{18}O compared to the regional groundwater record before $\sim 7.4\text{ka}$. This offset between the records indicates that flowstone calcite deposition was not in isotopic equilibrium with its source water likely due to low flow regimes and extensive degassing of CO_2 . According to a model of isotopic disequilibrium that is driven by water supply, the Holocene portion of the flowstone record contains periods of relatively lower isotopic disequilibrium indicating possible higher water supply, and periods of relatively higher isotopic disequilibrium indicating possible lower water supply consistent with local and regional archives.

Reading the tea-tree leaves: *Melaleuca quinquenervia* leaves as a palaeoclimate proxy

Jacinta Greer¹, Francesca McInerney¹, John Tibby¹, Quan Hua², Cameron Schulz³, Cameron Barr¹, Jon Marshall³, Glenn McGregor³

¹University of Adelaide, Adelaide, Australia, ²Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, ³Queensland Department of Environment and Science, Brisbane, Australia

The analysis of organic material preserved in sedimentary records is a useful tool in reconstructing past climatic conditions. It has been suggested that the carbon isotope discrimination (Δ) calculated from the bulk leaf $\delta^{13}\text{C}$ of the modern *Melaleuca quinquenervia* tree responds to local precipitation in south-east Queensland, Australia [1]. The preservation of these leaves in lake sediments on Minjerribah (North Stradbroke Island) dating to the mid-Holocene presents the opportunity to produce species-specific stable isotope-based records of precipitation.

Here, we test the potential for *M. quinquenervia* to be used as a palaeoclimate proxy by examining the preservation of the bulk leaf $\delta^{13}\text{C}$ over time and the relationship of Δ values to historical records of precipitation. Due to the varying rates of degradation of the different chemical constituents of plant matter, it is possible $\delta^{13}\text{C}$ ratios to be altered by early diagenetic processes before, or during, the incorporation of leaves into the sediment. Therefore, modern studies are needed to establish what factors influence the discrimination derived precipitation record.

Focusing on the *M. quinquenervia* growing at Swallow Lagoon on Minjerribah, we studied the changes to the bulk leaf $\delta^{13}\text{C}$ ratios of exposed leaves over an eighteen-month field study. We then applied our findings to the measured $\delta^{13}\text{C}$ ratios of bulk leaf material retrieved from a core taken from the lagoon. The Δ values calculated based on these measurements were then compared to instrumental rainfall data from the past century to test the established relationship with modern precipitation through time.

By bisecting each leaf used in this study, we were able to compare the experimentally degraded leaves directly to their corresponding control halves. We observed that decay causes an approximate decrease of 1 ‰ in $\delta^{13}\text{C}$, as the leaves become more ^{13}C depleted relative to the control leaf halves that were dried immediately. Quantifying this offset enables adjustment of values to be comparable to the calibration equation established using natural fall leaves from modern *M. quinquenervia*. Comparing the adjusted Δ values for lake core leaves from the last century to corresponding rainfall data the relationship to local precipitation seems to be preserved.

Understanding exactly how early diagenesis changes the stable isotope composition of *M. quinquenervia* leaf material over time allows us to adjust for the offset between modern and sub-fossil bulk leaf $\delta^{13}\text{C}$ and advances the potential to use this species as a reliable climate proxy in the future.

A 5.3-million-year history of monsoonal precipitation in northwestern Australia.

Jan-Berend Stuut^{1,2,3}, Patrick De Deckker⁴, Mariem Saavedra-Pellitero⁵, Franck Bassinot⁶, Anna-Joy Drury², Maureen Walczak⁴, Kana Nagashima⁷, Masafumi Murayama⁸

¹NIOZ - Royal Netherlands Institute for Sea Research, dept of Ocean Systems, and Utrecht University, Texel, Netherlands, ²MARUM - Center for Marine Environmental Sciences, Bremen University, Bremen, Germany, ³Vrije Universiteit Amsterdam, Faculty of Science, dept. of Earth Sciences, Amsterdam, Netherlands, ⁴ANU - Australian National University, Research School of Earth Sciences, Canberra, Australia, ⁵Bremen University, dept. of Geosciences, Bremen, Germany, ⁶LSCE - Laboratoire des Sciences du Climat et de l'Environnement, Gif-sur-Yvette, France, ⁷JAMSTEC - Japan Agency for Marine Earth Science and Technology, Yokosuka, Japan, ⁸Kochi University, Center for Advanced Marine Core Research, Kochi, Japan

Australia is the driest inhabited continent on the planet, with its moisture mostly sourced from the tropical monsoon in the north and the southern westerlies in the south. The continent has experienced large climate fluctuations in the geologic past, but long continuous records of palaeo-environmental changes are lacking, particularly prior to ~0.55Ma. Here, we address this paucity by presenting a continuous record of continental aridity and monsoonal activity in northwestern Australia since the Pliocene (5.3 Ma). Our records are based on bulk-chemical XRF-scans and particle-size distributions of the terrigenous fraction, in two cores from the northwestern Australian continental shelf: MD002361 and ODP122-762B. In our records we distinguish between aeolian- and fluvial sediments that were deposited at sea. Support for the distinction between aeolian and fluvial sediment fractions in the two marine sediment cores is found in the bulk-chemical composition of aeolian- and fluvial material in the potential source areas in northern West Australia. Our records show a warm and dry early Pliocene (~5.3 Ma) on the northwestern Australian continent, which experienced a gradual increase in humidity peaking at about 3.8 Ma with higher than present-day rainfall. Between 3.8 and about 2.8 Ma, climate became progressively more arid with more rainfall variability. Coinciding with the onset of the northern hemisphere glaciations and the intensification of the northern-hemisphere monsoon, aridity continued to increase overall from 2.8 Ma until today, with greater variance in precipitation and an increased frequency of large rainfall events. We associate the observed large-scale fluctuations in Australian aridity with variations in Indian Ocean sea-surface temperatures, which largely control the monsoonal precipitation in northwestern Australia.

P-4491

A U-Th-dated speleothem pollen record of environmental changes in southwest Western Australia, during the late glacial to early Holocene.

Kale Sniderman, John Hellstrom, Jon Woodhead
University of Melbourne, Melbourne, Australia

The pre-Holocene palaeoenvironmental and palaeoclimatic history of southwest Western Australia remains almost completely unknown, so that this region constitutes a major gap in understanding of late Pleistocene environmental change in the Southern Hemisphere. Here we present a pollen record from a stalagmite collected in the Yanchep Cave system on the Northern Swan Coastal Plain (NSCP), ca. 60 km north of Perth, Western Australia. The pollen record, supported by a detailed U-Th age model, documents environmental changes from ca. 15.5 ka to ca. 6.5 ka, spanning the late glacial and the Pleistocene-Holocene boundary.

At the commencement of the record, the *Eucalyptus* open forests and woodlands that dominate the NSCP today were largely absent, and the pollen record was dominated by Asteraceae, *Banksia* (Proteaceae), Poaceae and Goodeniaceae. From ca. 14.2 ka, chenopods and Leptospermeae/Chamelaucieae (ca. 30 genera of sclerophyllous shrubs within the Myrtaceae; herein, "Myrtaceous shrubs") began to increase in importance, implying drying and/or cooling that coincided with the timing of onset of the Antarctic Cold Reversal (ACR), as observed in the West Antarctic ice sheet (WAIS) Divide $d^{18}O$ record. At ca. 12.2 ka, within no more than ~two centuries, *Eucalyptus* values increased from trace values up to ca. 10% of the pollen sum, and Myrtaceous shrubs increased to high values, at the expense of chenopods. Thereafter, very little change in pollen proportions is observed across the Pleistocene-Holocene boundary, formally defined at 11.7 ka. However, at ca. 11 ka, within a few centuries, Myrtaceous shrubs and chenopods rapidly collapsed to low values, while *Eucalyptus* values increased to 20-40%, suggesting that a substantial *Eucalyptus*-dominated tree cover had been established.

The vegetation changes observed on the NSCP appear to correlate closely with some changes observed in the WAIS $d^{18}O$ record. One intriguing link is the vegetation shift at 12.2 ka, which coincides with the abrupt termination of the ACR, several centuries prior to the Pleistocene-Holocene transition. On the other hand, the most important change in the record, at ca. 10.8 ka, the collapse of Myrtaceous shrublands and the rapid expansion of *Eucalyptus* canopy cover, does not correspond to any feature in the Antarctic record, and may therefore primarily reflect a moisture-, rather than temperature-related climatic response.

New Zealand climate and environmental change through the Holocene: a review

Andrew Lorrey¹, Helen Bostock², Shaun Eaves³, Katharine Holt⁴, Chris Moy⁵, Joe Prebble⁶, Andrew Rees³, Paul Augustinus⁷, Guiseppe Cortese⁶, Llsa Dowling³, Liz Keller⁶, David Lowe⁸, Matt McGlone⁹, Rewi Newnham³, Jonathan Palmer¹⁰, Matthew Ryan³, Valerie Van den Bos³, Marcus Vandergoes⁶, John-Mark Woolley¹, Janet Wilmshurst⁹
¹National Institute of Water and Atmospheric Research LTD, Auckland, New Zealand, ²National Institute of Water and Atmospheric Research LTD, Wellington, New Zealand, ³Victoria University Wellington, Wellington, New Zealand, ⁴Massey University, Palmerston North, New Zealand, ⁵University of Otago, Dunedin, New Zealand, ⁶GNS Science, Wellington, New Zealand, ⁷University of Auckland, Auckland, New Zealand, ⁸University of Waikato, Hamilton, New Zealand, ⁹Landcare Research, Lincoln, New Zealand, ¹⁰University of New South Wales, Sydney, Australia

The Southern Hemisphere Assessment of Paleoenvironments (SHAPE) international focus group within PALCOM has drawn together researchers from the Southern Hemisphere who are interested in climate variability and environmental change through the Quaternary. One focus for SHAPE has been the Holocene, with aims to test mechanisms of change, identify abrupt shifts, and characterise impacts from different modes of variability on terrestrial, ocean and cryosphere environments.

As part of our contribution to the hemisphere-wide SHAPE integrations, we have drawn together a comprehensive range of Holocene palaeoenvironmental and palaeoclimate evidence from the New Zealand region. This area is located in the middle latitudes of the Southern Hemisphere and it has teleconnections to a range of tropical and polar climate processes. We have gathered only published records that cover part or all of the Holocene, including tree rings, speleothems, lacustrine and peat cores, and discontinuous stratigraphic records of glaciation, alluvial sedimentation and fire occurrence. Our team has applied consistent protocols for dating and developing age models for records that are temporally constrained using cosmogenic dating, tephrostratigraphy, Uranium-Thorium, and radiocarbon chronologies.

From the New Zealand data collection, we evaluate the austral applicability of the recent formal Greenland-centric Holocene subdivision, including the inter-regional consistency for timing of the main transitions, the duration of climate excursions, and several anomalous climatic intervals at millennial to multi-decadal scales. In this presentation, we highlight the onset of the Holocene, whether an early optimum occurred, and whether there was an obvious mid-Holocene shift in the climate state on land and at sea. We interrogated a subset of our records covering the Common Era to examine what intervals temporally aligned to the Medieval Climate Anomaly and the Little Ice Age in Europe were like, and contextualise our data interpretations in an atmospheric circulation regime context.

The identified gaps in the national data network indicate more quantitative records of hydroclimate (particularly from lakes and speleothems) are required from northern and eastern regions. Expanded chronologies of glacier activity, droughts, floods and pre-human fires would be helpful for contextualising long-term alpine changes and extremes. Updates for many tree ring records will improve calibrations with instrumental climate records and reanalysis data, and will also help to refine reconstruction uncertainties. The expanded tool box of proxy techniques that are readily available now will also allow former study sites to be revisited to expand on the basic evidence that has been developed so far for the Holocene.

P-4493

Glacial chronology and Holocene environmental history of Lake Tennyson, North Canterbury, New Zealand

John-Mark Woolley¹, Andrew Lorrey¹, Timothy Barrows², Shaun Eaves³, Peter Almond⁴, Paul Augustinus⁵, Fiona Shanhun⁴

¹National Institute of Water and Atmospheric Research, Auckland, New Zealand, ²University of Wollongong, Wollongong, Australia, ³Victoria University Wellington, Wellington, New Zealand, ⁴Lincoln University, Lincoln, New Zealand, ⁵University of Auckland, Auckland, New Zealand

Lake Tennyson is located in the northern South Island of New Zealand. The site is critically positioned at the boundary between regional climate districts with very different precipitation regimes and is highly sensitive to atmospheric circulation changes. Evidence from this location can provide a backdrop for testing hypotheses about what drives New Zealand glacier responses to climate variability and change. However, few detailed studies on the late glacial and post glacial history exist on the northeast fringe of the main divide outside of the central Southern Alps.

We addressed this aforementioned knowledge gap by establishing the timing of the glacial sequence emplacement at Lake Tennyson. At this site, there are well-defined end moraines marking the southern margin of the lake basin, and the catchment has a simple geometry. Our work employed geophysical, stratigraphic and geomorphic approaches that included pedology, tephrostratigraphy, cosmogenic analysis, radiocarbon dating, and modelling.

The most recent maximum ice extent was achieved close to ~18.6ka at Lake Tennyson. However, an older advance of similar extent, limited by local accommodation space, is likely for MIS4 at ~64ka. Kawakawa Oruanui Tephra is also inferred as a cryptotephra within a well-developed podzolised soil capping the moraine that marks maximum local ice extent at Lake Tennyson. Inboard recessional moraines mark glacier (and presumably climate) variations during the early part of the last termination through to ~17.1ka. Replicated cosmogenic ages on the cirque sill of Princess Bath, which fed into the main glacier that filled Lake Tennyson, suggest ice had mostly evacuated the catchment by 11.2ka.

Sediment cores change from inorganic to organic sedimentation following small tree and shrub expansion at the expense of herbs prior to 10.5ka cal BP. Beech (*Fuscopora*) pollen has been present since prior to 10.5ka, and has been elevated for at least the last 1000 years. Additional dates on moraines located inboard of the LGM sequence are forthcoming.

P-4494

What happened at the end of the mid-Pleistocene transition in the Southern Hemisphere? Insights from western Tasmania, Australia

Michael-Shawn Fletcher¹, Agathe Lisé-Pronovost¹, Tom Mallett², Michela Mariani^{1,3}, Sarah Cooley¹, Jan-Hendrik May¹, Patricia Gadd⁴, Andy Herries², Maarten Blaauw⁵, Henk Heijnis⁴, Dominic Hodgson⁶, Joel Pedro⁷

¹University of Melbourne, Carlton, Australia, ²La Trobe University, Bundoora, Australia, ³University of Nottingham, Nottingham, Australia, ⁴Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, ⁵Queen's University Belfast, Belfast, United Kingdom, ⁶British Antarctic Survey, Cambridge, United Kingdom, ⁷Antarctic Climate and Ecosystems, Hobart, Australia

The current southward shift in the southern westerlies that is stripping southern Australia of rainfall is unprecedented over the past 12 kyr years at least, and is due to the effects of both the anthropogenic hole in the ozone layer and greenhouse gas-driven global warming. Predictions of future climate suggest the Earth is moving in to a "super-interglacial" (peak warming) because of anthropogenic greenhouse gas release. "Super-interglacials", which are warmer than today, are uncommon in the geological record. A recent increase in the frequency of these peak warming events since ca. 450 ka (the end of the mid-Pleistocene transition; MPT) is associated with a 7° latitude southward shift of the southern westerlies and an increase in atmospheric CO₂ that warmed the atmosphere - a stark similarity to current trends.

Here, we present multi-proxy analyses of two closely spaced (<50 km) sediment cores that comprise a complete sequence from the mid-Pleistocene to the present from western Tasmania, Australia - in the mid-latitudes of the Southern Hemisphere. Lake Selina is a modern-day lake with a continuous ca. 230 kyr sediment sequence, while Darwin Crater is a palaeo-lake within a meteorite impact crater that formed at ca. 816 ka and which completely in-filled during MIS5 (ca. 120 ka). We report on petrophysical whole core logging, lithological core description, spectrophotometry, grain size, natural gamma ray, paleo- and rock-magnetism, loss-on-ignition, pollen analyses and micro-XRF geochemistry. The composite record is unique in the Australian sector of the Southern Hemisphere and we discuss the data in the context of the global and regional changes that occurred at the end of MPT, paying particular attention to impact of the shift toward warmer super-interglacials, the large-scale southward shift of the southern westerlies and higher atmospheric CO₂ content that occurred at ca. 450 ka (MIS11 to present).

P-4495

From stormtracks to savannah: modeling the climate and environment of early humans in Southern Africa during the last glacial-interglacial period

Stefan Sobolowski^{1,2}, Odd Helge Otterå^{1,2}, Zhongshi Zhang^{1,2}, Margit Simon^{1,2}

¹NORCE and the Bjerknes Centre for Climate Research, Bergen, Norway, ²The Centre for Early Human Behaviour, Bergen, Norway

The Centre for Early Sapiens Behaviour (SapienCE) at the University of Bergen (Norway) aims to understand where, when and why early humans in southern Africa started to think and behave as we do today. Current archaeological evidence, though limited, suggests that the period 100-50kya was a watershed for human cognitive, technological and social development. The climate reconstruction team at SapienCE seeks to elucidate the regional to hemispheric environmental conditions and the role these may have played in shaping early human development and movements. Key questions are: What were the regional climate characteristics over southern Africa during periods of early human habitation? Can shifts in climate and circulation patterns/regimes help explain early human 'disappearances'/ 'reappearances' in the region? The present work focuses on one of these 'disappearances'. Most of the period 100-50kya falls within the later part of the MIS5 interglacial, which may have had a climate conducive to early human cultural and cognitive development. However, shortly after 70kya the southern hemisphere entered what has been described as a nearly glacial state in MIS4. Evidence from caves along the southern African coastline show a thick dune layer that closed off the caves to human occupation, while sea levels may have dropped 80m or more, shifting the coastline many tens of kilometers from the caves. The present work focuses on this MIS5-MIS4 (~63-76kya) period straddling the transition. Coupled AOGCM simulations show robust changes in sea level pressure (higher) and temperature (cooler) both locally and remotely as the climate transitioned. The poleward flank of the southern hemisphere jet is weakened (strengthened) in DJF(JJA) and the DJF(JJA) Hadley circulation (weakens)strengthens. These have implications for weather variability and extremes, especially in the midlatitudes. However, many of these changes are modest and changes in the hydrological cycle such as precipitation rates and moisture flux divergence/ convergence are even less robust. Results are compared with speleothem data from the region and sediment cores from the Agulhas plateau gathered by SapienCE colleagues. While there is general agreement on direction of change there are some areas of disagreement. In particular, the hydrological cycle response remains uncertain. Some studies/records indicate cooler wetter conditions, others cooler drier. Our simulations suggest the latter over southern Africa, but needs further investigation to improve confidence. Towards this end we perform sensitivity studies on the effects of changes to the Antarctic sea-ice extent, which is hypothesized to have extended into the present day polar front during MIS4. We also statistically assess the robustness of the climate simulations by comparing the simulated climate signals against the natural variability simulated in baseline control simulations. The potential implications of these climatic changes for the population of early humans in southern Africa are discussed.

P-4496

A multi-proxy record of climatic changes and Southern Westerlies dynamics in the subtropical Andes of South America since 12ka

Antonio Maldonado Castro¹, Maria Eugenia de Porras², Nora Maidana^{3,4}, Julieta Massaferrero^{5,6}, Robert Negrini⁷, Jose Luis Antinao^{10,8,9}, Rachel Tiner⁷

¹CEAZA, La Serena, Chile, ²IANIGLA, Mendoza, Argentina, ³Universidad Nacional de Buenos Aires, Buenos Aires, Argentina, ⁴CONICET, Buenos Aires, Argentina, ⁵CENAC, Bariloche, Argentina, ⁶CONICET, Bariloche, Argentina, ⁷California State University Bakersfield, Bakersfield, USA, ⁸Desert Research Institute, Reno, USA, ⁹CIGIDEN, Santiago de Chile, Chile, ¹⁰Indiana University, Indiana, USA

The subtropical Andes of South America are a key area to study the interaction of tropical and extra-tropical climatic systems. The climate is characterized by wet winters and dry summers related to its position at the northern edge of the Southern Westerlies Wind Belt (SWWB) which migrate seasonally so that during the austral winter they expand equatorward to about 30°S. The SWWB is modulated by the presence of the Southern Eastern Pacific Subtropical Anticyclone (SEPSA) which migrates in conjunction with the SWWB determining the strong precipitation seasonality of Subtropical Andes. Thus, the interplay of the SWWB modulated by the SEPSA at millennial-centennial scale superimposed to the interannual scale variability related to the Southern Oscillation is reflected in precipitation patterns over the Andes allowing to trace the winter activity of SWWB at millennial-to-interannual time scales.

This paper presents the dynamics of the northern edge of the SWWB since 12ka based on a multi-proxy record of Laguna El Cepo located at 30°S (2900masl).

The pollen record is dominated of Poaceae with maximum values between 12-11ka, 9.6-8ka and since 5.8ka which suggest moderate humid conditions peaking since 2.2ka given the increase of Portulacaceae and Apiaceae. Dry phases characterized by increases of *Ephedra* occurred between 11-9.6ka and particularly 8-5.8ka. Pollen accumulation rates recorded the driest conditions between 11-5.8ka. The charcoal record shows that fire occurrence increased from 7ka onwards with maximum values between 7-6ka, during the driest period for the whole record.

The diatom record reflects cold temperature of the water given the high values of *Eunotia spp* at 12-10.5ka and 4.8-3.8ka alternating with warm conditions between 10-8.5 and 8-6ka pointed out by *Chamaeopinnularia sp* which together with *Chamaeopinnularia hassiatica* reveal the warmest conditions around 6.4ka. High percentages of *Kobayasiella micropundata* between 8.5-8ka and at 5.5ka indicate the occurrence of exogenous input into the lake. High values of *Eunotia spp* during the late Holocene reflect cooler conditions during the last 5ka, compared to the early-mid Holocene conditions.

The chironomid record show high percentages of *Cricotopus* suggesting littoral environment dominance at 12ka. Cold conditions associated to discrete increases of *Smitia* between 8.5-8ka and 5ka. The presence of *Chironomus* between 8-4.8ka and its highest percentages at 7.3-6.4ka suggest warm conditions. Sedimentological proxies suggest a recurrence of storms around 8.5-8ka and 5.8-4ka and a decrease productivity of the lake between 7.7-5.4ka.

The joint interpretation of different proxy records suggests cold and humid conditions during the end of Pleistocene while the basin was still becoming a lake. During the early and mid-Holocene up to 5.8ka, dry and warm conditions dominated, with increased occurrence of storms around 8.5-8ka. The last 5.8ka appeared to be relatively more humid and colder conditions than the early and mid-Holocene. FONDECYT#1180413;1170408

P-4497

Early spread of rainforest trees during the Last Glacial Termination along the eastern slopes of the Central Patagonian Andes (45°S)

Isabel Vilanova¹, Rodrigo Villa-Martinez², Patricio Moreno³

¹CONICET-Museo Argentino de Ciencias Naturales BR, Ciudad Autonoma de Buenos Aires, Argentina, ²GAIA ANTARTICA, Universidad de Magallanes, Punta Arenas, Chile, ³Universidad de Chile. Nucleo Milenio Paleoclima, Santiago de Chile, Chile

Few studies have examined in detail the structure of vegetation and climate changes during the Last Glacial Termination (T1, ~11-18 ka, ka= 1000 cal yr BP) in central Patagonia (45°- 48°S). This region is adjacent to the zone of maximum southern westerly wind (SWW) influence in South America, and features strong climatic gradients along and across the Andes. These gradients influence vegetation composition and structure, resulting in zonation of evergreen and deciduous rainforests from the pacific coast upslope into the high-Andean meadows. Deciduous forests dominate the eastern slopes of the Andes and transition into the Patagonian Steppe toward the east. Here we present palynological results from Lago Unco (45°34'29.4''S; 71°43'7.6''W, 756 masl), a small closed-basin lake located in the modern forest-steppe ecotone, in direct association with moraines deposited during the Last Glacial Maximum (LGM). Our aim is to document the composition, tempo and mode of vegetation changes during T1 to infer the climate evolution through this interval and the spatial/temporal patterns of afforestation.

The pollen record features predominance of herbs and shrubs characteristic of cold high Andean environments and the Patagonian steppe between 17.8-11 ka, with dominance of Poaceae, Asteraceae, Fabaceae, and Apiaceae between ~17.8-17.3 ka. The record then shows dominance of Poaceae, Ericaceae and Asteraceae, along with *Acaena* and *Gunnera* until 15 ka. A sustained rise in *Nothofagus* is evident starting at 16.5 ka accompanied by the hygrophilous cold-tolerant conifers *Fitzroya/Pilgerodendron* and *Podocarpus nubigena*, the rainforest tree *Drimys winteri*, and the hygrophilous pteridophytes *Blechnum* and *Lycopodium magellanicum*.

These data suggest an increasing trend in humidity and SWW influence starting at 16.5 ka until it reaches its maximum at 15 ka. Our findings constitute the earliest occurrence of cold-resistant hygrophilous taxa at the east of the Andes during T1, suggesting that they thrived near the eastern margin of the PIS during the LGM and may have been a source for the postglacial dispersal and colonization of trees currently dominant in rainforests along the pacific coast of central Patagonia. *Nothofagus* forests established between 11-10 ka near Lago Unco, concomitant with a decline in hygrophilous taxa and increased fire activity. We interpret these changes as a warm pulse and decline in precipitation brought by diminished influence of the SWW at ~11 ka.

New Zealand paleoclimate reconstruction from speleothem fluid inclusion measurements

Brittany Marie Ward¹, Adam Hartland¹, Thomas Bauska², David Hodell²

¹University of Waikato, Hamilton, New Zealand, ²University of Cambridge, Cambridge, United Kingdom

New Zealand's location makes it a particularly advantageous place to study past Southern Hemisphere climate dynamics and their impact on terrestrial hydroclimate. Few New Zealand speleothem-based studies exist beyond a handful of stable isotope records. It is increasingly understood that multi-proxy speleothem records are needed to unravel the various drivers embedded in complex carbonate stable isotope signals. Here, we present preliminary speleothem fluid inclusion (FI) $\delta^{18}\text{O}$ and δD measurements, and carbonate $\delta^{18}\text{O}$ measurements from Waipuna Cave (Waitomo, New Zealand; 30°S), dating back 16,000 years, as part of an on-going New Zealand paleoclimate reconstruction project. Speleothem FI measurements have the potential to directly measure fossil dripwater composition, but are still underutilized due to analytical barriers, particularly with respect to $\delta^{18}\text{O}$ measurements.

We present data from a new fluid inclusion extraction system at the Godwin Lab for Paleoclimate Research, Cambridge University. In addition to measurements from Waipuna Cave, we measured an in-house water standard ($n=40$) at varying sample sizes via an injection port in the crusher system, upstream from the crushing block. Further, we measured two different types of speleothem samples from three climatologically distinct regions, India (stalagmite; $n=4$), Siberia (stalagmite; $n=3$), and New Zealand (2 flowstone sites; $n=25$). The water standard average measurements were $\delta^{18}\text{O} = -7.4 \pm 0.3$ and $\delta\text{D} = -51.0 \pm 3.1$, including all samples sizes from 0.05 – 0.5 μL . Average water standard values of each sample size are within error of known values, suggesting sample size does not influence measured values for injected water standards. Cubes of varying mass were cut from each speleothem sample for FI measurements. We found water concentration ($\mu\text{L/g}$) varied among cubes, even among cubes from the same speleothem, with a range of 0.1 – 6.8 $\mu\text{L/g}$ across all samples. Further, there exists inverse relationship between water concentration and D_{excess} suggesting samples with lower concentrations report inaccurate values of fossil dripwater, and notably the stalagmite samples reported lower water concentrations than the flowstones. Whether this issue is analytical or due to in-cave processes is unclear and necessitates further experiments. Down-core FI δD and $\delta^{18}\text{O}$ values from Waipuna cave are stable from ~16 – 10 ka, and exhibit variability during the Holocene. This shift from a stable deglacial to variable Holocene is also exhibited in the carbonate $\delta^{18}\text{O}$ values from of the same flowstone, which exhibit an excursion to lower values during from the deglacial to the Holocene.

Vegetation and climate reconstruction from marine cores east and west of South Island, New Zealand, during past interglacials

Matthew Ryan¹, Rewi Newnham¹, Gavin Dunbar², Marcus Vandergoes³, Helen Neil⁴, Silke Steph⁵, Brent Alloway⁶, Helen Bostock⁴, Ashwaq Sabaa⁷, Bruce Hayward⁷, Joseph Prebble³, Linda Heusser⁸, George Scott³, Andrew Rees¹, Ralf Tiedemann⁵, Xun Li³

¹Victoria University of Wellington, Wellington, New Zealand, ²Antarctic Research Centre, Wellington, New Zealand, ³GNS Science, Wellington, New Zealand, ⁴NIWA Ltd, Wellington, New Zealand, ⁵Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ⁶Auckland University, Auckland, New Zealand, ⁷Geomarine Research, Auckland, New Zealand, ⁸Lamont-Doherty Earth Observatory, Columbia University, New York, USA

Previous terrestrial palynological records of mid-latitude Southern Hemisphere interglacial periods are often fragmentary and poorly dated. Here, these problems are circumvented by extracting terrestrial palynomorphs from marine sediment cores collected from the levee banks of submarine canyons to the west (MD06 2990/2991) and east (DSDP 594) of southern New Zealand. These cores have been dated by $\delta^{18}\text{O}$ stratigraphy, ^{14}C chronology, and the identification of two widespread silicic tephra horizons at 25.6 ka and ~345 ka, sourced from the central North Island. The cores cover the last 500 kyrs and have an average sedimentation rate of ~7-20 cm/kyr. The continuity and chronology of these records provides an opportunity to examine changes in vegetation between interglacials of different warmth.

The records show that 'super-warm' interglacials of MIS 1, 5e and 11 each side of the South Island are characterised by more pollen of conifer and thermophilous taxa than cooler interglacials of MIS 7 and 9 by ~50%. MIS 7 and 9 are characterised by increased southern beech pollen and suggests that the beech forest 'Biotic Gap', which characterises both flanks of the central South Island today, developed after MIS 7.

The characteristics of each interglacial can be further illuminated by comparing west and east NZ, across which there is a major rainfall gradient of 12,000 and 3,000 mm/yr over the Southern Alps. During peak warmth, MIS 11 sea surface temperatures were up to 3°C warmer than present west of NZ in the Tasman Sea. In southwestern NZ, this corresponds with a notable expansion and dominance of the thermophilous shrub *Ascarina lucida* at the expense of the currently dominant tall tree conifer *Dacrydium cupressinum*. The MIS 11 forest composition in this highly humid region also contrasts markedly with reconstructions of forest conditions during periods inferred to be up to 1.5°C warmer than present in early MIS 1 and 5e, when *D. cupressinum* remained dominant in the region. In contrast in southeastern NZ, the tall tree conifer pollen reaches the highest values in MIS 11, which is consistent with warm and wet conditions, which is possibly related to more southerly incursions of sub-tropical air masses. For each interglacial period the prominent expansion of tall tree conifers in southeastern NZ lags that in the west. The longest lag (~10 kyr) occurred during the MIS 12/11 transition. The delayed afforestation between west and east likely resulted from harsher local climate conditions (cooler and drier) east of the Southern Alps, forest disturbances, changing seasonality and competition. This suggests climate processes in Southern Hemisphere mid-latitudes during MIS 11 is fundamentally different to other Late Quaternary interglacials.

Stable isotopes as tracers for elucidating the origin of siderite in the volcanogenic Lake Inawashiro-ko, Japan

Satish Kumar Madhusoodhan¹, Kyoko S. Kataoka¹, Yoshitaka Nagahashi²

¹Niigata University, Niigata, Japan, ²Fukushima University, Fukushima, Japan

Lake Inawashiro-ko, Fukushima Prefecture, Japan, is the largest volcanogenic freshwater lake in Japan. A 29-m-long core from the lake was studied in order to understand the eruptive impacts onto the lake system which hosts active Adataro and Bandai volcanoes in the upstream of their catchment. The core has 71 subaqueous flow event deposits intercalated in the background hemipelagic sediments mostly associated with volcanic activity of two volcanoes in the past 50,000 years. The present study focuses on event deposits bearing siderite mineral grains in lacustrine environments concerning with volcanic and hydrothermal sediment supply and early diagenesis.

The brown event deposits (Bm/Bs) are concentrated in the stratigraphic interval older than 15 ka. The clay-rich brown deposits are centimeters thick and are characterized by the common presence of organic material and fresh glass shards derived from Bandai volcano, suggesting volcanic density flows generated by subaerial eruptions. The Bm/Bs deposits appear in two colors: 1) brown to brown gray color or 2) olive gray to dark brown gray. Micro-XRF analysis reveals that the dark colored Bm/Bs deposits has high Fe₂O₃(total iron) and MnO contents. Microscopic observation and XRD analysis show the presence of siderite in the deposits. SEM images clarified that some siderite grains overgrow fresh glass shards indicating post-depositional precipitation of siderite *in situ*. The yellow event deposits (Ys) occur in the lower part of the core sequence, i.e. >29 ka in age. The thinly layered deposits, appearing in a few millimeters to 2 cm thick, are massive and semi-consolidated by cementation. The deposit has very high content of Fe₂O₃(mean value ~32 wt%) and high MnO contents as well (2.9%). XRD results and SEM images indicate the preponderance of highly crystalline siderite grains and coherent crystal growth, implying a post-depositional formation of siderite. Incidentally, sulfur-rich gray event deposits (Gm/Gs) derived from Adataro volcano do not contain siderite.

Carbon and oxygen isotopes of siderite were analyzed for the siderite-bearing layers and the results show distinct difference between the siderite in the Bm/Bs deposits and Ys deposits. The Ys siderite has a positive $\delta^{13}\text{C}_{\text{PDB}}$ values (up to 10 ‰), whereas Bm/Bs deposits have a lower values of between -1 and +7 ‰. The $\delta^{18}\text{O}_{\text{PDB}}$ values are also different between the two deposits with Bm/Bs siderites showing negative $\delta^{18}\text{O}_{\text{PDB}}$ values when compared to Ys samples. We interpret these differences in carbon and oxygen isotopes due to a difference in primary source of carbon such as entrainment of terrestrial organic materials, volcanic gas, and hydrothermal fluids, and the interplay of siderite formative process of sulfate reduction and methanogenesis. A detailed evaluation of siderite genesis in a volcanogenic lacustrine environment of Lake Inawashiro-ko will be presented.

P-4501

Multi proxy records of dynamic climate changes during the Last Interglacial in Central and Eastern Europe basing on speleothems studies.

Jacek Pawlak, Helena Hercman, Marcin Błaszczuk

INSTITUTE of GEOLOGICAL SCIENCES, POLISH ACADEMY of SCIENCES, Warsaw, Poland

During quaternary period, the Earth's climate has been dominated by ice age cyclicality. Long cold periods (glacials) have been interrupted by shorter and warmer intervals, known as interglacials. The duration of the last interglacial (LIG) has conventionally been set at 129 - 116 ka. Recent research shows, that the LIG climate was more unstable in comparison to Holocene; this instability has been caused by changes in the dynamic of the North Atlantic Meridional Overturning Circulation. However the full understanding of the LIG climate mechanisms is still difficult.

The lack of suitable dating techniques and precisely defined absolute age benchmarks like: dated tephra layers or magnetic excursions, is one of the problems for present LIG studies. Therefore many of LIG chronologies base on indirect dating techniques like record alignment strategies. In this context, speleothems are valuable paleoclimate archives because of their capability to be dated by U-series method. In Europe LIG speleothem records are known mostly from western part of the continent. We present four new stable isotopic records of LIG age, from speleothems located in central and south-eastern Europe. This region is especially interesting for LIG climate studies because of the possible influences of Atlantic circulation, the Mediterranean Sea and the monsoonal system over the East Mediterranean and Levant regions.

Three from presented stalagmites come from Tatra Mountains (Poland), one from Low Tatra Mountains (Slovakia) and one from Ruse region (Bulgaria). The stalagmites from Tatra Mountains and Low Tatra Mountains represents the period of time between ca. 180 and 90 ka. Stalagmite from Bulgaria records the period of time ca. 129 –112ka.

All stalagmites were analyzed petrographically in terms of their micro fabric. The geochemical analyses include the stable isotopic composition of calcite and trace elements content. All stalagmites (except the part of Bulgarian stalagmite not included in research) are built from clean calcite with low porosity. The time scales were constructed by MOD-AGE software basing on obtained U-series ages. All analyzed geochemical proxies point to dynamic changes in the environment during the at the time of interglacial development (129-126.5 ka), the beginning of last interglacial optimum is connected with a rapid change to more humid and warm conditions. During interglacial demise local climate become more dependent on regional settings.

As a result of our studies, we are going to present the synthetic comparison of speleothem stable isotopic records from different regions of Europe and Middle East in a terms of local differences and their changes during the whole LIG period. Finally we will compare the speleothem proxies with other regional and global proxies.

P-4502

Variations in carbon isotope ratios of plants across a temperature gradient and their relevance to paleovegetation reconstruction

Jiazhu LI¹, Guoan WANG²

¹Institution of Desertification Studies, Chinese Academy of Forestry, Beijing, China, ²College of Resources and Environmental Sciences, China Agricultural University, Beijing, China

Carbon isotope values ($\delta^{13}\text{C}$) of plants reflect the balance between photosynthesis and stomatal conductance and vary with environmental conditions. Temperature is an important influential factor for plant $\delta^{13}\text{C}$; however, variations of plant $\delta^{13}\text{C}$ across temperature gradients have yet to be quantified. This impedes interpretation of variability of $\delta^{13}\text{C}$ in ancient terrestrial organic matter and reconstructions of paleoclimate and paleoecology. In this study, the effect of temperature on $\delta^{13}\text{C}$ of C3 and C4 plants was assessed by comprehensive investigation of a large number of species (118 C3 plants and 17 C4 plants) from 29 sites across a temperature gradient along the 400mm mean annual precipitation isoline in north China. After deducting the effects of precipitation on plant $\delta^{13}\text{C}$, a strong positive relationship is found between $\delta^{13}\text{C}$ values of C3 plants averaged for each site and mean annual temperature, with a coefficient of 0.104‰/°C; however, no significant correlation is found for C4 plants. Based on this results, we conduct a sample reconstruction of paleovegetation of the central Chinese Loess Plateau and demonstrate that, to a certain extent, our paleovegetation reconstruction is affected by temperature corrections.

P-4503

Spatial change of precipitation during the Paleocene-Eocene Thermal Maximum in East Asia

Zuoling Chen¹, Xinxin Dong², Xu Wang¹, Zihua Tang¹, Shiling Yang¹, Min Zhu³, Zhongli Ding¹

¹Institute of Geology and Geophysics, CAS, Beijing, China, ²Bureau of General Affairs, Chinese Academy of Sciences, Beijing, China, ³School of History, Beijing Normal University, Beijing, China

The Paleocene-Eocene Thermal Maximum (PETM) was a transient greenhouse climate interval associated with a huge release of carbon to the ocean-atmosphere system ~56 million years ago. The estimated input amount of carbon during the PETM is comparable in magnitude to that which could occur over the coming centuries, it thus provides a geological case study for the effect of rapid global warming on regional hydroclimate. Here we calculated carbon isotope fractionations (Δ) of C₃ plants across the PETM in the Fushun and Nanyang Basin of China. The Δ values show significant increase at both basins (Nanyang Basin: 1.5‰; Fushun Basin: 3‰) but with greater magnitude in the Fushun Basin during the PETM. The general increase and marked spatial difference in Δ values are explained as a response to regional precipitation. Using the relation between mean annual precipitation and the Δ values of living C₃ plants, the mean annual precipitation at both sites was quantitatively estimated. The result suggested that East Asian continent generally became more humid with relatively more precipitation occurring at higher latitudes in response to the PETM warming. Our results support the prediction that continuous anthropogenic warming will lead to a wetter climate in East Asia with relatively more precipitation in higher-latitude lands.

P-4504

Spatiotemporal changes in C₄ plant abundance in China since the Last Glacial Maximum and their driving factors

Wenqi Jiang^{1,2}, Haibin Wu^{1,2,3}, Qin Li^{1,4}, Yating Lin^{1,2}, Yanyan Yu^{1,3}

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ²University of Chinese Academy of Sciences, Beijing, China, ³CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ⁴CAS Center for Excellence in Tibetan Plateau Earth Sciences, Beijing, China

Knowledge of changes in the distribution of C₃ and C₄ plants in relation to climate change is the key to predicting the biosphere's response to future climatic warming. There are significant differences in the spatiotemporal evolution of C₄ plant abundance at different latitudes since the Last Glacial Maximum (LGM), and the factors responsible remain debated. In this study, we reconstructed the spatiotemporal pattern of C₄ plants in China since the LGM, based on a synthesis of $\delta^{13}\text{C}$ records of soil organic matter from paleosol sequences and $\delta^{13}\text{C}$ records of individual n-alkanes from lake and marine sediments. The results indicate that, spatially, maximum C₄ abundance during the LGM was in South China; while maximum C₄ abundance occurred in the Chinese Loess Plateau in North China during the early and mid-Holocene. Temporally, in North China, C₄ plant abundance initially increased since the LGM, reached a maximum during the early and mid-Holocene and then decreased; however, the opposite trend occurred in South China. Combined with a physiological-process model used to study the sensitivity of C₃ and C₄ plants to changes in climate and atmospheric $p\text{CO}_2$ in different regions, our results reveal that temperature was the dominant factor driving C₄ plant expansion in North China, whereas atmospheric $p\text{CO}_2$ and precipitation were the main factors controlling C₄ plant abundance in South China.

P-4505

Revisiting Lake Garba Guracha in the Bale Mountains, Ethiopia – rationale, chronology, geochemistry, and paleoclimate implications

Lucas Bittner¹, Graciela Gil-Romera^{2,3}, David Grady², Marcel Bliedtner⁴, Bruk Lemma¹, Henry Lamb², Bruno Glaser¹, Sönke Szidat⁵, Gary Salazar⁵, Michael Zech^{1,6}

¹Soil Biogeochemistry, Martin-Luther-Universität Halle-Wittenberg, Halle (Saale), Germany, ²Department of Geography and Earth Sciences, Aberystwyth University, , Aberystwyth, United Kingdom, ³Pyrenean Institute of Ecology, CSIC, Zaragoza, Spain, ⁴Department of Physical Geography, Institute of Geography, Jena, Germany, ⁵Department of Chemistry and Biochemistry & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ⁶Institute of Geography, TU Dresden, Dresden, Germany

Our knowledge about East African paleoclimate history is largely based on marine cores and paleolimnological studies. Accordingly, more humid climatic conditions such as the African Humid Period (AHP) are usually associated with summer insolation-driven increased monsoonal precipitation.

In order to contribute to the paleoclimate reconstruction of the Bale Mountains, Ethiopia, within the DFG Research Unit 2358 'The Mountain Exile Hypothesis: How humans benefited from and re-shaped African high-altitude ecosystems during Quaternary climate changes' we revisited Lake Garba Guracha, a continuous and high altitude (3950 m asl) lacustrine archive (e.g. Umer et al., 2007; Tiercelin et al., 2008). Basal calibrated radiocarbon bulk sediment ages of around 16 cal. ka BP from the bottom-most sediments are in contradiction to cosmogenic nuclide dating results of moraine boulders at lower altitude in the research area and especially in the same valley (around 14 ka) documenting landscape stabilization following glacial retreat. We therefore propose that old carbon accumulated in the basal sediments during glacial retreat. By contrast, a robust chronology could be established for the Late Glacial and Holocene sediment cores based on radiocarbon dating of bulk sedimentary organic matter, charcoal, and *n*-alkane biomarkers.

Results from organic geochemical and XRF analyses document that minerogenic input dominated during the Late Glacial and organic matter input increased considerably only from 11 cal. ka BP on. We also investigated sugar and lipid biomarkers as well as their compound-specific stable oxygen and hydrogen isotopic composition ($\delta^{18}\text{O}_{\text{sugar}}$ and $\delta^2\text{H}_{n\text{-alkane}}$) to infer past hydrological patterns. Most negative $\delta^{18}\text{O}_{\text{sugar}}$ and $\delta^2\text{H}_{n\text{-alkane}}$ values characterize a maximum moisture availability concurring with the African Humid Period during the Early Holocene. The $\delta^2\text{H}_{n\text{-alkane}}$ record is interpreted to reflect paleo leaf water, whereas the $\delta^{18}\text{O}_{\text{sugar}}$ record is interpreted to reflect paleo lake water. The coupling of $\delta^2\text{H}_{\text{alkane}}$ with $\delta^{18}\text{O}_{\text{sugar}}$ allows the establishment of a deuterium excess record (cf. Zech et al., 2013) that can be interpreted in terms of lake water evaporation. We thus have evidence that a perennial lake overflow occurred from about 10 to 8 cal. ka BP, whereas during the period before and afterwards (from about 8 to 5 cal. ka BP) the lake experienced at least seasonal evaporation.

P-4506

Ice cores and isotopic climate emulation to reconstruct the Last Interglacial Greenland Ice Sheet

Irene Malmierca-Vallet^{1,2}, Louise Sime¹, Dario Domingo³, Emilie Capron¹, Jochen Voss³

¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Bristol, Bristol, United Kingdom, ³University of Leeds, Leeds, United Kingdom

The Greenland Ice Sheet (GIS) contribution to the Last Interglacial (LIG) sea level high stand is uncertain. Published studies show wide range of LIG ice loss estimates, varying from 0.3 to 5.5 meters of sea level equivalent. Here we propose to combine, for the first time, a compilation of stable water isotopic ($\delta^{18}\text{O}$) information from Greenland deep ice cores with isotopic climate emulation to provide new constraints on GIS ice volume and configuration changes during the LIG. Greenland ice records show that between present-day and the LIG climatic optimum, there was a rise in $\delta^{18}\text{O}$ of at least 2.5‰.

Isotopic LIG climate simulations are performed with a wide range of GIS morphologies. The outputs from the isotope-enabled climate model (HadCM3) are used to build an emulator of the response of $\delta^{18}\text{O}$ to all possible changes in the shape and extent of the GIS at 125ka. By applying this rather novel emulation technique, we show that strong ice loss occurred over southern Greenland, possibly resulting in a two dome structure, with a small remnant dome covering the south of Greenland and a larger one in the north. We also demonstrate the sensitivity of the solution to DYE3 ice core data. This shows where the most valuable ice core data lies in order to reduce uncertainties on GIS ice volume change estimates during the LIG.

P-4507

Speleothem record from the Swiss Alps highlights Last Interglacial climate variability

Paul Wilcox¹, Christoph Spötl¹, Charlotte Honiat¹, Lawrence Edwards²

¹University of Innsbruck, Innsbruck, Austria, ²University of Minnesota, Minneapolis, USA

The Last Interglacial (LIG), ~130,000 to 115,000 yr BP, is an important time period in recent Earth history, when temperatures were warmer and sea level was higher than present. Examining the climate and vegetation during the LIG in the Alps will provide invaluable feedback on the current warming trend in this region which is twice as large as the mean of the Northern Hemisphere. However, only a handful of studies have been published on the LIG so far, with discrepancies in the fine-scale structure, highlighting the need for replication. A new speleothem from Neotectonic Cave in Melchsee-Frutt (Switzerland), which opens at 1727 m a.s.l., covers almost the entire LIG at high resolution (~9 yr resolution). The $\delta^{18}\text{O}$ record shows an initial warming at 130,150 yr BP. This warming trend is interrupted by a hiatus between 129,200 and 127,000 yr BP, possibly suggesting flooding of the cave passage. After the hiatus, an early optimum is identified between 126,700 and 125,700 yr BP. Significant isotopic variability exists at the end of the optimum at 125,700 yr BP, suggesting abrupt swings in climate and vegetation. Slight cooling occurs at 124,500 yr BP, followed by stable conditions until 118,100 yr BP. Deteriorating climate is observed after 118,100 yr BP, with a sharp increase in $\delta^{13}\text{C}$ suggesting a decrease in soil bioproductivity; however, the $\delta^{18}\text{O}$ decrease (suggesting cooler temperatures) is more subdued.

P-4508

The early Marine Isotope Stage 5 record of IODP Site U1390, Gulf of Cadiz (NE Atlantic)

Antje H. L. Voelker^{1,2}, Andreia Rebotim^{1,2}, Henning Kuhnert³

¹IPMA, Div. Geologia e Georecursos Marinhos, Lisbon, Portugal, ²Center of Marine Research (CCMAR), Faro, Portugal,

³MARUM, Univ. Bremen, Bremen, Germany

During Integrated Ocean Drilling Program (IODP) Expedition 339 – Mediterranean Outflow IODP Site U1390 (36°19.11'N, 7°43.08'W, 992 m water depth) was drilled into sediments of the central middle slope of the Gulf of Cadiz. While its open water location allows to monitor changes in the subtropical surface waters advected into the Gulf of Cadiz by the Azores Current, bottom conditions are dominated by the presence –as nowadays– or absence of the Mediterranean Outflow Water (MOW). IODP Site U1390 exhibits extremely high sedimentation rates of 75 cm/ky during the late Pleistocene and we made use of this to generate centennial-scale climate records for surface and intermediate-depth water conditions during Marine Isotope Stage (MIS) 4 to MIS 6. Here we focus on the interval covering the glacial/interglacial transition from MIS 6 into MIS 5e (Eemian) and subsequently the interglacial demise and onset of glacial conditions during MIS 5d. Surface-water conditions are reconstructed using the stable isotope records of planktonic foraminifer species *G. ruber* white and *G. bulloides*, whereas conditions in the intermediate depth water column, i.e. in the MOW level, are reflected in the benthic foraminifer stable isotope data. In addition, the mean grain size of the bulk fraction <63µm, the weight percent of the sand fraction >63µm and the XRF-derived ln(Zr/Al) data reveal variations in bottom current strength with maxima in all three proxy records indicating a stronger current, namely the MOW, and the formation of a contourite layer.

The planktonic foraminifer stable isotope records show high-frequency oscillations throughout the whole interval, including the interglacial interval. In addition, the *G. bulloides* oxygen isotope record clearly reflects marine impressions of Greenland interstadials 25 and 24. During the interglacial period, the current strength related proxy records indicate a sluggish bottom flow – a phenomenon that is linked to the formation of sapropel 5 in the Mediterranean Sea and subsequent changes in the outflow. The very negative benthic carbon isotope values, contemporary with the low current speed, point to Antarctic Intermediate Water replacing MOW during this period in the intermediate depth of the central Gulf of Cadiz. On the other hand, maxima in bottom flow strength, together with relative high benthic carbon isotope values, during the terminal cold event of the glacial/interglacial transition, during the glacial inception and during stadial MIS 5d indicate the presence of the MOW. The Site U1390 records therefore reflect millennial-to-centennial scale hydrographic changes in the surface to intermediate depth waters in the Gulf of Cadiz.

Study funded by FCT (Portugal) through projects MOWCADYN and CCMAR.

Implications of mid-Holocene and Last Interglacial changes in insolation seasonality on high and mid-latitude climate

Bette L. Otto-Bliesner¹, Pascale Braconnot²

¹National Center for Atmospheric Research, Boulder, USA, ²IPSL/LSCE, Laboratoire mixte CEA-CNRS-UVSQ, Gif sur Yvette Cedex, France

The mid-Holocene (MH), 6000 years BP, and the Last Interglacial (LIG), 127,000 years BP, are key reference periods for the 4th phase of the Paleoclimate Modeling intercomparison Project (PMIP4, Kageyama et al., 2018; Otto-Bliesner et al., 2017), and will contribute to the overall understanding of the response of the climate system to external forcing as part of CMIP6. These two interglacial periods are characterized by enhanced (reduced) seasonality of the incoming solar radiation at the top of the atmosphere in the northern hemisphere (southern hemisphere). In the annual mean, larger obliquity also increases solar radiation in high latitudes and decreases it in the tropics. Trace gas atmospheric concentrations are similar to pre-industrial values.

We will present the new sets of available simulations with the aim to characterize the differences in snow and ice feedbacks in high latitudes resulting from differences in the magnitude of the changes in seasonality between the two periods. The impact of this feedback on polar amplification will be investigated. Also both periods are characterized by enhanced monsoons in the tropical regions. These first analyses will investigate how monsoon seasonality is related to the characteristics of the solar forcing and to feedbacks from ocean circulation and land surface properties. For both periods, model results can be analyzed in the light of available paleoclimate reconstructions. In addition, the mid-Holocene is considered as an entry card for the paleoclimate simulations in CMIP6, because it has been a reference period for PMIP since the first PMIP phase (Joussaume and Taylor, 1995). A comparison with previous MH PMIP simulations will highlight the evolution of model performances in simulating a climate state different from the modern one.

P-4510

A study of Late Quaternary benthic foraminiferal assemblages from Kongsfjordhallet, (North-West Svalbard)

Debolina Chatterjee¹, Anupam Ghosh¹, Helena Alexanderson²

¹Jadavpur University, Kolkata, India, ²Lund University, Sölvegatan, Sweden

The Quaternary environment of the Arctic varied profoundly due to glacial-interglacial cycles in the last 200 ky and this variation created a large impact on the arrangement of hydrographic and biological systems of that region. Though there are uncertainties in older glaciations, the Late Quaternary glacial extent and deglaciation record of the North West Svalbard (High Arctic) sector of the Svalbard-Barents Sea ice sheet has been well documented (e.g. Alexanderson *et al.* 2018). The Kongsfjorden area contains key locations for the present understanding of the two last glacial cycles (MIS 6 to present); such as Kongsfjordhallet where five major glacial advances during the last 200 ky have been identified (Alexanderson *et al.* 2018). These glacial advances are separated by interglacial or interstadial intervals characterized mainly by glaciomarine mud and littoral sands containing abundant microfossils and molluscan shells. The application of benthic foraminifera can be a key proxy for assessment of the past hydrological conditions that prevailed during those interglacial or interstadial events and can be correlated with other proxy records, e.g. sedimentological data, and with radiocarbon and OSL dating.

Three fine grained units (Unit-1, Unit-4 and Unit-8b) from the upper part of sedimentary succession at Kongsfjordhallet (Alexanderson *et al.* 2018) have been investigated. These units, being deposited in high relative sea level during deglaciations, are significant in the stratigraphy of Kongsfjordhallet; They are indicative of preceding large scale glaciations and their fossil content makes them suitable for paleoceanographic reconstructions. Sediments from these three units have been collected, processed and sorted in the laboratory for identification, abundance, diversity and facies interpretation from benthic foraminiferal assemblages. The uppermost Unit 8b correlated with post Last Glacial Maximum (17 ky) shows low to moderate number of total calcareous benthic foraminifera specimens; Unit 4, representing the last Interglacial (MIS 5e-Eemian), shows well where as Unit 1, indicative of Early Saalian Glaciation (Early MIS 6), shows abundant total number of benthic foraminifera specimens with dominance of *Cassidulina reniforme*, *Islandiella norcrossi*, *Elphidium excavatum*, *Haynesina orbiculare* and *Nonionella labradorica*. The assemblages of Unit 8b and Unit 4 from Kongsfjordhallet represent glacial intermediate, inner shelf environment where as Unit 1 represent glacial proximal inner shelf environment with a seasonally open connection to the ocean.

The study of foraminiferal assemblages from Kongsfjordhallet together with lithostratigraphy and OSL dates will help to delineate past environment change within and between interglacials and interstadials.

Refining Last Interglacial biostratigraphies: A novel palynological record from the Swiss North Alpine Foreland Basin

Patrick Schläfli^{1,2,3}, Erika Gobet², Willy Tinner^{2,3}, Jacqueline van Leeuwen², Elisa Vescovi², Guilhem Douillet¹, Michael Schwenk¹, Dimitri Bandou¹, Fritz Schlunegger¹

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland, ²Institute of Plant Sciences, University of Bern, Bern, Switzerland, ³Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland

The Last Interglacial (Eemian, c. 130 ka) has been a major focus of recent research efforts because its warmer-than-today conditions offer unique possibilities to assess vegetational responses to a warmer climate in the future. Nevertheless, the biostratigraphic position and the plant succession during the Eemian have not been fully deciphered and characterized yet. In fact, the numerous palynological records from the Swiss North Alpine Foreland Basin (Welten 1982, 1988; Wegmüller 1992) are all lacking well-constrained independent internal chronologies. It is the major scope of this project to improve the characterization and the temporal calibration of Eemian biostratigraphic records. To address this scope, we plan to perform a high-resolution investigation of a novel palynological record from Spiezberg, Switzerland, coupled with independent dating techniques (²³⁰Th/U and luminescence dating). The planned analyses would represent a major scientific advance in Quaternary biostratigraphy, as they would, for the first time, generate independent internal chronologies of Eemian pollen records from the North Alpine Foreland Basin. In addition, refining and chronologically constraining the Eemian biostratigraphies with state-of-the-art approaches will allow better foundations for biostratigraphic comparisons of European pollen archives.

Transient simulations of the last and penultimate deglaciations using MIROC AOGCM

Takashi Obase¹, Ayako Abe-Ouchi^{1,2}

¹Atmosphere and Ocean Research Institute, the University of Tokyo, Kashiwa, Japan, ²Japan Agency for Marine-Earth Science and Technology, Yokohama, Japan

The last deglaciation (~21-9 thousand years before present) is the transition from the last glacial maximum to the present interglacial, as well as the penultimate deglaciation (~138-128 ka) is from the penultimate glacial maximum to the Last Interglacial (LIG, ~129-116 ka). The Last Interglacial was characterized with warmer surface temperature of high-latitude and higher sea level compared to the present interglacial. There were some significant differences in magnitude and temporal evolution of climates between the last two deglaciations. As the response times of climate systems such as ice sheets and deep-ocean circulations are long, the climate states and ice sheets might have been influenced by the gradual changes that occurred during the preceding deglaciations. A working group has been set up as part of the Paleoclimate Modelling Intercomparison Project (PMIP) phase 4 to investigate the responses of the climate systems during deglaciations. The protocols have been proposed to perform transient simulations of the last deglaciation and penultimate deglaciation (Ivanovic et al. 2016; Menviel et al. 2018).

We are conducting transient deglaciation experiments using an atmosphere-ocean coupled general circulation model MIROC4m. The experiments are both realistic simulations following above protocols, and idealized simulations investigating the roles of respective boundary conditions. We will present preliminary results and discuss influences from respective boundary conditions on climate evolution.

P-4513

The UK contribution to paleoclimate modelling for CMIP6/PMIP4: Results from the mid-Holocene & Last Interglacial, and comparison to the preindustrial era

Charles Williams¹, Maria Guarino², Joy Singarayer³, Louise Sime²

¹University of Bristol, Bristol, United Kingdom, ²British Antarctic Survey, Cambridge, United Kingdom, ³University of Reading, Reading, United Kingdom

The use of physically-based tools, such as Global Climate Models (GCMs) or Earth System Models (ESMs), to better understand environmental and climate changes during the geological past (such as the late Quaternary) is a well-established technique. Moreover, the modelling of paleoclimate is regarded as an excellent way to test the GCMs/ESMs currently being used for future climate change projections, by providing an out-of-sample test for the models. By simulating past climates, and comparing these simulations to existing proxy data, the models' ability to reproduce climates that were radically different from our own can be assessed. Due to this, the Paleoclimate Modelling Intercomparison Project (PMIP, now at phase 4) spearheads the paleoclimate contribution to the current phase of the Coupled Model Intercomparison Project (CMIP6).

In preparation for the forthcoming IPCC Assessment Report (AR6), PMIP4 is coordinating the modelling of 5 separate time periods: the Last Millennium (past1000), the Last Glacial Maximum (LGM), the mid-Pliocene Warm Period (midPliocene), the mid-Holocene (MH) and the Last Interglacial (LIG). Concerning the UK contribution to these 5 experiments, using the UK Met Office's most recent GCM (HadGEM3.1), the MH and LIG have now been completed, and the others are currently underway or imminently about to start. Some of these will be repeated in the near future using the UK Met Office's most recent ESM (UKESM1).

Here, we will present preliminary results from the MH and LIG simulations (~6kya and ~127kya, respectively), grouped together as they both represent, in very general terms, a warmer world with greater seasonal temperature variations in the Northern Hemisphere, primarily due to changes in the Earth's orbital configuration. Both of these will be compared to the preindustrial control simulation (piControl), concerning firstly their spin-up runs (to test whether the simulations have reached acceptable equilibrium) and secondly their production runs (to test, via model-data comparisons, whether the simulations are correctly reproducing the expected climate during these periods).

P-4514

An Antarctic ice core as a potential global boundary stratotype section and point (GSSP) for the Upper Pleistocene Subseries

Martin Head

Brock University, St. Catharines, Canada

The Upper/Late Pleistocene Subseries/Subepoch has yet to be defined formally. The term was in use during the Second International Conference of the Association pour l'étude du Quaternaire européen (a precursor of the International Quaternary Association [INQUA] and its congresses) in Leningrad in 1932, and later employed in a formal sense in English in 1935. The Upper Neopleistocene in the Russian scheme is an exact equivalent. During the Leningrad Conference in 1932, it was decided that the base of the Upper Pleistocene should coincide with that of the last interglacial (the Eemian regional Stage in Europe), and at the 12th INQUA Congress in Ottawa in 1987, a proposal was approved to use the base of MIS 5 (termination II) to define the boundary. Two sections have been suggested as possible candidates for a Global Boundary Stratotype Section and Point (GSSP): the Fronte section, Taranto, Italy and an Antarctic ice core. The Fronte Section has yielded an excellent last interglacial marine record, although Termination II marking the base of MIS 5 is apparently not preserved. A proposal submitted in 2008 based on a non-marine to marginal marine succession in the Amsterdam Terminal borehole failed to achieve ratification. Although the pollen record in this borehole clearly marks the base of the Eemian Stage, it is now known that the base of MIS 5 is about 6 kyr older than the base of the Eemian pollen stage. Leads and lags in the climate-ocean system challenge efforts to define the base of the Upper Pleistocene, with isotope stratigraphy giving Atlantic over Pacific leads of several thousand years for the past six terminations, and North Atlantic high-latitude temperatures lagging southern hemisphere records likewise by several thousand years. Given these limitations, an Antarctic ice core should be considered for the GSSP, with the abrupt methane rise seen in ice cores at Termination II potentially serving as the primary guide to the boundary. This methane rise is a distinctive global event closely related to rising temperatures in the higher northern latitudes. To provide a more recent comparison, methane lagged temperature rise by less than 30–70 years for the last glacial interval in Greenland, and its abrupt increase during Termination II in Antarctica is thought to reflect essentially synchronous abrupt warming of the air above Greenland. Termination II has a gas orbital age of 132.4 ka at its midpoint, with a subsequent steep methane increase at 128.51 ± 1.72 ka in the EPICA Dome C core that leads the onset of the Eemian in southern Europe by ~2 kyr. Although an ice core is an unconventional choice for a GSSP, the Lower and Middle Holocene subseries GSSPs are both defined in Greenland ice cores.

P-4515

Last Interglacial temperature changes from the North Atlantic to the Southern Ocean based on a coherent and precise chronological framework

Lucie Bazin¹, Aline Govin¹, Emilie Capron², Catherine Kissel¹, Sébastien Nomade¹, Claire Waelbroeck¹, Elisabeth Michel¹, Franck Bassinot¹, Amaelle Landais¹

¹LSCE, Gif-sur-Yvette, France, ²CIC, Niels Bohr Institute, Copenhagen, Denmark

The Last Interglacial (LIG, ~129-116 ka) is a key period to decipher the interactions between the different components of the climate system under warmer-than- preindustrial conditions. Modelling the LIG climate is now part of the CMIP6/PMIP4 targeted simulations. As a result, recent efforts have been made to propose surface temperature compilations focusing on the spatio-temporal evolution of the LIG climate, and not only on its peak warmth as previously proposed. However, the major limitation of these compilations remains in the climatic alignment of records (e.g. temperature, foraminiferal $\delta^{18}\text{O}$) that is performed to define the sites' chronologies. Such methods prevent the proper discussion of phase relationship between the different sites.

Thanks to recent developments we propose for the first time a global compilation of LIG temperature changes based on a coherent and precise chronological framework using key absolutely dated tephra layers from the Mediterranean region and the alignment of independently dated paleomagnetic variations of reference sites within the different ocean basins.

Based on this chronological framework, we discuss the sequence of events of surface temperature changes during the LIG that will serve as reference for future model- data comparison of the up-coming CMIP6/PMIP4 LIG simulations.

P-4516

Speleothem record from western Germany suggests a relatively late timing (124-114 ka) of the Last Interglacial in Central Europe

Denis Scholz¹, Dirk Hoffmann², Christoph Spötl³, Peter Hopcroft⁴, Henning Bauch⁵, Detlev Richter⁶

¹Institute for Geosciences, University of Mainz, Mainz, Germany, ²Max Planck Institute for Evolutionary Anthropology, Department of Human Evolution, Leipzig, Germany, ³Institute of Geology, University of Innsbruck, Innsbruck, Austria, ⁴School of Geography, Earth & Environmental Sciences, University of Birmingham, Birmingham, United Kingdom, ⁵GEOMAR, Kiel, Germany, ⁶Ruhr-Universität Bochum, Institute for Geology, Mineralogy and Geophysics, Bochum, Germany

We present high-resolution $\delta^{18}\text{O}$, $\delta^{13}\text{C}$ and trace element profiles for three stalagmites from western Germany, which grew during Marine Isotope Stage (MIS) 5. All stalagmites were precisely dated by MC-ICPMS $^{230}\text{Th}/\text{U}$ -dating. Stalagmite HBSH-1 from Hüttenbläuserschachthöhle grew between 130 and 80 ka and provides a climate record with decadal to centennial resolution. The other two stalagmites grew faster than HBSH 1, but their growth phases are shorter. Stalagmite HBSH 5 grew between 129 and 122 ka, whereas stalagmite BR 5 grew between 126 and 122 ka.

The record of HBSH 1 shows four growth interruptions coinciding with Greenland Stadials (GS) 21, 22, 24, 25, and 26. This shows that growth of this stalagmite is a very sensitive proxy for cool and dry conditions in the North Atlantic realm and enables us to precisely determine the timing and duration of the GS.

We interpret stalagmite $\delta^{18}\text{O}$ values as a proxy for supra-regional temperature changes in the North Atlantic realm, which is particularly evident from their close resemblance with the $\delta^{18}\text{O}$ values of the NGRIP and NEEM ice core records. Stalagmite $\delta^{13}\text{C}$ values primarily reflect changes in hydrological balance and vegetation density and are, thus, interpreted as a proxy for terrestrial climate in central Europe. The $\delta^{13}\text{C}$ record shows three pronounced negative peaks during MIS 5, and their timing is in agreement with MIS 5e, 5c and 5a. This suggests generally warm and humid climate in central Europe during these phases.

Interestingly, the evolution of the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values during the Last Interglacial (MIS 5e) is not parallel. The $\delta^{18}\text{O}$ values progressively increase from 130 ka, peak at 125 ka and subsequently show a gradual decrease. The $\delta^{13}\text{C}$ values, in contrast, start to decrease at 124 ka, show a negative peak at 120 ka and an abrupt increase at 114 ka. This suggests a decoupled evolution of temperature, precipitation and vegetation density in Central Europe and that the Eemian sensu strictu lasted from 124 to 114 ka. This is in agreement with a marine record from the Norwegian Sea and indicates a strong influence on central European climate from high northern latitudes.

Climate modelling simulations performed with the general circulation model HadCM3 confirm the decoupled evolution of temperature and precipitation in Europe during the Last Interglacial and suggest a strong influence of atmospheric circulation.

P-4517

The Past and Future of Antarctic Sea Ice: The Last Interglacial

Louise Sime, [Louise Sime](#)

British Antarctic Survey, Cambridge, United Kingdom

According to the most recent IPCC report, sea ice is expected to decline in both the Southern and Northern Hemispheres in the future. In particular, current climate models predict a reduction of the Antarctic sea ice of about 50–60% by the next two centuries.

Recent modelling and paleoclimate reconstruction studies indicate a substantial (up to 50-60%) retreat of the Southern Hemisphere (SH) sea ice during the Last Interglacial (LIG) period, between 130 000 and 116 000 years Before Present (BP).

Because there has not been a recent retreat event in the Southern Hemisphere to constrain climate models, the analogy between the Last Interglacial and the projected sea ice retreat events offers a unique opportunity to improve our understanding of what drives a (major) sea ice retreat.

We propose to test a set of hypotheses on the causes of the LIG sea ice retreat. To do so, we set up a CMIP6-PMIP4 last interglacial experiment (lig127k) using the global coupled HadGEM3-GC3.1 model. This experiment has now run for 200 model-years.

The lig127k experiment is designed to address how the Earth system responds to the stronger orbital forcing that occurred 127 ka, compared to today. Here we present our preliminary results on the climate response to the last interglacial orbital forcing. We investigate the role of the radiative forcing in causing a reduction of SH sea ice by analysing Sea Ice Concentration, SST, Surface Air Temperature and other climate variables. We compare the LIG both against reference CMIP6 preindustrial and historical simulations, and against observations.

We find that time series of annual mean sea ice area during the LIG shows a negative trend. However, the decline is small. We suggest that radiative forcing alone is unlikely to explain the major LIG sea ice retreat event. Additional sensitivity tests to test the effects of a weakened AMOC (because of the concomitant melting of the Greenland Ice Sheet) and the consequences of a collapse of the West Antarctic Ice Sheet on the atmospheric and oceanic circulation are thus in the process of being set up. The lig127k experiment will be the reference simulation against which these additional sensitivity experiments will be examined.

P-4518

Grain size and magnetic properties of Loess in the southeastern margin of the Chinese Loess Plateau and their paleoclimate implications

Qu CHEN, Lidong ZHU, Wei YE
Zhejiang Normal University, Jinhua, China

The mechanism of magnetic susceptibility enhancement of loess deposits has long been debated. Though pedogenetic enhancement model was regarded to be dominant, in the fringe areas of the Chinese loess plateau it was indicated that the relationship between pedogenetic intensity and susceptibility were more complicated. Detailed studies in the fringe areas can help shed insight on paleoclimatic evolutions and eolian deposition. Systematic grain size and rock magnetism measurements were made on loess samples from two typical sections in the Southeastern margin of the Chinese Loess Plateau. The results show that: [1] the <5 μm fraction and 30-50 μm fraction of loess samples from the southeastern margin of the Loess Plateau increased from bottom to top of the sections, while the magnetic susceptibility exhibited a reverse upwards weakening trend, which was in line with the Quaternary globe change. In contrast, for loess deposits which are distributed in the northwestern margin of the loess plateau and close to arid source areas, the susceptibility demonstrates an up-section increasing trend. It was indicated that original eolian input did not play a significant role in magnetic enhancement in the southeast margin as in the northwest margin of the loess plateau. [2] The paleoclimatic evolution since the last interglacial recorded by the studied sections are consistent with previous reports in east Asia monsoon areas and Greenland Ice Core records. Paleoclimatic variations in MIS5 and MIS4 could be traced and correlated to other geological records. Compared to other proxies, frequency-dependent susceptibility was more sensitive to paleoclimatic changes. For MIS3, the frequency-dependent susceptibility variations in one of the studied sections can be correlated to the grain size variations of the Huining Section in the northwest of the Chinese loess Plateau. [3] Holocene paleoclimate constructed using rock magnetic proxies and grain size demonstrated a step-like cooling trend and can be correlated to the grain size variations in the loess from the northwest of the Chinese loess Plateau. [4] On the whole, pedogenetic enhancement dominated in the loess-paleosol sequences. Significant magnetic enhancement could be frequently observed, which could be attributed to local eolian input and was probably relative to the watercourse changes of Yellow river. Low magnetic intensity corresponding to fine grain size might result from waterlogging or excessive moistening conditions. It is suggested that the southeastern margin of the Chinese loess plateau experienced a generally cooling Quaternary paleoclimate. The mechanism of magnetic variation was more complicated and therefore the magnetic signals have to be studied carefully before they are used to trace paleoclimatic changes.

P-4519

Upper ocean temperatures and productivity in the Ross Sea from MIS 5 to the Holocene: Biomarker results from IODP-Site-U1524

Gema Martínez Méndez¹, Juliane Müller^{1,2}, Expedition 374 participants³

¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²MARUM, Reserach Faculty, University of Bremen, Bremen, Germany, ³International Ocean Discovery Program, College Station, USA

Marine based ice sheets are very vulnerable to warming. Understanding the past dynamics of sea ice and ocean temperature in the Antarctic continental margin, particularly during the last interglacial, a period considered as an analog of the coming warmer global climate, will help elucidate the near future evolution of the vulnerable West Antarctic Ice Sheet.

Long sediment sequences from five sites were retrieved during the International Ocean Discovery Program (IODP) Expedition 374 on the Ross Sea continental shelf and slope with a targeted aim of investigating past warm climates.

This work focusses on biomarker analyses of sediments collected at IODP Site U1524 (74°13.05'S, 173°37.98'W, 2394 m water depth) covering the last interglacial to the present. Located on the continental slope of the Ross Sea, Site U1524 is sensitive to advances and retreats of the sea ice edge and changes in the Antarctic Slope Current and Antarctic Bottom Water formation. We present preliminary highly branched isoprenoid (HBI), phytosterol and glycerol dialkyl glycerol tetraether (GDGT) data that will provide for estimates of past (ice algae) productivity and ocean temperature changes. These records will contribute to the understanding of mechanisms related to ocean-atmosphere heat and gas exchange, bottom water formation and polar amplification.

P-4520

Last Interglacial marine molluscan assemblages from Uruguay: palaeoenvironmental reconstruction in mid latitudes of the southwestern Atlantic

Alejandra Rojas

Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay

Quaternary marine fossiliferous beds from Uruguay preserve relevant information for the reconstruction of the biotic, palaeoecological and palaeoenvironmental conditions of the Southwestern Atlantic Ocean during the last thousands of years. Three molluscan assemblages originated in the Late Pleistocene are recorded in emerged deposits in Puerto de Nueva Palmira, Zagarzazú (boundary between the Río Uruguay and the Río de la Plata estuary) and La Coronilla (northeastern Atlantic coast) localities. A recent systematic sampling effort of these deposits allowed to increase their molluscan species diversity and to make new palaeoenvironmental inferences through the palaeoecological analysis of the recorded taxa. We identified 132 molluscan species (4 polyplacophorans, 65 bivalves and 63 gastropods), increasing by 40% the previously known richness of the Late Pleistocene deposits. The three assemblages included a majority of marine molluscan species, so an intense influence of marine waters from the southwestern Atlantic reached the nowadays Río de la Plata estuary and even the current Río Uruguay mouth. However, in the western assemblages, the high abundance of typical euryhaline species and the record of two estuarine taxa, may indicate fluctuating salinity conditions on this coastal sector today dominated by freshwater. Soft substrate taxa were the most abundant in the Late Pleistocene assemblages. Dead shells are inferred to have provided the bottom for the settlement of hard substrate taxa in the La Coronilla assemblage. Regarding the biogeographic origin of the molluscan species of the deposits, it is noticeable the almost absence of cold water species that today reach the Uruguayan coast due to the cold Malvinas (Falkland) Current and the high representation of tropical-subtropical species influenced by the warm Brazilian Current. More than 40 species were warm-water extralimitals, with current southern Atlantic endpoints of distribution located on the Brazilian coast. These pieces of evidence indicate that the recorded molluscan assemblages had settled in the Uruguayan coast during a time interval of higher sea level and warmer temperatures than today, such as the Last Interglacial or MIS 5e (about 130 ky BP), a time lapse when similar faunal migrations occurred around the world. However, the palaeoenvironmental signal contrasts with the numerical dating obtained for the fossiliferous beds. The minimum radiocarbon ages for the three assemblages (about 30-35 ky BP) and the OSL ages (about 80-88 ky BP) yielded by the Puerto de Nueva Palmira and Zagarzazú deposits provide conflicting results with the environmental evidence yielded by the molluscs. Besides considering the molluscan deposits as corresponding to the Last Interglacial, it should be further evaluated if the western assemblages may have been deposited during a younger MIS 5 substage as suggested by the OSL results. This is a contribution to PEDECIBA-Biología, PEDECIBA-Geociencias, CSIC and ANII.

P-4521

A comparison of interglacial episodes from Crevice Cave, Missouri in the North American midcontinent

Jeffrey Dorale

Dept. of Earth & Environmental Sciences, Univ. of Iowa, Iowa City, USA

The well-dated speleothem record from Crevice Cave, Missouri (37°45'N, 89°50'W) now covers nearly 400,000 years and provides critical paleoclimate information for a highly underrepresented area throughout much of this time. The record captures paleoclimate information through various proxies, including stable isotopes, flood laminae, growth onset and cessation, and breakage (possibly by earthquakes). A brief consideration of the entire MIS 5 through MIS 1 sequence in the speleothem record helps put the interglacial episodes in perspective. Speleothem deposition was abundant during most of the last interglacial/glacial cycle from MIS 5 through MIS 2, even somewhat during the last glacial maximum, but slowed and ceased during the late glacial, from approximately 17-12 ka, suggesting uniquely cold/dry conditions during that time. Growth resumed during the early Holocene. The record documents a large transition in climate around 55 ka, from overall warmer to cooler conditions and including all the millennial-scale frequency variation seen in the Greenland ice core record superimposed on the larger trends. One of the most unique periods is early MIS 4, from 74 to 72 ka, a time when global ice buildup was occurring rapidly, yet conditions at Crevice Cave were distinctly non-cold; and according to proposed correlations with nearby lake sediments containing insightful paleoecological evidence, were distinctly "interglacial" in character.

A comparison between MIS 5e and the Holocene reveals some distinct differences between these two classic interglacial periods. Whereas widespread paleoecological sites from the Upper Midwest shows ubiquitous evidence for a distinct "prairie period" between forested intervals during the Holocene, the Lower Midwest, as represented by Crevice Cave, indicates nearly unchanging, savanna-like vegetation during the last 8,000 years. In contrast, the MIS 5e record contains a distinct prairie period between forested intervals, precisely occurring between 128 and 125 ka, and plausibly related to a peak in summer insolation. Finally, the flood laminae record reveals that the Holocene is unique in the last 400,000 years in its frequency of large flood events. The most active period of flooding in the last 400,000 years was from 900 to 600 years ago.

P-4522

Magnetostratigraphic dating of the Shixia red sediments and implications for formation of Nihewan paleo-lake, North China

Ping Liu¹, Huafeng Qin², Shihu Li², Baoyin Yuan², Chenglong Deng², Rixiang Zhu²

¹University of Chinese Academy of Sciences, Beijing, China, ²Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

The sedimentary sequence in Nihewan Basin, northern China, is rich in mammalian fossils and Paleolithic sites. Extensive magnetostratigraphic investigations have been carried out in the Nihewan sediments, but precise age control on the earliest Nihewan red sediments, which have a fluvio-lacustrine origin in the upper part and an eolian origin in the lower part, has remained unavailable. The formation process of Nihewan paleo-lake, therefore, remains unclear. Here we contribute to understanding the age of the early Nihewan reworked and eolian red clays by presenting detailed magnetostratigraphic and rock magnetic results from the Shixia section coupled with geochemical and petrographic analyses. Magnetite and hematite are the main carriers of characteristic remanent magnetizations documented in the Shixia section, eastern Nihewan Basin. Our new magnetostratigraphic results indicate that the underlying eolian red clay in the Shixia section is slightly younger than the Cochiti subchron, that is 4.19 Ma. The main bulk minerals in the studied sediments are quartz, calcite, albite and ferrosilite, with smaller concentrations of albite and clay minerals. REE patterns are characterized by LREE enrichments with relatively flat HREE distributions. A slight negative Eu anomaly also occurs in most of the studied samples. The reworked red clay formation in the Shixia section is one of the sources of the earliest fluvio-lacustrine Nihewan Formation sediments. These results indicate that prior to initiation of Nihewan paleo-lake, the Shixia red clay had an eolian origin in the Nihewan Basin during the Pliocene and was then redeposited as the Nihewan Formation. With tectonic development of a graben basin, early red clay was deposited first in Nihewan Basin during the Early Pliocene before giving way to lacustrine environments in Nihewan paleo-lake. Geochemical and petrographic results indicate a wind-blown origin for the lower red clay deposits, which have been reworked and mixed with conglomerates produced by local tectonic activity to produce the basal Nihewan sediments. Later formation of carbonate nodules has given rise to the sediments that are now exposed in Nihewan Basin.

P-4523

The paleoclimate of Pliocene-Pleistocene transition based on stable isotopes analysis from flowstones profiles in the Javoříčské jeskyně Caves (Czech Republic)

Paula Sierpień¹, Helena Hercman¹, Ivan Horáček², Pavel Bosák³, Petr Pruner³

¹Institute of Geological Sciences, Polish Academy of Sciences, Warsaw, Poland, ²Department of Zoology, Faculty of Natural Sciences, Charles University, Praha, Czech Republic, ³Institute of Geology of the Czech Academy of Sciences, Praha, Czech Republic

Along the corridors of the Javoříčské jeskyně Caves (Central Moravia, Czech Republic) a number of profiles composed of clastic sediments interbedded with speleothems have been observed. Two profiles were selected for the study. The first (JV) is located around 10 m from the cave entrance. The second one (JC) is located in the central part of the cave (around 600 m from cave entry). The thickness of the speleothem profiles is about 150 cm and 230 cm, respectively. Paleomagnetic results combined with zoopaleontology (small mammals) indicate the age of sediment deposition from ca 3.6 to 1.77 Ma ago.

Isotopic records of oxygen and carbon preserved in speleothems allow reconstructing the isotopic composition of the water from which speleothem crystallized, i.e. climatic conditions incl. the amount of the rainfall or temperature in the area of the cave.

Stable isotopic composition analyses of flowstones were performed in the Institute of Geology PAS (Warsaw, Poland). The value of $\delta^{18}\text{O}$ changes within the range of ca 3 ‰ (from -3.96 to -7.06 ‰) for JV profile. The range of the carbon isotopic changes is wider and reaches ca 4 ‰ (the $\delta^{13}\text{C}$ changes from -4.11 to -8.04 ‰). In JC profile the value of $\delta^{18}\text{O}$ changes within the range of ca 2.5 ‰ (from -5.86 to -8.36 ‰). Again, the extent of the carbon isotopic composition changes is wider and reaches ca 5 ‰ (the $\delta^{13}\text{C}$ changes from -5.88 to -10.94 ‰). Obtained isotopic records were correlated with global and regional paleoclimatic data. The analysis resulted in first data concerning Pliocene/Pleistocene transition climatic conditions in the studied area.

P-4524

Climatic changes during the Plio-Pleistocene transition as recorded by the isotopic composition of pedogenic carbonates.

Elisa Beilinson¹, María Sol Raigemborn¹, Numa N. Sosa²

¹Centro de Investigaciones Geológicas (CONICET-UNLP), La Plata, Argentina, ²Facultad de Ciencias Naturales y Museo (UNLP), La Plata, Argentina

Plio-Pleistocene continental deposits in south-eastern Buenos Aires province (Argentina), correspond to fluvio-alluvial deposits interbedded with palaeosols. The Pliocene units show little participation of carbonatic features in their palaeosols, which are classified as Argillisols. The late Pliocene-Pleistocene palaeosols show a much higher participation of pedogenic carbonates and are classified as Calcisols. Could this change from Argillisols to Calcisols be related to the global-scale climatic change during the Plio-Pleistocene boundary?

For the pedogenic carbonates here-by studied, the $\delta^{13}\text{C}$ values range between -9.92 and -5.62‰ and the $\delta^{18}\text{O}$ values range between -4.19 and -2.80‰ . These values are typical for calcretes, and particularly the $\delta^{18}\text{O}$ values indicate formation under the influence of meteoric water. If we consider that soil carbonate $\delta^{13}\text{C}$ values higher than -8‰ are indicative of the presence of C_4 plants, then the obtained $\delta^{13}\text{C}$ curve can be divided into a lower and an upper section, the boundary between both of them suggestively coinciding with the Plio-Pleistocene boundary (Fig. 1). Most of the average $\delta^{13}\text{C}$ values of the lower section are lower than the -8.00‰ $\delta^{13}\text{C}$ threshold, (-9.72 , -9.67 and -8.32‰ PDB), which could be related to a plant community dominated by C_3 vegetation. In contrast, the average $\delta^{13}\text{C}$ values of the upper section are higher than the -8.00‰ $\delta^{13}\text{C}$ threshold (-6.80 , -6.65 , -7.20 , -6.02 , -6.86 , -7.87‰ PDB), which could be related to a plant community dominated by C_4 vegetation.

$\delta^{18}\text{O}$ values can be related to climate, especially to mean annual temperature. For the studied palaeosols, $\delta^{18}\text{O}$ values show little variation (Fig. 1), except for a negative excursion during the late Pliocene, interpreted as a cold event. Although MAT and MAP values for the middle and late Pleistocene are still being analysed, the values for the late Pliocene and lower Pleistocene show a cooling and drying trend, and the abundance of Calcisols suggest the continuance of this trend up to the late Pleistocene. When comparing the $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, MAT and MAP curves, positive and negative excursions of all 4 values coincide among them (Fig. 1) and also with well-known climatic events in the region: till deposits in Patagonia of $\sim 3,5$ Ma and $\sim 1,8$ Ma and the Middle Pliocene Climatic Optimum between 3,3 - 3 Ma.

In summary, for the Pampean Region, climatic conditions changed since the Pliocene from warm and humid to more cold, dry and seasonal. This change is reflected in the transition from Pliocene Argillisols to Pleistocene Calcisols and in the plant community, which changed from C_3 -dominated to C_4 -dominated, in accordance to worldwide records.

Figure 1. Schematic sedimentological profile of the studied units. $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, MAT and MAP curves and their suggested correlation with regional climatic events.

P-4525

Palynological implication for paleoenvironments of the Eastern South Korea Plateau (ESKP), East Sea during the Plio-Pleistocene climate transition

Yongmi Kim^{1,2}, Sangheon Yi², Gil-Young Kim², Eunmi Lee²

¹Korea University of Science and Technology (UST), Daejeon, Korea, Republic of, ²Korea Institute of Geoscience and Mineral Resources (KIGAM), Daejeon, Korea, Republic of

A terrestrial and marine palynomorph analysis from the IODP Exp. 346 Site U1430 was carried out to reconstruct the paleoenvironments during the late Pliocene to early Pleistocene climate transition period. East Sea is controlled by climatic and oceanographic conditions, especially East Asian monsoon (EAM) and Tsushima Warm Current (TWC), respectively. Site U1430 provides a good opportunity to monitor paleoclimate and oceanographic changes caused by intensity of EAM and TWC. According to results of the palynofloral analysis, two pollen and dinocyst zones are established with a boundary at ca. 3.0 Ma. Prior to ca. 3.0 Ma (P-I, D-I), long-term oscillation of the East-Asian winter monsoon (EAWM) is suggested by fluctuations in the abundance of pollen taxa, representing cold-dry and cool-wet climates. After ca. 3.0 Ma (P-II, D-II), an increase in cold-dry conifer pollen indicates an enhanced and stable EAWM. In addition, the xerophytic herb, *Artemisia* dramatically increases markedly in P-II, suggesting open grassland on the exposed South Yellow Sea shelf during the sea level lowstand in cold-dry climate conditions. *Artemisia* pollen are interpreted to have been delivered to the coast through paleo-channels in this grassland environment, and subsequently transported to the East Sea inflow of a weak Tsushima Warm Current (TWC) through the narrow Korea Strait. The TWC intrusion signal is represented by an influx of *Tuberculodinium vancampoeae*, a warm-water dinoflagellate species, in the western Pacific region. The High abundances of cold-dry conifer pollen and cold-water dinocyst elements after ca. 2.8 Ma suggest an intensified EAWM. Meanwhile, a short-term increase in moisture-loving *Tsuga* pollen after ca. 2.5 Ma was likely due to soil moisture derived from snowfall caused by evaporation of heated seawater from the weak TWC in the East Sea under cold climate conditions.

Evidence of the middle Pliocene climate changes on the southeastern Tibetan Plateau caused by the development of Northern Hemisphere glaciation

Chunxia Zhang^{1,2,3}, Shihu Li⁴, Xiaoyan Zhang^{1,5}, Chenglong Deng^{4,5}, Pei Li^{1,5}, Haibin Wu^{1,2,5}, Zhengtang Guo^{1,2,5}, Rixiang Zhu^{4,5}

¹Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ²CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ³College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, China, ⁴State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, ⁵University of Chinese Academy of Sciences, Beijing, China

Late Miocene to Pliocene was a period that the global environmental pattern has been greatly changed, including the development and spread of C₄ grasses, the aridification of the interiors of continents and the development and evolution of the Asian monsoon climate. Intensive studies have been carried out to reconstruct the history of the Asian Monsoon system. However, the evolution of the Asian Monsoon system, especially, the South Asian monsoon, on geological time has been highly debated. The records of the South Asian monsoon evolution during the late Miocene to Pliocene are mainly from marine sediments of Arabian Sea and fluvial sediments of Siwalik Group in the South part of Himalaya, which resulted in that the South Asian monsoon intensity variation characteristics and driving factors remain controversial.

To obtain a better understanding of the South Asian monsoon evolution history during the late Miocene to Pliocene, we present sedimentary, mineralogy, geochemical and palynological proxies from a late Miocene-Pleistocene sedimentary sequence (~6.0-1.0 Ma) from the Dasongping section in Dali Basin on the southeast margin of the Tibetan Plateau. Multiple proxies indicate changes of sedimentary facies from swamp/shore lake facies to fluvial and alluvial facies with a clear two-stage climate change. During ~6.0-3.3 Ma (Unit I), the enrichment of quartz, illite, kaolinite content, stronger degree of chemical weathering and warm mixed forest (WAMF) or temperate deciduous forest (TEDE) suggest relatively warm and humid climate conditions. During ~3.3-1.0 Ma (Unit II), the increase of smectite, vermiculite, calcite and dolomite content, weaker degree of chemical weathering than Unit I, and cool mixed forest (COMX) or cool coniferous forest (COCO) suggest relatively cool and dry climate conditions. Comprehensive comparisons among records from marine and continental records demonstrate that the ongoing global cooling with the development of Northern Hemisphere glaciation (NHG) have played a dominant role in the climate changes from warm and humid to cool and dry conditions in Dali Basin since the mid-Pliocene, as well as the progressive aridification during the late Pliocene in East and interior Asia.

Sedimentological and palynological assessment of three wells in eastern Dahomey Basin, southwestern Nigeria. West Africa

Olugbenga BOBOYE¹, Christabel Chidiebere²

¹University of Ibadan, Ibadan, Nigeria, ²Shell Petroleum Development Company(SPDC), Warri, Nigeria

Integrated studies have been carried out on one hundred and eleven (111) ditch samples retrieved from Lagos coastal area of Nigeria. The study aim at determining the provenance, heavy mineral assemblages, establishing the lowstand-highstand Quaternary episodes, deducing the palaeoenvironment and age estimation of the sediments. The lithofacies constitute sandstones and siltstones with thin beds of lignite. The sandstone range from medium to fine grained with the lignite consisting of plant fragment remains. The petrographic results show abundant detrital minerals with average modal composition of quartz (90%), feldspar (2%) and rock fragments (4%). The Quartz-Feldspar-Rock fragments (QFR) ternary plots revealed that the sands are super-matured quartz arenites derived from the continental block under humid climatic setting which have experienced medium transportation history and have been subjected to mechanical and chemical weathering. Heavy mineral assemblages suggest matured sediments. The Zircon-Tourmaline-Rutile (ZTR) index indicates the super maturity of the sediments. The Apatite: Tourmaline (ATi) ratio showed variations within the wells indicating differences in the rate of weathering and period of residence on the flood plain despite similar provenance and fluctuation in ratios suggesting sea level changes. Fifty two (52) species of palynomorphs recovered include *Rhizophora* sp., *Avicennia africana*, *Acrostichum auruem*, *Laevigatosporites* sp., *Combretaceae* sp., *Mitrogynaciliata*, *Sapotaceae* sp., *Disopyros* sp., *Elaeis guineensis* and *Alchronea* sp. The palaeoenvironment of deposition suggest graduation from mangrove to fresh water swamp due to occurrence of *Zonocostites ramonae*, *Acrostichum aureum* and *Avicennia africana*. The abundance of *Podocarpus milianjanus* and *Retitricolporites hians* and the absence of Miocene diagnostic forms suggest Pleistocene age (Tarantian 0.126Ma).

Human settlement and past environmental change on the Comoros, far western Indian Ocean

Simon Haberle^{1,2}, Susan Rule^{1,2}, Georgia Roberts^{2,3}

¹Archaeology and Natural History, College of Asia and the Pacific, Australian National University, Canberra, Australia,

²ARC Centre of Excellence for Australian Biodiversity and Heritage, Australian National University, Canberra, Australia, ³Indigenous Studies Centre, Monash University, Clayton, Australia

As humans have colonized new places, they often initiate dramatic environmental change, even in the distant past. On remote islands, where levels of endemism are high, species and environments are often particularly vulnerable to the effects of introduced species like humans, and the plants and animals they deliberately or accidentally bring with them. The first study of the environmental history of the Comoros, a volcanic archipelago in the far western Indian Ocean, was conducted in 2016 in order to test the hypothesis that the Comoros were stepping stones for prehistoric human migration from east Africa to Madagascar. This research will contribute to our understanding of patterns and chronologies of human colonisation, as well as the environmental impacts that humans have had. The pollen and charcoal records show dramatic changes in vegetation and fire regimes in the last 1500 years that are best explained through the influence of human settlement. Such studies of the past are extremely useful for better understanding and mitigating the effects of human-induced environmental change today.

P-4529

Fossil antelope teeth to reconstruct Plio-Pleistocene environments in eastern and South Africa (3.5 - 0.5 Ma)

Lucile Crété¹, Lauren C. Sewell¹, Gildas Merceron², Jean-Renaud Boisserie^{2,3}, Philip Hopley⁴, Ellen Hambleton¹, John R. Stewart¹, Ross A. Hill¹, Sally C Reynolds¹

¹Bournemouth University, Bournemouth, United Kingdom, ²PALEVOPRIM, UMR 7262 CNRS INEE (Université de Poitiers), Poitiers, France, ³CFEE, USR 3137 CNRS INSHS (Ministry of Europe and Foreign Affairs), Addis Ababa, Ethiopia, ⁴Birkbeck University of London, London, United Kingdom

Antelope remains are abundant in the African fossil record, and have often been used to facilitate palaeoenvironmental reconstructions. The springbok (genus *Antidorcas*) is one of the most abundant, herbivorous, mixed-feeding antelopes, in the South African Plio-Pleistocene fossil record, and is represented in the east African fossil record, where the mixed-feeding impala (genus *Aepyceros*) is also very abundant. Present-day springbok and impala are known to adapt their diets according to the prevailing vegetation conditions. Such a high dietary adaptability can provide interesting data regarding changes in paleovegetation and paleoclimate through time, not least because variations in food intake might reflect potential shifts in vegetation conditions at regional/local scales.

Fossil teeth of impalas (*Aepyceros*) and springboks (*Antidorcas*) from the Turkana Depression (Kenya and Ethiopia) and from the Cradle of Humankind (South Africa) are studied to investigate past changes of vegetal resources and climate conditions between 3.5 Ma and 0.5 Ma. Dental use-wear analysis provides the lifetime (mesowear) and end of life (microwear) dietary signals, supplemented by the early years signal from stable isotope analysis (carbon and oxygen). Further paleoenvironmental conditions, such as precipitation levels (oxygen isotopes) and possibly exogenous grit/dust particles (use-wear) are inferred from use-wear and isotope analysis.

In both regions, there is a great dietary variability among fossil impalas and springboks, reflecting various degrees of mixed-feeding, as expected when considering their modern relatives. Such dietary variability could reflect the presence of a wide range of resources, but could also be due to seasonal differences in food and other habitat resources. An underlying paleoenvironmental trend of increased aridity and open grasslands is apparent with a marked shift around c. 1.7 Ma from the analysis of *Antidorcas* species from the Cradle of Humankind. Around 1.7 Ma, *Antidorcas* dietary changes display high inter- and intraspecific variation, implying increased paleoenvironmental instability and habitat heterogeneity. These behavioural adaptations coincide with climatic changes around 1.7 Ma, such as the onset of the Walker Circulation. However, no significant differences in dietary signals through time were observed among the *Aepyceros* and *Antidorcas* specimens from the Turkana Depression.

The dietary adaptability of these antelope species can help us to understand the habitat structure and seasonality experienced by faunal communities in the Turkana Depression and the Cradle of Humankind between 3.5 Ma and 0.5 Ma, and gain greater insight into how local environments might differ in these two regions due to differential factors such as latitudinal range, as well as climatic and tectonic processes.

P-4530

A 8.5 kyr high-resolution multi-proxy paleoclimate record from lake Voëlvlei, Southern Cape, South Africa

Paul Strobel¹, Torsten Haberzettl², Marcel Bliedtner^{1,3}, Thomas Kasper¹, Julian Struck¹, Matthias Zabel⁴, Roland Mäusbacher¹, Michael E. Meadows^{5,6}, Roland Zech¹

¹Physical Geography, Friedrich-Schiller-University Jena, Jena, Germany, ²Physical Geography, Institute of Geography and Geology, University of Greifswald, Greifswald, Germany, ³Institute of Geography and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, ⁴MARUM – Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany, Bremen, Germany, ⁵Department of Environmental and Geographical Science, University of Cape Town, Rondebosch, Cape Town, South Africa, ⁶School of Geographic Sciences, East China Normal University, Shanghai, China

South Africa is a key region for paleoclimatic studies, because it is affected by both, the Southern Hemisphere temperate Westerlies and the tropical Easterlies. However, due to the scarcity of natural archives, the climatic and environmental evolution of South Africa during the late Quaternary is highly debated. Today, Voëlvlei is an episodic lake that is situated at the junction/interplay of both climate systems near the Southern Cape coast, and thus an ideal archive to investigate past regional environmental changes. A 13 m long sediment core was retrieved from this site and analysed using a multi-proxy approach, including granulometric and elemental analyses, as well as leaf wax *n*-alkanes and their compound-specific $\delta^{13}\text{C}$ isotopic signature. The chronology is based on 16 radiocarbon ages and reveals a basal age of 8,480 $^{+150}_{-240}$ cal BP. Elemental analyses, e.g., Ca/Mg ratios indicate marine influence between 8,480 $^{+150}_{-240}$ and 4,140 $^{+510}_{-490}$ cal BP related to sea levels higher than today. Ever since, Voëlvlei has evolved to a purely lacustrine system without marine influence due to sea level lowering. Between 8,480 $^{+150}_{-240}$ and 8,140 $^{+210}_{-240}$ cal BP enhanced terrestrial input (e.g., high Al, Fe, Si, Ti) suggest enhanced runoff in the catchment of Voëlvlei. Contemporaneously depleted leaf wax $\delta^{13}\text{C}$ values point to overall moist conditions in the area. Afterwards, drier conditions persisted between 8,140 $^{+210}_{-240}$ and 6,900 $^{+220}_{-160}$ cal BP, which are indicated by lower terrestrial input and enriched leaf wax $\delta^{13}\text{C}$ values. From 6,900 $^{+220}_{-160}$ to 4,140 $^{+510}_{-490}$ cal BP, highly variable climatic conditions with several marine and/or terrestrial flooding events occurred at the southern Cape coast.

From 4,140 $^{+510}_{-490}$ cal BP until today, Voëlvlei is a purely lacustrine system without marine influence. Between 4,140 $^{+510}_{-490}$ and 2,580 $^{+360}_{-450}$ cal BP enriched leaf wax $\delta^{13}\text{C}$ values indicate dry climatic conditions at the southern Cape coast. The aridity led to an opening of the landscape becoming highly vulnerable to soil erosion, which resulted in increased input of terrestrial sediments into the lake (elevated Al, Fe, Si, Ti). Since 2,580 $^{+360}_{-450}$ cal BP, depleted leaf wax $\delta^{13}\text{C}$ values point to moister conditions at the southern Cape coast leading to a more stable vegetation cover resulting in lower sedimentation rates and reduced input of terrestrial input. Granulometric parameter indicate two large fluvial flooding events (at 700 $^{+440}_{-480}$ and 10 $^{+50}_{-60}$ cal BP), which deposited large amounts of sediment (~15 cm and ~30 cm).

These findings contribute to a more detailed understanding of paleoenvironmental and –climatic conditions at the southern Cape coast of South Africa. Future leaf wax $\delta^2\text{H}$ analyses will give insights to past changes of moisture sources and atmospheric circulation.

Quaternary Sea Level record in Maio Island (Cape Verde): Preliminary results

Caridad Zazo¹, José L. Goy², Claude Hillaire-Marcel³, Cristino J. Dabrio⁴, Ana Cabero⁵, Angel Gozález-Delgado², Vicente Soler⁶, Javier Lario⁷, Teresa Bardají⁸

¹Museo Nal. CC. Nat., CSIC, Madrid, Spain, ²Universidad de Salamanca, Salamanca, Spain, ³GEOTOP-Univ. du Québec à Montréal, Montréal, Canada, ⁴Universidad Complutense de Madrid, Madrid, Spain, ⁵Escuela Politécnica Nacional, Quito, Ecuador, ⁶Insto. de Productos Naturales y Agrobiología, CSIC, La Laguna (Tenerife), Spain, ⁷Universidad Nacional Educación a Distancia, Madrid, Spain, ⁸Universidad de Alcalá, Alcalá de Henares, Spain

Quaternary geology of Maio Island (Cape Verde) has revealed a quite complete sequence of marine terraces that allows us to reconstruct the history of sea level changes in this island. Geomorphological, isotopic and sedimentological analyses have been carried out supported by paleomagnetic analyses and Th/U - ¹⁴C dating.

The whole sequence is composed of at least 18 marine terraces, developed from +80m to 0m in a staircase or offlap disposition.

Palaeomagnetic measurements have been carried out in order to identify the Early to Middle Pleistocene transition in a sequence located between +80-85 and +32 m asl.

Within the Middle Pleistocene the most widely developed terrace around the island is located at around +6m asl attributed to MIS 11, and a younger terrace located at +4-5m, has yielded ages correlatable to MIS9.

MIS5 on its turn is located at low tide sea level or up to few decimeters asl and bsl. This low altitude of sea level for MIS5 is however compatible to the GIA models of Creveling et al. (2017) for low latitude settings.

MIS1 coastal units are widely represented by beachrocks around almost the whole the island, and spit barrier – lagoon systems in the southwestern part of the island, evidencing a higher input of longshore drift in this part.

Macropalaeontological content has been also analyzed as well as the isotopic oxygen signal from calcite shells of *Ostrea*, showing a close relationship between lighter signal and higher biodiversity in those marine terraces related to warmer climate.

The Palaeoecology of the springbok (*Antidorcas*)

Lauren Sewell

Bournemouth University, Poole, United Kingdom

The rich biodiversity of Plio-Pleistocene South Africa offers a wealth of information on the palaeoenvironmental status and changes therein of the landscape and of smaller scale habitats. The majority of research may select a select group within a given assemblage to inform on aspects of the climate, environment or other landscape dynamics. This research takes an in-depth focus on one of the most abundant fossil taxa in Plio-Pleistocene African faunal assemblages: The springbok (genus *Antidorcas*). This approach hopes to eradicate the generalised picture that can be gained from averaging diverse faunal communities and offer the finer scale detail that can be obtained regarding aspects such as likely habitat presence and subtle environmental changes that may be intangible from larger scale studies.

A multi-method approach was used to establish the palaeoecology of this abundant, believed mixed-feeding bovid. Multiple complementary methods establish the dietary breadth and complexity of the genus and of each of the fossil (and extant) species. The method used to identify dental remains taxonomically is presented. Dental measurements were taken to support taxonomic identification of specimens. Further linear measurements were used to establish evolutionary advances within the genus through the Plio-Pleistocene. Dental use-wear (mesowear and dental microwear texture analysis (DMTA)) was conducted to establish the lifetime (mesowear) and last few days-weeks diet of the individuals and species. This information was combined with stable isotope (carbon and oxygen) analysis to establish the early years dietary signal and hydrological (oxygen isotopes) aspects of habitat and dietary preference.

This research established that the extant *Antidorcas marsupialis* is a seasonal, mixed-feeding species, with individuals falling anywhere along the broad dietary spectrum from grazing to browsing. The ancestral *Antidorcas recki* was a predominantly browsing species but interestingly also showed some individuals to have practiced obligate grazing. Fossil species *Antidorcas bondi*, the believed grazing springbok, appears to have practiced seasonal mixed-feeding, with the species displaying only browsing inclinations via DMTA evidence from the early Pleistocene onwards.

This research found little support for the presence of a potential fourth species at the Cradle of Humankind sites, from the assemblages used (primarily, Sterkfontein, Swartkrans and Kromdraai).

Here, the ecology of each of the fossil *Antidorcas* species and of the extant species (and sub-species) is presented, as established via dental evidence from modern and palaeontological South African specimens. *Antidorcas* is found in many important African hominin deposits throughout the Pliocene, Pleistocene and into the Holocene. The detail gained here can help to establish robust palaeoenvironmental indicators for shared landscapes.

Radiocarbon dated oak tree-ring sequence from a submerged 6,000-year-old archaeological site in the Northern Adriatic

Katarina Jerbic¹, Lisa Shindo²

¹Flinders University, Adelaide, Australia, ²Aix Marseille University/CNRS/CCJ, Aix-en-Provence, France

In this paper, authors will try to use a new oak tree-ring sequence set in time with radiocarbon dates, from a submerged archaeological site in Zambratija Bay, Croatia, as dendroarchaeological evidence for links between environmental and cultural changes that were happening around the Alpine Adriatic during the 6th and 5th millennium BP. Underwater archaeological investigations revealed that the Zambratija site is a pile-dwelling, originally placed over a freshwater environment, and positioned today three metres under the Adriatic Sea. A combination of archaeological evidence and one preliminary radiocarbon date range between 4,230–3,980 calBC implied that human activity occurred there sometime between the Late Neolithic and the Early Bronze Age. The settlement was built on the outer edges of a karstic sinkhole filled with muddy lake and peat sediments, with preserved wooden piles protruding from the seabed, indicating a connection to the then contemporary building tradition around the Alpine glacier lakes. The 20th century discovery of dendrochronological analysis and its accuracy revolutionised not only the research of paleoclimate, but also the absolute chronology of Central European prehistory. As a result, the occupation of pile-dwellings of the Northern Alpine range can be followed back to the Neolithic on a calendrical time scale. Long tree-ring databases in combination with archaeological research can answer further questions, determining the relationships between past environmental changes and the human adaptations to climate events. In 2017, as a part of an archaeological PhD research, a series of interdisciplinary fieldwork activities were performed in Zambratija resulting in 7 seabed sediment cores and 20 waterlogged wood samples, with the aim to test the submerged Late Neolithic/Early Bronze Age pile-dwelling hypothesis. The wooden samples were then analysed in the dendrochronological laboratory at Aix-Marseille University, with results revealing a 62-year-old oak (*Quercus* sp.) tree-ring sequence. Several samples present irregular growth rhythms, with sets of narrow rings. Two wood samples, one from the beginning of the dendrochronological sequence and the other from the end, were then sent for AMS radiocarbon dating. This made it possible to set the sequence in time, where the new dates aligned with the preliminary one. The differences in the chronologies of pile-dwellings in the Northern as opposed to the Southern Alps are due to specific environmental variables in the tree-ring data. This is why the Northern Alpine sequence is continuous, while the Southern one is still developing. With the submerged settlement being positioned on the southern edges of the Alpine Adriatic, the new radiocarbon dated oak tree-ring sequence from Zambratija represents a valuable addition to the growing Southern Alpine dendrochronological database, as well as to the discussion on the intense social networks and material culture exchange of the Central European Middle Holocene.

Growth behavior of fir and pine in response to climate and glacial variability along the altitude in Kashmir Himalaya

Bency David Chinthala¹, Parminder Singh Ranhotra¹, Mayank Shekhar¹, Amalava Bhattacharyya¹, Mohit Phulara², Utsa Singh¹, Rajesh Joshi²

¹Birbal Sahni Institute of Palaeosciences, LUCKNOW, India, ²G. B. Pant National Institute of Himalayan Environment and Sustainable Development, Almora, India

Continuous rise in the global average temperature puts concern on the future growth trend of the treeline tree species in the mountain regions. Himalayas though highly vulnerable to climate change and characterized with variety of treeline structures has remained poorly investigated in terms of treeline response to climate change. Few studies from central and western Himalaya however show complexity in the treeline response, either due to variations in the climate-species interaction or other biotic factors. To understand the impact of climate on the growth behavior of Himalayan conifers we analysed tree ring data of two subalpine conifers, *Abies spectabilis* (Silver fir) and *Pinus wallichiana* (Blue pine) growing at different elevations in the westerly dominant Kashmir region of western Himalaya. Noticeable variability has been observed amongst the lower (~2400 masl) and treeline elevation (3200 to 3500 masl) silver fir and middle elevation (~3200 masl) blue pine in response to climatic and glacier mass balance data. Growth of silver fir though show positive and negative relationships respectively with mean temperatures of winter (JFM) and summer (MJJA) months, but for lower elevation fir, strong negative relation is observed from May to August, compared to July and August for higher elevation fir. For precipitation, summer (AMJJA) months show positive relationship, with lower elevation fir strongly related compared to higher elevation fir. Palmer drought severity index (PDSI), another climate factor, also show strong positive relation with growth of lower elevation fir for summer months (AMJJ). Relatively higher temperature and early melting of snow at the lower elevation could lead to early growth and hence more demand of moisture in summer months. Blue pine, growing on drier south facing slopes, show contrasting positive relationship with mean temperature of summer months (AMJJA). Also strong negative relation with PDSI of both winter and summer months could explain low moisture demand and warm winter and summer months for the growth of pine at the region. With the glacier mass balance data, both fir and pine show negative correlation. More prominent relationship is recorded for higher elevation fir ($r=-0.54$) compared to lower elevation fir trees ($r=-0.33$). Katabatic winds blowing through glaciers significantly regulate the growth of trees at treeline, thus providing sensitive tree-ring sequences comparable to the changing glacial mass balance. Pine is moderately correlated ($r=-0.394$) here. Fir growing at treeline are reported more sensitive compared to pine in responding the climatic changes and glacier dynamics at Kashmir region. Growth of silver fir shows increased trend at treeline but decline at lower elevation. Whereas, pine show increased growth during recent years. More analyses are required to understand the tree growth – climate relationship on spatial and temporal scale from Himalayas.

P-4535

Tree-ring based seven century long snowfall reconstruction from semi-arid Lahaul-Spiti, Himachal Pradesh, India

Krishna G. Misra¹, Vikram Singh¹, Sandhya Misra¹, Akhilesh K. Yadava¹, Ram R. Yadav²

¹Birbal Sahni Institute of Palaeosciences, Lucknow, India, ²wadia institute of Himalayan Geology, Dehradun, India

Over high-altitude semi-arid to arid western Himalaya snowfall variation is incredibly momentous as snowmelt is the only source of water for agrarian economy and its variation severely affects the socioeconomic activities related to hydroelectric projects and tourism. The vegetation in Lahaul-Spiti, Himachal Pradesh is mainly isolated and bushy, but forest of Himalayan cedar is found in pure scattered patches occasionally associated with other conifer species. The tree-ring data of Himalayan cedar generated from network of twelve well replicated moisture-stressed sites, where winter precipitation is the main source for tree-growth. Ring-width chronologies of Himalayan cedar from Lahaul-Spiti, Himachal Pradesh were used to reconstruct snowfall records back to AD 1290 and extend earlier reconstruction around two centuries. The snowfall reconstruction showed annual to decadal scale variations. The reconstruction revealed severe droughts in 18th century and comparable with the low river discharge in the Indus and Satluj, flowing in the winter monsoon dominated areas of the western Himalaya. The reconstructed snowfall showed significant correlation with the precipitation and gridded PDSI data available for the region. The reconstruction is also comparable with winter river flow of Chenab, flowing from semi-arid regions of Lahaul-Spiti. The findings endorse that extended snowfall reconstruction developed from well replicated tree-rings should provide a baseline data for socioeconomic activities in Lahaul-Spiti, Himachal Pradesh in long-term perspective.

P-4536

Tree-ring based drought reconstruction for the western Qilian Mountains of China over the past 1775 years

Yong Zhang¹, Xuemei Shao¹, Zhi-Yong Yin²

¹Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China,

²Environmental and Ocean Sciences, San Diego, USA

Moisture conditions, especially decadal droughts, have profound impacts on society, especially in arid and semi-arid areas. However, the lack of a high-resolution climatic proxy series for the past two thousand years greatly limits our understanding of the variations of droughts and their impacts. Here, we present an 1882 year (181–2015 CE) tree ring width chronology based on Qilian Juniper trees (*Juniperus przewalskii* Kom.) from the western Qilian Mountains, China. The tree-ring index significantly correlated with the May-June self-calibrating Palmer Drought Severity Index (scPDSI) and thus was employed to reconstruct moisture variations in May-June since 241 CE. The reconstruction demonstrated obvious decadal variations of moisture over the past two millennia. The wet periods were 241-259, 286-311, 527-540, 634-640, 797-801, 842-851, 890-895, 966-999, 1091-1094, 1187-1192, 1204-1214, 1233-1244, 1357-1393, 1570-1584, 1612-1622, 1735-1743, 1767-1785, 1801-1813, and 1862-1871 CE; the dry periods were 364-379, 457-497, 508-511, 693-714, 739-764, 902-909, 1007-1011, 1110-1114, 1124-1132, 1146-1155, 1256-1264, 1271-1275, 1455-1465, 1468-1472, 1476-1512, 1670-1681, 1685-1698, 1706-1724, 1823-1829, 1925-1932, and 1952-1971 CE. The driest and wettest periods are the late 5th century and the 3rd century, respectively, while the drought duration in the 17th century is the longest. Comparing tree-ring data and other proxy data across neighbouring records, decadal droughts often have large spatial extents with compound impacts on social activities in ancient times.

P-4537

Oxygen isotopes from Ethiopian tree-rings demonstrate the seasonal migration of the ITCZ

Iain Robertson¹, Marcin Koprowski², Eyob Gebregeorgis², Zewdu Eshetu³, Tommy Wils⁴, Park Williams⁵

¹Swansea University, Swansea, United Kingdom, ²Nicolaus Copernicus University, Torun, Poland, ³Addis Ababa University, Addis Ababa, Ethiopia, ⁴Rotterdam University, Rotterdam, Netherlands, ⁵Columbia University, New York, USA

Reconstructing Ethiopian hydroclimate is complex as precipitation is largely controlled by the seasonal migration of the Intertropical Convergence Zone (ITCZ) with precipitation originating from both the Indian and Atlantic Oceans. Although there is a general scarcity of high-resolution proxy records at these lower latitudes, absolutely-dated tree ring records offer the potential to extend our understanding of hydroclimate into the pre-instrumental era. However, dendrochronology is generally acknowledged as a challenge as aseasonal climate causes the formation of indistinct tree-rings. The adoption of a re-iterative approach supported by radiocarbon dating confirms that *Juniperus procera* growing in the Ethiopian Highlands forms annual rings that can be used as an indirect measure of past climate. The determination of oxygen isotopes from these samples has also enabled inferences to be made about wider atmospheric circulation patterns in the region.

P-4538

Precipitation reconstruction based on tree-ring width over the past 279 years in the northeastern Xiao Hinggan Mountains, northeast China

Mingqi Li¹, Xuemei Shao^{1,2,3}, Zhi-Yong Yin⁴

¹Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China, ²University of Chinese Academy of Sciences, Beijing, China,

³Chinese Academy of Sciences Center for Excellence in Tibetan Plateau Earth System Sciences, Beijing, China,

⁴Department of Environmental and Ocean Sciences, University of San Diego, San Diego, USA

Quantitative Reconstructions can provide a necessary framework to evaluate the realism of high-resolution climate simulations, increasingly used for predictions and impact studies. Precipitation has an important effect on the forest and agriculture in the northeast China. It has a critical significance for forestry management and agriculture production to understand the long-term precipitation regime in this region. This study presents a 279-year precipitation reconstruction for the Xiao Hinggan Mountains, northeast China based on tree-ring width data from 99 tree-ring cores of *Pinus koraiensis* Sieb. et Zucc. from two sample sites. The reconstruction explained 43.9% of the variance in precipitation from the previous October to current June during the calibration period (1956-2017). On the decadal scale, we identified two prominent drought periods during AD 1739-1788 and 1867-1985 and two prominent moist periods during AD 1789-1866 and 1986-2017, and the AD 1986-2017 was a wettest period in the past 279 years. Inter-annual (2-7 year) cycle was detected in our reconstruction, which may be correlated with El Nino-Southern Oscillation.

P-4539

Links between orbital forcing and interannual rainfall variability from a South African speleothem

Philip Hopley¹, Chris Brierley², Graham Weedon³

¹Birkbeck, University of London, London, United Kingdom, ²University College London, London, United Kingdom,

³Met Office, Wallingford, United Kingdom

Our understanding of the interannual variability of African rainfall is limited by short instrumental records and a lack of high-resolution palaeoclimate proxy records. Here we present an annually-resolved 91,000 year Early Pleistocene record of hydroclimate from the early hominin-bearing Makapansgat Valley, South Africa. Novel confocal microscopy methods were used to image and measure annual laminae in the Buffalo Cave Flowstone and the chronology was established via annual-lamina counting, oxygen isotope tie-points and magnetostratigraphy. Changes in annual band thickness are dominated by precession over four consecutive orbital cycles with strong millennial-scale periodicity. The frequency of interannual variability (2.0-6.5 year oscillations) does not change systematically, yet its amplitude is modulated by the orbital forcing. These long-term characteristics of interannual variability are reproduced with transient climate model simulations of water balance for South Africa from the Late Pleistocene to Recent. Based on these results, we suggest that the frequency of interannual variations in tropical net rainfall is likely to be stable under anthropogenic warming, but that the size of year-to-year variations may increase. In addition to the lamina-thickness hydroclimate record, we present a carbon and oxygen isotope record at approximately 20-year sample resolution. Rapid carbon isotope transitions over intervals of approximately 50 years indicate threshold behaviour in the vegetation response to half-precession cycles in hydroclimate. Attempts to model these vegetation responses are underway.

P-4601

Improving chronological control for environmental sequences from the last glacial period

Rebecca Briant¹, Fiona Brock², Beatrice DeMarchi³, Harold Langford¹, Kirsty Penkman⁴, Danielle Schreve⁵, Jean-Luc Schwenninger⁶

¹Birkbeck, University of London, London, United Kingdom, ²Cranfield University, Shrivensham Campus, United Kingdom, ³University of Turin, Turin, Italy, ⁴University of York, York, United Kingdom, ⁵Royal Holloway, University of London, Egham, United Kingdom, ⁶University of Oxford, Oxford, United Kingdom

Recognition of palaeoclimatic instability in the Greenland ice cores has spurred researchers to identify corresponding evidence in other terrestrial records from the last glacial stage. Such evidence is critical for establishing how much environmental stress precipitated Neanderthal and Late Pleistocene megafaunal extinctions, although a need for improved chronology has been consistently highlighted. In formerly glaciated and periglaciated areas of northern Europe, palaeoenvironmental sequences are frequently discontinuous. These often yield high-resolution proxy-based quantitative palaeotemperature estimates but can be hard to date, due to difficulties in removing contamination from biological samples at the limits of the radiocarbon technique (c.30-50kya). Here we demonstrate, for the first time using samples with independent age control, that different radiocarbon pretreatments can generate different age data and that gentler, less effective treatments applied to avoid sample loss may not yield reliable age-estimates. We advocate alternative harsher pretreatment using a strong acid-base-acid protocol. This provides an acceptable balance between contamination removal and excessive sample loss and generates more accurate ages, significantly enhancing our ability to detect and understand the impacts of palaeoclimatic instability in the terrestrial record of the last glacial.

P-4602

Infrared-Radiofluorescence (IR-RF) Dating of loess samples with independent age control from central Alaska

Tobias Lauer^{1,2}, Michel Lamothe¹

¹Département des sciences de la Terre et de l'atmosphère, GEOTOP-UQAM-McGill, Université du Québec à Montréal, Montréal, Canada, ²Max Planck Institute for evolutionary Anthropology, Department of Human Evolution, Leipzig, Germany

Infrared Radiofluorescence (IR RF) dating is a method to determine the last sunlight exposure of feldspar-grains and is suitable to date back several 100 ka. Hence, the dating method is an important alternative to luminescence dating and it is especially relevant to establish chronological frameworks for Middle Pleistocene sediments. Until now, there are still several methodological issues related to IR RF, that need to be solved and only few dating laboratories apply IR RF. To obtain a higher acceptance of the method among dating specialists and Quaternary scientists further investigations are mandatory and it has to be outlined that IR-RF yields resilient chronological results. We here present first results from an ongoing research project testing IR RF on fine-grain samples with independent age control mainly taken from northern American loess-palaeosol sequences (Gold Hill and Halfway House sections, central Alaska). The age of the samples ranges from the Holocene to the Middle Pleistocene. We will present results from dose recovery tests, bleachability- and saturation experiments.

Additionally, the reliability of equivalent dose measurements and age determinations will be discussed.

P-4603

Simultaneous analysis of radiogenic ($^{228}\text{Th}/^{228}\text{Ra}$) and stable isotopes ($\delta^{18}\text{O}$) to validate reliability of the $^{228}\text{Th}/^{228}\text{Ra}$ dating method in coral skeleton

Wuhui Lin^{1,2}, Kefu Yu^{1,2}, Yinghui Wang^{1,2}, Hao Ma³

¹Coral Reef Research Center of China and School of Marine Sciences, Guangxi University, Nanning, China, ²Guangxi Laboratory on the study of Coral Reefs in the South China Sea, Nanning, China, ³Department of Engineering Physics, Tsinghua University, Beijing, China

Isotopes provide significant tools in coral chronology, which play a fundamental role in coral reefs as archives to reconstruct climate change and environmental pollution. In the present study, we exhibited a novel approach of the $^{228}\text{Th}/^{228}\text{Ra}$ dating method in coral chronology. The $^{228}\text{Th}/^{228}\text{Ra}$ disequilibrium was widely observed in modern coral genera with distinct morphologies from the fringing reefs in the coastal ocean to the atoll reefs in the open South China Sea (SCS) using High Purity Germanium (HPGe) γ spectrometry in the ground laboratory and China Jinping Underground Laboratory (CJPL) with the deepest rock overburden in the world. The $^{228}\text{Th}/^{228}\text{Ra}$ dating method was used to estimate the $^{228}\text{Th}/^{228}\text{Ra}$ disequilibrium-derived age based on the assumption of the ingrowth of ^{228}Th from ^{228}Ra in coral skeleton. To validate the $^{228}\text{Th}/^{228}\text{Ra}$ dating method, the radiogenic ($^{228}\text{Th}/^{228}\text{Ra}$) and stable isotopes ($\delta^{18}\text{O}$) were simultaneously measured for the calculation and comparison of the absolute age and relative age in *Porites* coral skeleton. The $^{228}\text{Th}/^{228}\text{Ra}$ disequilibrium-derived absolute age was in agreement with the relative age based on the $\delta^{18}\text{O}$ curve. Additionally, the uncertainty of age was demonstrated to constrain the dating limits of the $^{228}\text{Th}/^{228}\text{Ra}$ dating method in addition to the radionuclide's half-life. Therefore, the $^{228}\text{Th}/^{228}\text{Ra}$ dating method is proposed as a novel approach to obtain absolute age in distinct coral genera with variable morphologies at the time scale of 0-10 a and provides a supplementary to the existing coral chronological toolbox of $^{210}\text{Pb}/^{226}\text{Ra}$, ^{14}C , $^{231}\text{Pa}/^{235}\text{U}$, and $^{230}\text{Th}/^{238}\text{U}$ at the time scale from decades, hundreds to thousands of years.

Fig. 1. Typical time scales of several dating methods based on the radionuclide pairs including $^{228}\text{Th}/^{228}\text{Ra}$, $^{210}\text{Pb}/^{226}\text{Ra}$, ^{14}C , $^{230}\text{Th}/^{238}\text{U}$, and $^{231}\text{Pa}/^{235}\text{U}$ in coral chronology. The length of color rectangles represents the time scales of specific dating methods, which depends on the half-life of the radionuclide as well as the performance of instruments.

P-4604

Isochron-informed Bayesian age modelling for tephtras and cryptotephtras, and application to mid-Holocene Tūhua tephra, New Zealand

David J. Lowe¹, Andrew B.H. Rees², Rewi M. Newnham³, Zoë J. Hazell⁴, Maria J. Gehrels⁵, Dan J. Charman⁶, Matt J. Amesbury^{6,7}

¹School of Science (Earth Sciences), University of Waikato, Private Bag 3105, Hamilton, New Zealand, ² School of Geography, Environment, and Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand, ³School of Geography, Environment, and Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand, ⁴Historic England, Fort Cumberland, Fort Cumberland Road, Portsmouth, United Kingdom, ⁵Environment Department, University of York, York, United Kingdom, ⁶Geography, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom, ⁷ Environmental Change Research Unit (ECRU), Faculty of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland

Tūhua tephra is a distinctive peralkaline rhyolitic eruptive derived from Mayor Island (Tūhua) in the Bay of Plenty ~30 km east of North Island. The tephra, containing common aegirine and compositionally distinctive glass (SiO_2 ~73 wt%, Al_2O_3 ~10 wt%, Na_2O ~6 wt%, K_2O ~4 wt%, FeO_t ~6 wt%), forms a unique chronostratigraphic marker bed for the Holocene of North Island and adjacent marine deposits. Its deposition coincided with the Holocene relative sea-level high-stand ~8100–7200 cal BP when present sea-level was first attained. Deriving an accurate age for Tūhua tephra is a priority for palaeoenvironmental applications as well as volcanology and palaeopedology. Ten dates were obtained previously for the tephra, only one from Mayor Island itself on ‘charcoal logs’ in the base of the pyroclastic flow associated with the Tūhua eruption (7172 ± 393 cal BP) (95.4% probability-range, PR). Bayesian age-modelling of the Kaipō bog sequence in eastern North Island using Bacon (6577 ± 547 cal BP) and OxCal (*P_{sequence}*, 6947 ± 150 cal BP; *Tau_{boundary}*, 7027 ± 170 cal BP, $n=10$) (all 95.4%-PR) generated contradictory, imprecise ages on Tūhua from ~6600–7100 cal BP. Hence we use a new approach to dating Tūhua by applying explicitly a key principle of tephrochronology to Bayesian age modelling: tephtras are erupted and deposited effectively instantaneously forming isochrons so that a primary tephtra or cryptotephtra is identical in age everywhere it occurs. We modelled 54 ¹⁴C-dates, together with ages on nine interbedded tephtras or cryptotephtras in three peat cores from each of Kopouatai and Moanatuatua bogs in the Waikato region, North Island, to attain a new age for Tūhua tephtra, which occurs in all six cores. In applying the Bayesian *P_{sequence}* routine of OxCal, Tūhua tephtra was ‘cross-referenced’ (i.e., set as the same event) in each of the cores, and thus the modelling was ‘isochron informed’. Using SHCal13, the isochron-informed modelling yielded a new age for Tūhua tephtra of 7637 ± 100 cal BP (95.4%-PR), older and more precise than previous estimates. A similar age (~7630 cal BP) was obtained using *P_{sequence}* modelling whereby independent ages on Tūhua were estimated for each core without cross-referencing and then amalgamated using *Combine*. Finally, using independently-modelled age distributions, we defined Tūhua deposition as a ‘Phase’ set between start and end ‘Boundaries’, and then used OxCal’s *Difference* function to estimate the ‘Phase’ duration across cores (it should be zero years based on tephrochronology): it ranged from 0–730 years (95.4% confidence interval), mean 277 years but, reassuringly, was markedly skewed towards zero (i.e., instantaneous). This isochron-informed Bayesian age modelling approach could be readily applied in settings where one or more tephtra or cryptotephtra deposits occur in common with sequences of dates in peats or lake sediments in the same cores.

P-4605

OSL dating of the Late Pleistocene marine deposits in the Bengal Fan

Yan Li¹, Junyi Ge^{2,3,4}, Hao Long⁵, Ke Hu¹

¹School of Ocean Sciences, China University of Geosciences, Beijing, China, ²Key Laboratory of Vertebrate Evolution and Human Origins, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China, ³CAS Center for Excellence in Life and Paleoenvironment, Beijing, China, ⁴University of the Chinese Academy of Sciences, Beijing, China, ⁵State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences (NIGLAS), Nanjing, China

It is of significance to understand the marine sedimentation and the source-to-sink process in the entire terrestrial-marine sedimentary system under the various climate conditions. Approximately 80% of the material eroded from the Himalaya was deposited in the Bay of Bengal, which therefore hosts the most complete record. These sediments thus allow us to investigate the erosion of Himalaya and to reconstruct the accumulation history in the Bengal Fan to trace the paleomonsoon changes. Reliable chronology is required prior to the paleoenvironmental studies for different timescales.

The objective of this study is two-fold; first, we assess the applicability of the OSL dating for the marine deposits in the Bengal Fan. Secondly, we aim to reconstructing the sediments erosion, transportation and the accumulation processes in the Bengal Fan since the Late Pleistocene based on a reliable OSL chronology. The quartz OSL and polymineral post-infrared (IR) IRSL (pIRIR) dating approaches have been used to investigate the luminescence characteristics of the applied signals and to constrain the timing of the marine deposition in the Bengal Fan using thirteen fine-grained (FG; 4-11mm) samples collected from the cores U1454C and U1455D, which were obtained during the International Ocean Discovery Program (IODP) Expedition 354. Prior to the quartz OSL dating, dose recovery test and preheat plateau measurement were firstly conducted to determine the appropriate preheat temperature. The quartz OSL dating was then carried out using the single-aliquot regenerative dose (SAR) protocol. The FG polymineral fraction was measured using the pIRIR protocols with different thermal treatments. The degree of luminescence signal bleaching was assessed by comparing the ages determined by the quartz OSL and polymineral pIRIR dating. The reliability of the luminescence ages was then evaluated by age comparison with the AMS¹⁴C ages in core U1454B after stratigraphic correlation using magnetic susceptibility and sediment reflectance spectrum.

P-4606

How can we date loess older than MIS 3?

Christoph Schmidt, Ulrich Hambach
University of Bayreuth, Bayreuth, Germany

Loess palaeosol sequences (LPS) are important terrestrial archives for environmental changes. Thus, they require accurate chronologies of their formation to take full advantage of the palaeoclimatic information contained and to facilitate interregional and land-sea correlations. During the past decades, optically stimulated luminescence (OSL) dating has evolved as the method of choice for establishing direct chronologies of loess deposition. However, despite reliable ages for loess <50–60 ka, age underestimation has been reported beyond that threshold using the quartz OSL single-aliquot regeneration (SAR) protocol. Recently, it has been claimed that the post-infrared infrared stimulated luminescence (pIRIR) signal from potassium-rich feldspar at elevated measurement temperature (e.g., 290 °C, pIRIR₂₉₀) has sufficient long-term stability to accurately date loess up to MIS 6 or even older. Furthermore, infrared radiofluorescence (IR-RF) of potassium-rich feldspar was also suggested to be devoid of signal loss over time with saturation doses corresponding to an upper dating limit of ~200–400 ka in loess environments. Given the crucial importance of reliable dating tools for Upper and Middle Pleistocene loess records, the question arises as to which of these luminescence methods actually are capable of providing accurate ages for loess >60 ka. In an attempt to obtain age information for a palaeosol supposed to have formed during MIS 5 (based on stratigraphic and pedological considerations) and bracketing loess deposits at three locations in the lower Danube area (Dobrogea, Romania), we compare different dating efforts using a range of measurement protocols. In total, 15 samples from LPS at Vama Veche, Mircea Voda and Urluia were analysed with four different protocols (quartz: OSL-SAR; polyminerals: pIRIR₂₉₀ multiple-aliquot, pIRIR₂₉₀-SAR, IR-RF-SAR).

OSL-SAR ages obtained for silt-sized quartz samples taken from the supposed MIS 5 palaeosol range from 49 to 240 ka and are stratigraphically not always consistent. While the older ages seem to be overestimated, samples from below the palaeosol from Mircea Voda and Vama Veche yield much younger ages than expected (~85 ka). Giving additive laboratory doses on top of the natural dose of polymineral samples does not result in higher pIRIR₂₉₀ signals, so that no meaningful multiple-aliquot additive-dose ages could be calculated. Likewise, the level of the natural pIRIR₂₉₀ signal cannot be reached by multiple-aliquot laboratory regeneration. The more surprising is that the pIRIR₂₉₀-SAR protocol results in finite ages that largely comply with stratigraphic expectations at Mircea Voda and Vama Veche but which are highly scattered and possibly overestimated at Urluia. IR-RF tests on some polymineral silt-sized samples are not entirely conclusive.

We discuss our findings from a methodological viewpoint, and given the difficulties inherent to each of the applied methods, it still appears challenging to routinely date loess older than MIS 3 at our study sites with luminescence methods.

P-4607

Orbital tuning of palaeoclimate chronologies based on the transformation of heat flux to temperature

Anastasiia Gornostaeva, Dmitry Demezhko

Institute of Geophysics of the Urals Branch of RAS, Yekaterinburg, Russian Federation

Today there are a lot of methods for reconstructing past climate changes. Palaeoclimate is evaluated by the analysis of proxies such as tree rings, ice cores, deep-sea cores, pollen data and the others, as well as the direct sources of palaeoclimate information (long-term meteorological records and borehole temperature data). Therein whatever the method of palaeoclimate inversion the improving of timing accuracy of reconstructed palaeoclimate records is of crucial importance.

An accurate time scale is the basis for the correct interpretation of palaeoclimate records. All the existed dating methods have advantages and drawbacks. Orbital tuning is one of the most widely used method for correction of palaeoclimate chronologies (Bender, 2002; Martinson et al., 1987; Shackleton, 2000; Dreyfus et al., 2007). The principle of orbital tuning method is to adjust the time scale of palaeoclimate record to the chronology of insolation changes caused by the variations of Earth's orbital parameters. The main shortcoming of the orbital tuning is the hypothesis of a constant phasing between the external radiation and induced temperature reaction (Peixóto, Oort, 1984; Parrenin et al., 2007; Douglass, Knox, 2012). When comparing the insolation variations with reconstructed palaeotemperature records the existence of time lag between radiation forcing and induced temperature reaction must be taken into account. Current modifications of orbital tuning implement different ways to account for this time lag, however these approaches are predominantly not universal. Corrections are commonly applied only to a given frequencies of a signal or are completely ignored.

We proposed a new approach to orbital tuning based on the synchronization of palaeotemperature chronologies with the quasi-temperature curves obtained using the data on insolation changes. These quasi-temperature curves are calculated based on a simple physical model describing the relationship between the incoming radiation and subsequent ground surface temperature change. Such quasi-temperature curves are represented past temperature variations except for constant factor determined by the climate sensitivity value. The orbital quasi-temperature curves are calculated for a number of latitudes, covering the entire globe, for a period of the last million years. The use of calibration quasi-temperature curves will eliminate the problem of the determining of delay in temperature response to external radiative forcing changes. It will make the procedure of timing of palaeoclimate reconstructions more valid and formalized versus traditional dating methods.

The study was supported by the Russian Foundation for Basic Research (RFBR) – projects № 19-05-00058-a.

P-4608

Chronology of Paleolithic sites in the north Hunan Province of China based on luminescence dating

Jia-Fu Zhang¹, Yi-Yuan Li², Hai-Cheng Lai¹, You-Ping Wang¹, Liping Zhou¹

¹Peking University, Beijing, China, ²Institute of Cultural Relics and Archaeology of Hunan Province, Changsha, China

Recently, several Paleolithic sites have been found and excavated in the north Hunan Province, China, where lots of stone artifacts have been discovered, indicating occupation on the region by hominins. To evaluate the potential archaeological significance of the artifacts from the sites, their accurate ages and the regional chronology of the sites are essential. These sites are located on fluvial terraces, and the archaeological deposits are characterized by the fact that they have been strongly chemically weathered due to temperate climate, resulting in the removal of dateable materials such as organics for radiocarbon dating. It appears that optically stimulated luminescence (OSL) dating method is the only one that can be used for dating these sites since this method utilizes quartz grains as natural dosimeter. This is because quartz grains are resistant to chemical weathering and are almost ubiquitous. In this study, the sediment samples from the Paleolithic sites of Shiligang, Wuyashan and Tiaotougang were investigated and optically dated. The grain-size analyses show that the deposits are mainly composed of fine silt, and the results of X-ray diffraction analysis indicate that feldspar grains almost disappeared due to chemical weathering. Various luminescence techniques were employed on fine-grained quartz and polyminerals. The preliminary results show that the quartz samples have excellent luminescence properties such as fast component and high sensitivity for the single-aliquot regeneration dose (SAR) method. The SAR-OSL D_e values obtained vary from about 90.5 ± 2.2 to 694 ± 54 Gy, and the dose rate from 3.44 ± 0.31 to 4.06 ± 0.36 Gy/ka. Correspondingly, the quartz OSL ages obtained range from about 23.8 ± 2.0 to 202 ± 24.2 ka. The dose-response curves and large D_e values obtained indicates that quartz SAR-OSL signals from samples are close to saturation. It is noted that D_e values in the high dose range of OSL quartz is generally problematic, resulting in underestimation of the true burial ages. In this case, pIRIR and TT-OSL methods and other tests will be carried out on fine quartz and polyminerals to evaluate the reliability of the quartz SAR-OSL ages obtained for these sites, and to attempt to establish the chronology of the sites in this region.

OSL dating in agrarian settings: dealing with post-deposition mixing of sediments

Marijn van der Meij^{1,2}, Tony Reimann¹, Arnaud Temme³, Jakob Wallinga¹, Michael Sommer²

¹Wageningen University and Research, Wageningen, Netherlands, ²Leibniz-Centre for Agricultural Landscape Research, Müncheberg, Germany, ³Kansas State University, Manhattan, USA

Humans triggered or accelerated erosion and deposition processes since prehistoric times through agricultural practices. Optically Stimulated Luminescence (OSL) dating is often used to quantify the phases and rates of these deposition processes, by measuring the last moment grains were exposed to daylight. However, natural and anthropogenic mixing processes, such as bioturbation and tillage, complicate the use of OSL as grains of different ages become mixed, and grains may be exposed to daylight even long after the depositional event of interest. The youngest ages carried by the grains thus represent the stabilization age, indicating when sediments were buried below the active mixing zone, rather than the deposition age.

We present a novel methodology to include tillage effects in OSL dating of colluvial sediments. We took 32 samples from five locations in the colluvial infilling of an agrarian kettle hole in northeastern Germany. We used a Minimum Age Model to select the grains that represent the stabilization ages of the samples. The uncertainty of the stabilization ages was constrained using a Bayesian approach which utilized the stratigraphic order of the samples. These stabilization ages were combined with an archeological reconstruction of historical ploughing regimes to correct for the post-depositional mixing by reconstructing the former soil surface as a function of time of deposition.

Consideration of post-bleaching by tillage is required for correct interpretation of sediment dynamics in colluvial settings. It prevents underestimation of deposition rates during times when a shift in land use occurred, and prevents overestimation of deposition rates near the soil surface. The larger uncertainty in age that originates from the heterogeneous sediments was effectively constrained by the use of Bayesian techniques. Our results show the need for numerical dating techniques that take archeological and soil-geomorphological information into account to correctly interpret landscape dynamics in anthropogenically influenced hilly landscapes.

OSL surface exposure dating of wave-emplaced tsunami and/or storm boulders from Morocco

Dominik Brill¹, Simon Matthias May¹, Nadia Mhammdi², Dennis Wolf¹, Christoph Burow¹, Georgina King³, Helmut Brückner¹

¹Universität zu Köln, Köln, Germany, ²Universite Med V Rabat, Rabat, Morocco, ³University of Lausanne, Lausanne, Switzerland

Fields of wave-emplaced blocks and boulders represent impressive evidence of cyclone and tsunami flooding over Holocene time scales. Unfortunately, their use for coastal hazard assessment is in many cases impeded by the absence of appropriate dating approaches, which are needed to generate robust chronologies. The commonly applied AMS-¹⁴C, U/Th or ESR dating of coral-reef rocks and marine organisms attached to the clasts depends on a – mostly hypothetical – coincidence between the organisms' death and boulder displacement, and inferred event chronologies may be biased by the marine ¹⁴C-reservoir effect and reworked organisms. Here we discuss the potential of the recently developed optically stimulated luminescence (OSL) surface exposure dating technique to directly date the relocation process of wave-emplaced boulders.

For this, we sampled 11 coastal boulders from the Rabat coast, Morocco, which were either relocated by tsunami-induced flooding (e.g. during the 1755 Lisbon tsunami and similar events) or by exceptional North Atlantic winter storms. All sampled boulders (i) show clear indication of overturning during wave transport in the form of downward-facing bio-eroded surfaces; (ii) are composed of sandstones that contain quartz with adequate luminescence signals; (iii) are of Holocene age and, therefore, in the dating range of OSL surface exposure dating. The measured signal-depth profiles indicate time-dependent resetting of luminescence signals in the freshly exposed post-transport surfaces of all investigated boulders.

Calibration samples with known exposure ages of 2 years are used to determine local values for light attenuation in the rock and signal resetting at the rock surface. These parameters are required to transform signal-depth profiles of sampled boulders into exposure ages. Results so far indicate that dating accuracy of most boulders is significantly affected by post-transport erosion of the surfaces. However, the approach nevertheless provides relative age differences for boulder dislocation, and the observed patterns agree with the relative chronology expected due to the macroscopic appearance of the boulder surfaces.

Luminescence isochron dating of glacial sediments using cobbles

Geoffrey A.T. Duller¹, Helen M. Roberts¹, Geraint T.H. Jenkins¹, Richard C. Chiverrell², Xianjiao Ou^{1,3}, Neil F. Glasser¹
¹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom, ²Department of Geography and Planning, School of Environmental Sciences, University of Liverpool, Liverpool, United Kingdom, ³School of Geography and Tourism, Jiaying University, Meizhou, China

Application of luminescence methods to date Quaternary sediments assesses the time elapsed since the last exposure of the mineral grains to daylight. If sediment grains were not exposed to sufficient daylight at deposition to reset ('bleach') the luminescence signal then the ages may be overestimated. This type of incomplete bleaching may occur in a number of depositional environments, but glacial sediments are especially challenging because of the nature of the deposition processes.

In recent years the optically stimulated luminescence (OSL) signal from single grains of quartz has been used successfully to identify whether samples were incompletely bleached or not, and statistical models such as the minimum age model (MAM) developed to allow dating even where only a proportion of the mineral grains had their luminescence signal reset at deposition. The BRITICE-CHRONO project has demonstrated the success of this approach (e.g. Chiverrell et al., 2018). However, this approach has significant drawbacks, the most important of which is that scatter in the apparent ages of individual grains may be caused by a number of factors other than the extent to which they were exposed to daylight at deposition. This may make application of the MAM challenging.

This presentation describes the application of a novel luminescence dating method that allows an unambiguous assessment of whether a sample was exposed to daylight for sufficient period of time at deposition. Large clasts (cobbles and pebbles) are drilled and subsamples from different depths are measured. Light absorption in the clast (Ou et al. 2018) makes it possible to test for the presence of an optical-isochron i.e. where the age does not vary with depth into the clast. The existence of such an isochron is very strong evidence that the luminescence signal was sufficiently reset at deposition to yield an accurate age.

Optical-isochrons have been observed in cobbles from glacial sediments from the retreat of the last British-Irish Ice Sheet at various sites. For example, at Orrisdale on the Isle of Man, three cobbles with optical-isochrons have been dated, yielding ages of 20.8 ± 1.2 ka, 21.2 ± 1.1 ka and 20.6 ± 0.5 ka, giving a combined age of 20.7 ± 0.3 ka demonstrating the precision possible with this technique (Jenkins et al. 2018). The potential of this method, and the challenges that are faced, are discussed in this presentation.

Beyond the border: Infrared Radiofluorescence as a new tool for extending the age range of luminescence dating in palaeoenvironmental research

Thomas Kolb, Markus Fuchs
Justus-Liebig-University, Giessen, Germany

For palaeoenvironmental reconstruction, a wide variety of methods is applied comprising innovative techniques from different scientific disciplines such as sedimentology, micromorphology and mineralogy. However, the informative value derived from such sedimentary archives and their significance for paleoenvironmental research strongly depend on an accurate and precise dating of the investigated sediments. Numerical ages are of fundamental importance for a coherent interpretation of findings based on various investigated proxies. Thus, a reliable local or regional chronology is indispensable for the reconstruction of past environmental conditions.

Triggered by a set of technical and methodological improvements and allowing the determination of sedimentation ages by directly dating the sediments of interest, luminescence dating has become a popular tool in palaeoenvironmental and geoarchaeological research. This is particularly true for the quartz based single aliquot regenerative (SAR) dose protocol, which meanwhile has achieved the status of a well-established standard dating procedure for late Pleistocene and Holocene sediments. A major limitation of quartz-based techniques, however, is the relatively low saturation dose of quartz minerals regularly reported to be in the range of 150-200 Gy corresponding to an upper dating limit of approximately 50-150 ka.

For extending the dating range beyond the border of the last glacial-interglacial-cycle, infrared stimulated luminescence (IRSL) dating of feldspar-dominated samples in principle offers a suitable approach, using the fact that saturation doses of feldspar minerals are usually found to be an order of magnitude higher than those reported for quartz separates. However, feldspar based luminescence measurements have long been known to suffer from a phenomenon called 'anomalous fading', an athermal loss of luminescence signal over time that might result in significant age underestimations and therefore prevented feldspar based IRSL measurements from becoming a routine dating application for Quaternary sediments.

Over the last years, different approaches to cope with the problem of anomalous fading have been suggested, amongst others various fading correction methods and measurement procedures (e.g., post-IR IRSL protocols and pulsed-IRSL measurements) trying to isolate luminescence signals not affected by the fading problem. In this contribution, we would like to draw attention to an alternative approach, originally proposed as 'IR-SAR protocol' during the late 1990s and early 2000s. We will present the basic principles as well as technical and methodological innovations developed during recent time, which led to some kind of revival of the so-called Infrared Radiofluorescence (IR-RF) method. We will illustrate its potential and discuss the still manifold challenges and problems that are associated with this promising dating tool.

Chronology of a late Neolithic site along the coast of the east China sea

Jianhui JIN¹, Zhizhong LI¹, Yunming Huang², Xuechun FAN², Feng JIANG¹, Yan CHENG¹, Zhiyong LING³, Xiuming LIU¹
¹Fujian Normal University, Fuzhou, China, ²Fujian Museum, Fuzhou, China, ³Qinghai institute of salt lake, Chinese Academy of Sciences, Xining, China

Shell mounds are the foremost type of Neolithic sites found in coastal areas of South China. These sites can provide significant information on prehistoric human activity and climate change; however, only a few shell mounds have a systematic chronology in South China. In this study, optically stimulated luminescence (OSL) and ¹⁴C dating techniques were employed to establish a systemic chronological framework for a Neolithic shell mound found at Pingfengshan in the coastal area of Fujian Province, southern China. In addition, the possible reasons for human coastal migrations that took place during this specific period, along with their associations with climate change, are discussed. The results showed that the obtained OSL ages were reliable and consistent with the ¹⁴C chronology. The age of the Pingfengshan site was found to be approximately 4.0–3.3 ka. Additionally, it was found that post-depositional anthropogenic disturbances can have various influences on the resultant OSL and ¹⁴C ages. Cross-validation between different dating methods proved to be of great importance to adequately determine the chronology in archaeological sites. The study revealed that climatic changes played a crucial role in prehistoric human migration during the Huangguashan cultural period (4.3–3.2 ka). Sea level fluctuation may have affected onshore living space and site selection of prehistoric settlements, and intensive winter monsoons may have caused the recession of the Huangguashan culture.

Accelerated luminescence dating: application and assessment of the standardised growth curve approach

Daniela Mueller, Frank Preusser

Institute of Earth and Environmental Sciences, Albert-Ludwigs-University Freiburg, Freiburg i. Br., Germany

Luminescence dating is an important but time-consuming geochronological tool, especially when applied to an extensive number of samples. Samples of old age (i.e. high D_e values) or those requiring a large number of aliquots to be measured for a statistically significant age determination demand prolonged reader times. This is mainly due to irradiation times necessary to create a dose response or growth curve for each measured aliquot as suggested by the commonly applied single-aliquot regenerative dose (SAR) protocol. In order to reduce measurement duration, a protocol that uses a standardised growth curve (SGC) for all aliquots has been proposed. Recent refinement of the SGC protocol (e.g. Li et al. 2015, 2016) along with the release of two R packages (*Luminescence* and *numOSL*) are prospective for the decrease of machine time as well as for the fast analysis of produced data.

In this study, the SGC approach is applied to polymineral, quartz and feldspar samples from proglacial deposits of Northern Switzerland. D_e values are derived for datasets using the SAR and SGC protocols and compared to independent SGC datasets. Dataset size for determination of SGC parameters and grain size dependency as well as the scope of applicability are investigated.

Using violet stimulated luminescence (VSL) to date Quaternary sediments

Debra Colarossi¹, Geoff A.T. Duller², Helen M. Roberts²

¹Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany, ²Aberystwyth University, Aberystwyth, United Kingdom

The violet stimulated luminescence signal (VSL; stimulated at 405 nm) in quartz has been shown to grow to much higher doses than the blue optically stimulated luminescence signal (OSL; stimulated at 470 nm) normally used for dating (Ankjærgaard et al. 2016). This makes VSL an enticing prospect for dating as it has the potential to extend the age range of quartz luminescence throughout the whole Quaternary period. Different measurement protocols have been used for VSL, including the single aliquot regenerative dose (SAR) protocol (Colarossi et al. In press, Porat et al. 2017, Ankjærgaard et al. 2013) and the multiple aliquot additive dose (MAAD) protocol (Ankjærgaard et al. 2016), with mixed results.

The aim of this study is to use the VSL signal with a range of protocols to date samples from multiple sites in South Africa which possess independent age control, in the form of palaeomagnetic analyses, quartz optically stimulated luminescence (OSL) ages and K-feldspar post-infrared infrared stimulated luminescence (post-IR IRSL) ages. Preliminary results for two samples from St Paul's, KwaZulu-Natal showed the ages calculated using the VSL signal to be within uncertainty of the ages obtained using OSL and post-IR IRSL. Although these data represent preliminary measurements, they are encouraging and further investigation into the merits of the single aliquot regeneration added dose (SARA) protocol for the VSL signal is ongoing. These data will improve the understanding of VSL signal characteristics, which is imperative before the broad-scale application of VSL to dating Quaternary sediments can be achieved.

The truth, the whole truth, or incremental adjustments? A reflection on 20 years of applying age-estimates to Pleistocene fluvial deposits

Harold Langford

Department of Geography, Birkbeck University of London, London, United Kingdom

When I started research on the Pleistocene geology of the Peterborough area of eastern England in 1989, ambitions of establishing a robust chronology were severely limited by the techniques then available. New techniques, however, were being developed, such as optically stimulated luminescence (OSL) and amino acid racemization (AAR), that now are able to support robust chronostratigraphical interpretation and bode well for future applications. This presentation reflects on my experience of applying age-estimate techniques to Pleistocene fluvial deposits in the Peterborough area of eastern England. Most applications of age-estimate techniques that I have been associated with relate to the complex sedimentary succession at Whittlesey: AAR established the first UK occurrence of *Theodoxus danubialis* in MIS 7 and verified the first wholly fluvial Ipswichian deposit of the River Nene catchment; OSL established aggradation in MIS 6, MIS 5e, MIS 5b/a and MIS 3; ¹⁴C established aggradation in MIS 3. Plentiful age-estimate data therefore are available for the Whittlesey sedimentary succession but although they establish the chronostratigraphic complexity of the deposit, it is still not possible to provide a robust chronostratigraphy for the succession as a whole. The available data, however, do provide important constraints for River Nene terrace stratigraphy and regional palaeogeographical reconstructions. New OSL and AAR data will be presented together with discussion of the stratigraphic difficulties encountered and those that remain. New AAR age-estimate data for the equally complex Sutton Cross site, within the River Nene catchment and about 15 km upstream of Whittlesey, will also be presented. Potential application of age-estimate techniques to further improve the chronostratigraphy at both sites will be identified and presented, for example the development of OSL dating of opercula and AAR dating of Foraminifera at the Whittlesey site. In my experience provided the technique is robust and its parameters known, and the sedimentary context is well established, age-estimate data will stand the test of time, retaining their relevance as research paradigms wax and wane. As our work at Whittlesey demonstrates, it may take decades but the necessary age-estimate data can be accrued incrementally and produce robust chronostratigraphic interpretation of complex fluvial deposits that in future will constrain fluvial terrace stratigraphy and palaeogeographical reconstructions. Our goal at Whittlesey is to provide a suitably robust long terrestrial Quaternary record that can contribute to regional and global palaeoclimate and palaeosea-level modelling efforts, as well as a testing bed for future development of age-estimate and palaeotemperature reconstruction techniques.

Recently it has been confirmed that extreme solar proton events can lead to significantly increased atmospheric production rates of cosmogenic radionuclides. The evidence of these events can be recorded in annually resolved natural archives, such as tree rings (¹⁴C) and ice cores (¹⁰Be, ³⁶Cl).

Here we show evidence for solar storm events during the past 3000 years based on ¹⁴C data from tree rings and ¹⁰Be & ³⁶Cl data from ice cores. These records allow us not only to investigate and reconstruct the behaviour of the sun with its potential implications for our technological society. They also enable the very precise synchronisation of records where these solar proton events can be identified. For example, this approach has helped to rectify the differences between ice core and tree ring chronologies over the past 2500 years. We will present this method, discuss its potential and limitations and show evidence for a newly discovered solar proton event around 2610 BP.

Through the Looking-Glass, and What Amino Acids Found There

Kirsty Penkman¹, Beatrice Demarchi², Molly Crisp¹, Peter Tomiak³, Marc Dickinson¹, Lucy Wheeler¹, Martina Conti¹, Sheila Taylor¹

¹University of York, York, United Kingdom, ²Universit degli Studi di Torino, Turin, Italy, ³University of Bristol, Bristol, United Kingdom

Chronology underpins our understanding of the past, but beyond the limit of radiocarbon dating (~60 ka), sites become difficult to date. Amino acid geochronology uses the time-dependent breakdown of proteins in biominerals, with the racemisation reactions (conversion between mirror-images) of amino acids having the potential to date the whole of the Quaternary. Recent studies have shown that a very small fraction of 'intra-crystalline' protein within mollusc shells, opercula, coral, eggshell and enamel forms a closed system, and if this is targeted, the difficulties due to leaching, contamination and environmental factors are removed. The analysis of a coherent calcite intra-crystalline system has enabled the development of a chronology back to at least 2.8 Ma, while enamel proteins allow time resolution well into the Pliocene.

Our research is now focusing on building chronological frameworks on a wide spatial and temporal scale, from Europe to Africa, Asia and Australia. Ever expanding the range of materials we are testing, we are also gaining an unprecedented understanding into biomineralisation, and the palaeoenvironmental signal that can be contained within the fossil protein. We present here both the potential and the limitations of the technique.

Radiocarbon dating in lake sediments: assessing the usefulness of very small samples using the Mini Carbon Dating System (MICADAS)

Paul Zander¹, Darrell Kaufman², Martin Grosjean¹, Sönke Szidat³, Maurycy Żarczyński⁴, Anna Poraj-Górska⁴

¹Oeschger Centre for Climate Change Research and Institute of Geography, University of Bern, Bern, Switzerland,

²School of Earth & Sustainability, Northern Arizona University, Flagstaff, USA, ³Oeschger Centre for Climate Change Research and Department of Chemistry and Biochemistry, University of Bern, Bern, Switzerland, ⁴ Faculty of Oceanography and Geography, University of Gdansk, Gdansk, Poland

Radiocarbon dating from plant macrofossils is the most commonly used technique for dating lacustrine sedimentary records that cover Holocene and late-Pleistocene times. Assessing the uncertainty of chronologies based on radiocarbon dates is challenging, in part because researchers must consider not only the analytical uncertainty associated with the measurement of ¹⁴C, but also potential offsets between the age of the dated material and the depositional age of the sediments. The Mini Carbon Dating System (MICADAS) is able to analyze samples in gas form, which allows for dating of very small sample sizes (>10 µg C) that were previously not practical with conventional graphitized samples. Smaller samples and lower costs make it possible to obtain more ages from sedimentary records with limited suitable material for dating, while reducing the time required for sample preparation and analysis. Additionally, the small sample size allows us to target specific types of material rather than mixing fragments of different material.

In this study, we compare the accuracy and precision of radiocarbon ages measured using a gas-ion source with ages measured using conventional graphitized targets. This information is used to investigate optimal strategies for constructing chronologies, in particular, the advantages and disadvantages of measuring more samples at lower precision versus fewer samples at higher precision. Terrestrial plant macrofossils were sampled from a ca. 11,000 year-long sedimentary record from Lake Żabińskie, NE Poland. Samples were measured using both graphitized targets (n=26, all >120 µg C), and the gas-ion source (n=36, 11-168 µg C). We focus on a section from approximately 2,000-6,500 cal yr BP, which contains well-preserved varves that provide an independent age verification. Within this section, we obtained 31 gas-source ages from 13 different stratigraphic levels (i.e. 2-4 individual samples per level); seven of these levels also have a graphite measurement. Gas source samples agree well with the graphitized samples from the same stratigraphic level, though smaller samples do have greater uncertainties. The average uncalibrated uncertainty of all gas-source samples is ±146 years compared to ±62 years for the graphite samples. However, the average uncertainty of gas-source samples larger than 40 µg C is only ±105 years (n=21). Age-depth models using exclusively graphitized and exclusively gas-source measurements were constructed using the software Bacon¹ for the period 2,000-6,500 cal yr BP. The two models differ insignificantly, suggesting neither method is uniquely biased. The average width of the 95% confidence interval of the model outputs are 311 and 357 years for the graphite- and gas-source-based models, respectively, suggesting that the larger uncertainties of the gas-source samples can be somewhat compensated for by greater sample density.

^{10}Be and ^{36}Cl surface exposure dating of man-made excavations in northern Lebanon: Phoenician structures or not?

Gilles Rixhon¹, Clément Flaux², Nicolas Carayon³, Lucy Semaan⁴

¹ENGEES/University of Strasbourg, LIVE UMR 7362, Strasbourg, France, ²CEREGE, Aix-en-Provence, France, ³Ipsos Facto/Archeomed, Marseille, France, ⁴University of Balamand, Department of Archaeology and Museology, Amioûn, Lebanon

The use of terrestrial cosmogenic nuclides as geochronometers has considerably increased over the last two decades owing to major theoretical and analytical progress. Although surface exposure dating still has an unrealized potential in archaeological settings, it can be applied to anthropogenic structures such as flattened bedrock platforms or ancient quarries (Akçar et al., 2009; Rixhon, 2018). In particular, the latter may represent a favourable context for this method, provided that major issues related to (i) erosion (i.e. pristine bedrock surfaces of quarry floor/walls) and (ii) inheritance can be avoided. The second point must be critically assessed given that muon-induced reactions produce cosmogenic nuclides at greater depths (i.e. several meters below the surface).

Two archaeological sites in northern Lebanon were selected for this study: Batroun and Anfeh. Although their excavation structures are well-studied, the so-called “*Phoenician sea-wall*” related to quarrying activity in Batroun and the “*great Phoenician trench*”, i.e. a moat structure excavated in the Anfeh promontory, their age remains unknown. These structures were respectively excavated in Late Pleistocene aeolianite and Eocene limestone. Samples for ^{10}Be (#5) and ^{36}Cl (#4) analysis were collected accordingly. Both sites present favourable characteristics to cope with inheritance: the moat floor is located ~10 m below the original surface whereas the top of the *Phoenician sea-wall* indicates quarrying depths reaching (at least) 4-5 m. Traces of former extracting activities on the quarry floor/walls are still conspicuous at several spots; the latter were preferentially targeted for sampling. Careful field measurements allowed a reliable assessment of topographic shielding, which plays a significant role in Anfeh. Sample preparation is currently under process. Surface exposure ages should be able to discriminate between a Phoenician origin or a latter excavation (e.g. during Middle Ages), without eluding a possible stepwise, polygenetic extraction process (especially in Batroun).

P-4621

Using Flow Cytometry to purify fossil pollen samples suitable for AMS radiocarbon dating

Christoph K. Steinhoff, Nadine Pickarski, Thomas Litt
University of Bonn, Bonn, Germany

Radiocarbon dating of terrestrial plant-remains is a traditional method for age estimations of lake sediments. The absence of sufficient large plant macrofossils required for AMS dating in continental records, especially larger lakes, outlines the limitation of this dating application. Due to their ubiquitous presence in sedimentary archives, especially pollen samples are suitable for radiocarbon dating. Nevertheless, their isolation and purification without significant carbon contamination still presents a challenge. Even though commonly applied separation techniques can be used to remove the predominant portion of foreign particles, the undesired transfer of these particles into the pollen samples cannot be completely excluded, yet. Flow cytometry, a biomedical application to identify and separate molecular cells, offers the possibility to isolate huge quantities of pollen in a short period of time. This application is a highly promising alternative to remove detrital particles and generate pure pollen samples from heterogeneous limnic sediments.

In this study we present the approach to separate sufficient quantities of pollen by flow cytometry for AMS radiocarbon dating. Furthermore, we were able to generate reliable radiocarbon ages of purified pollen samples extracted from Holocene sediment samples from Lake Van (Eastern Anatolia). Nevertheless, visual inspections of the separate pollen populations reveal that an isolation without contamination of foreign particles remains difficult. Here a strong relation between the sediment composition or the sediment's organic matter, the quality of the pollen isolation, and the AMS dating becomes apparent, ameliorating with decreasing detrital content.

Our results demonstrate the importance to further evaluate and optimize the applied processing steps of the chemical pretreatment and flow cytometry. In this process the primary objective is to improve the quality of the separation process and remove large detrital particles from the sediment sample before the cytometric analysis. It is necessary to adjust the processing steps to the pollen concentration and the pollen spectra expected for each individual sample. This allows a precise distinction between pollen and non-pollen palynomorphs. Further improvements of the laboratory routine for the purification of pollen samples using flow cytometry will allow the analysis of vast amounts of samples in a short period of time. In consequence, dating of enriched pollen samples can be used as a robust contribution and independent time control of existing age estimations of lake sediments in continental records.

Reconstruction of the coastal development of SW Sardinia by Optically Stimulated Luminescence (OSL) dating method

Neda Rahimzadeh¹, Manfred Frechen¹, Mauro Coltorti²

¹Geochronology section, Leibniz Institute for Applied Geophysics (LIAG), Hannover, Germany, ²Department of Environment, Earth and Physical Sciences, University of Siena, Siena, Italy

The development of aeolian deposits, such as loess and dunes, strongly depends on climate condition but also on sediment availability. Therefore, these deposits and landforms can provide valuable information about past atmospheric circulation, palaeoclimate, landscape evolution and land use and human impact. Sardinia has been considered tectonically stable, at least since the late Pliocene, and has been used as a reference for changes of mean sea level since the Last Interglacial (Coltorti et al., 2010). Within this generally stable setting, quaternary coastal deposits are very well exposed along the coast of Sardinia. Geomorphological studies and OSL-based dating are excellent tools to reconstruct the timing and formation of coastal dune fields. In this study, we provide the stratigraphy of the well-exposed quaternary deposits cropping out at Su Palloso, Porto Paglia and Capo Mannu, south western coast of Sardinia, based on the Optically Stimulated Luminescence (OSL) dating. In total 10 samples from 3 sections were studied by OSL and radiocarbon dating. The Post-IR POSL ages obtained from the Su Palloso section are in agreement with radiocarbon ages and giving evidence for dune accretion during the Holocene (3-6 ka). Apart from the uppermost ages from the Porto Paglia section, which are much younger (POSL age ~10 ka), all POSL ages of quartz are limited by saturation of the signal intensity towards high doses for the basal part, and therefore pIRIR₂₉₀ dating was applied, indicating sediment deposition during the late Pleistocene (~100 ka). For Capo Mannu section, both quartz and feldspar signals are in saturation. In conclusion, our OSL data do not only answer the question of the quaternary stratigraphy of the south western Sardinia coast, but improve our understanding on the formation of aeolian deposits and identify the roles of sea and climate changes in controlling the sedimentation.

Ice margin chronology of the North American Ice Sheet Complex: new data, new methods, new interpretations

April S. Dalton¹, Martin Margold²

¹Durham University, Durham, United Kingdom, ²Charles University, Prague, Czech Republic

The deglaciation of the North American Ice Sheet Complex (NAISC; consisting of the Laurentide, Cordilleran and Innuitian ice sheets) from its Last Glacial Maximum extent is a critical constraint for studies of sea level, glacial isostasy and Quaternary climate change. Currently, the most commonly cited work on this topic is from 15+ years ago and is based largely on the synthesis and evaluation of radiocarbon data from the glaciated region to infer the emergence of the North American landscape from under glacial cover (Dyke et al., 2003; Dyke, 2004). Over the past 15 years, improvements to geochronology and additional geological work provide the impetus to update and re-examine the NAISC deglaciation chronology. Most importantly, new dating methods (cosmogenic nuclides exposure dating and optically stimulated luminescence) allow for direct dating of the ice margin retreat instead of dating the onset of the deposition of organic material. In 2019, we are beginning a multi-year project to establish a new ice margin chronology that is independent of Dyke et al. (2003). Here, as a first step in this project, we present an updated inventory of deglaciation sites as well as an overview of key updates to the deglaciation sequence, including changes to the extent of glaciation and the timing of its retreat on Baffin and Banks islands in the Canadian Arctic, as well as in the large parts of the continental shelf. We also lay out the plans for future work, which will include a full implementation of all currently available dating methods, a new protocol for quality control of the ages included in the dataset, transparent description of the main local and regional issues and decisions taken regarding the reconstructed ice margin chronology, and the inclusion of error bounds for the individual reconstructed isochrones.

"Deep roots of human behaviour" - ESR dating of archaeological sites near the Victoria Falls, Zambia: first results

Marcus Richter¹, Sumiko Tsukamoto², Lawrence Barham³, Geoff A.T. Duller⁴, Andrew S. Hein⁵

¹Leibniz Institute for Applied Geophysics, Hannover, Germany, ²Leibniz Institute for Applied Geophysics, Hannover, Germany, ³School of Archaeology, Classics and Egyptology, University of Liverpool, Liverpool, United Kingdom, ⁴Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom, ⁵School of Geosciences, University of Edinburgh, Edinburgh, United Kingdom

Recent studies from Kenya suggest that the behavioural development of homo sapiens is closely linked to climate and landscape changes during the Middle Stone Age (MSA) around 300 ka (Potts et al., 2018). One of the behavioural aspects of human evolution during the Stone Age is the use of complex tool-making, and such artefacts can be found throughout the eastern hemisphere, especially in Africa. It is assumed that our ancestor, the homo heidelbergensis, who lived in Africa between 600 and 200 ka, was the first humans to be capable of a modern human behaviour (e.g. complex tool-making). This describes the transition from Early Stone Age (ESA) tool-making of hand axes to MSA tools like flakes or the use of hafting. However, the chronology of the homo heidelbergensis in Africa has been poorly constrained. With the further-developed ESR dating technique on sediments, a better insight in the chronology of stone tool formation is possible. ESR dating has a potential to extend the age range beyond the limits of luminescence dating techniques.

The Victoria Falls and their surroundings have been known to yield rich assembly of artefacts since the 1950s. Traces of early human life can be found along the sediments of the riverbanks of the river Zambesi. We took 19 samples from four different sites above and below the Victoria Falls. The morphology of the sites is various: Above the cataract, the wide riverbed is ascending to reddish sand scarps. Whereas below the fall, the river forms a narrow band zigzagging through steep basalt gorges, topped by reddish sand. We aim to establish a chronology of the stone tools by using ESR dating of the quartz-bearing sediments. Additionally, and for a better understanding in the Victoria Falls formation process, which is currently unknown, we also took luminescence samples for pairing the results with the ESR data as well as cosmogenic nuclide samples for an independent control.

Post-Isothermal IRSL as a new tool for dating sediments

Michel Lamothe, Laurence Forget Brisson, François Hardy
Université du Québec à Montréal, Montréal, Canada

Since the beginning of the present century, optically stimulated luminescence (IRSL) of feldspar has emerged as promising techniques for dating Quaternary events and timing environmental changes. Remarkably, even though feldspar luminescence can probe 10 times deeper than radiocarbon into geological time, age shortfalls have hindered the development of feldspar as dating tool. In luminescence dating of feldspar, laboratory induced luminescence necessary to assess the naturally acquired dose in the environment suffers from a poorly understood instability over time, known as anomalous fading (AF). AF is the source of commonly observed age underestimation in optical dating of feldspar. Approaches to circumvent AF include correction methods as well as attempts to measure directly an unfading component of feldspar luminescence (eg post-IR IRSL) protocols. The former has the advantage of measuring the easily bleachable traps but requires extended extrapolations of laboratory measured fading rates. High temperature post-IRSL methods are limited by the use of difficult-to-bleach traps and hence by potential age overestimations. Herein, we propose a new dating technique for feldspar that circumvents anomalous fading but nonetheless takes advantage of the easiest-to-bleach traps.

Post-isothermal laboratory induced luminescence (plt-IR) allows probing easily bleachable traps and measuring an equivalent dose (D_e) that is not dependent on time elapsed since irradiation. In this procedure, one measures two IRSL signals, first from an IR stimulation at low temperature (i.e. IR_{50}) followed by a second one, at a higher temperature (i.e. IR_{225}). Since both signals fade at different rates, D_e from IR_{50} is lower than that of IR_{225} . In plt-IR, a succession of thermal treatments is carried out before the measurement of laboratory-induced IR_{50}/IR_{225} ratio of luminescence. The dependence of D_e on thermal annealing is different for each IR signal so one can find which thermal treatment will yield the same D_e for both signals. This D_e is the true total radiation dose received by the feldspar minerals in nature following deposition for sediments, more properly known as the paleodose (P). Post-isothermal dating has been successfully applied to several samples of different ages and from various geological contexts. Post-isothermal luminescence is thus proposed as a way to circumvent AF, as extended isothermal annealing treatment is not shown to eradicate AF. The plt-IR method offers renewed hope in the quest of a truly robust and reliable dating method that could unravel the Pleistocene history of the continental landscape.

Testing the use of total beta counting for high-precision OSL chronologies

Alastair Cunningham^{1,2}, Jan-Pieter Buylaert^{1,2}, Andrew Murray¹

¹Department of Geoscience, University of Aarhus, Roskilde, Denmark, ²Center for Nuclear Technologies, Technical University of Denmark, Roskilde, Denmark

Individual OSL dates tend to come with an uncertainty in the range of 5-10 %. If samples have been well-bleached before deposition, the largest sources of uncertainty come in the 'dose rate' side of the equation. The dose rate can be estimated from the concentrations of the naturally occurring radionuclides — mostly K-40 and the decay chains of U-238, U-235 and Th-232. These measurements can be performed using a number of different methods, but usually some combination of mass spectrometry, gamma spectrometry, and alpha and beta counting. However, the quality control on dose rate measurements is not yet satisfactory, and a dating inter-comparison study has found that the radionuclide measurements are by far the largest source of uncertainty in standard OSL dating [1].

Recently, a new procedure has been developed for the measurement and analysis of dose rates using total beta counting, designed to produce accurate dose rates with a random uncertainty of <2 % [2]. The procedure has very simple requirements for sample preparation and analysis, and uses equipment that is both inexpensive, and already present in many laboratories.

Here, we test the application of total beta counting on two loess sequences. The sequences have been chosen because of their high sampling resolution and absence of obvious complexities (e.g. in stratigraphy, water content, grain size, etc). Using the new beta-counting procedure leads to a substantial improvement in the precision of the dose rate data (compared to HpGe gamma spectrometry), and more convincing age-depth relationships. We further improve the precision of each chronology using a Bayesian chronological model, designed specifically for luminescence data. We find that this combination of high-precision dose rate measurements, with customised chronological models, produces luminescence chronologies with unprecedented precision.

Electron Spin Resonance (ESR) dating of optically quartz grains: a light at the end of the tunnel ?

Mathieu Duval^{1,2}, Melanie Bartz³, Lee J. Arnold⁴, Martina Demuro⁴

¹Griffith University, Brisbane, Australia, ²CENIEH, Burgos, Spain, ³University of Cologne, Cologne, Germany,

⁴University of Adelaide, Adelaide, Australia

Although the first ESR dating attempt of optically bleached quartz grains extracted from Quaternary sediment was published > 30 years ago (Yokoyama et al., 1985), the application remains relatively poorly known and not widely accepted among the community of Quaternary scientists. This situation is contrasting with Luminescence, which has become instead increasingly popular over the last decades, thanks to several major methodological developments leading to significant improvements in terms of accuracy and reliability. In that regard, ESR can probably not compete with Luminescence dating, as there are some intrinsic technical limitations (e.g., impossibility/difficulty to run automated ESR measurements or to perform single grain analyses) that currently limit any major future developments. Additionally, the reduced number of ESR dating specialists around the world working on this application is clearly another limiting factor.

That said, there are nevertheless some situations where ESR can be of special interest in Quaternary studies. It can be used to take over Luminescence when this one shows apparent limitations, or provide some useful chronological constraints when no other numerical dating method is available (e.g. Sahnouni et al., 2018; Bartz et al., 2018). In the recent years, some efforts have been dedicated among the ESR dating community to start a standardization of the method (e.g. Duval et al., 2017). Additionally, the increasing systematic use of the multiple centre approach, in combination with cross-comparisons with independent dating methods (e.g., Mendez-Quintas et al., 2018, Bartz et al., 2019; Duval et al., submitted), show that ESR can be a reliable dating tool.

The present contribution will give an updated overview of the potential and current limitations of ESR dating method based on some recently published case studies for which semi-independent age control was available.

Sequential ^{14}C age measurements on peaty sediments to reconstruct high precision age model of marsh deposits

Yosuke Miyairi¹, Reisuke Kondo², Hiroko Fujita³, Yusuke Yokoyama¹

¹Atmosphere and Ocean Research Institute, The University of Tokyo, Chiba, Japan, ²educational Development Center, Kogakkan University, Mie, Japan, ³Botanic Garden, Hokkaido University, Hokkaido, Japan

Radiocarbon dating on sediment cores rely on the abundance of macrofossils such as plant remains. Alternatively, bulk sediment radiocarbon dates have been used to reconstruct the age model of sediment cores recovered from terrestrial environment. Here we employed sequential radiocarbon measurements to make better resolution and precision age model of cores retrieved from Sarutake river marshland in Hokkaido, northern Japan. High organic carbon content of the sediment allowed us to conduct bulk radiocarbon measurements relatively readily and it was supported from existence of water plants remains. However the sediment is still mixed with other materials thus the radiocarbon results are for both in-situ and ex-situ carbon. We employed sequential radiocarbon measurements (eg., Ishizawa et al., 2017;2018) to overcome this difficulties together with evaluations of reservoir effects using diatom based paleo salinity estimates (Sagayama et al., 2018). In order to evaluate the accuracy of that age model, we compare the age with the tephra with the history record. We did age comparison with Tarumae A (Ta-a) tephra erupted in 1839. The result was suggested that Sequential ^{14}C age measurements would enable high precision dating of peat deposits.

Moving beyond the age-depth paradigm in palaeoceanography: dual ^{14}C and stable isotope analysis on single foraminifera.

Bryan Loughheed¹, Brett Metcalfe², Ulysses Ninnemann³, Lukas Wacker⁴

¹Uppsala University, Uppsala, Sweden, ²Vrije Universiteit, Amsterdam, Netherlands, ³University of Bergen, Bergen, Norway, ⁴ETH Zürich, Zürich, Switzerland

Late-glacial palaeoclimate reconstructions from deep-sea sediment archives provide valuable insight into past rapid changes in ocean chemistry. Unfortunately, only a small proportion of ocean floor with suitably high sediment accumulation rate (SAR) is suitable for such reconstructions using the longstanding age-depth approach based on a traditional downcore stratigraphy. We employ ultra-small radiocarbon (^{14}C) dating on single microscopic foraminifera to demonstrate that the longstanding age-depth method conceals large age uncertainty caused by post-depositional sediment mixing, meaning that existing studies may underestimate total geochronological error. To overcome the problems associated with the age-depth paradigm, we use the first ever dual ^{14}C and stable isotope ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) analysis on single microscopic foraminifera to produce a palaeoclimate time series independent of the age-depth paradigm. This new state-of-the-art essentially decouples single foraminifera from the age-depth paradigm to provide multiple floating, temporal snapshots of ocean chemistry, thus allowing for successful extraction of temporally accurate palaeoclimate data from low SAR deep sea archives. This new method can address large geographical gaps in late-glacial benthic palaeoceanographic reconstructions by opening up vast areas of previously disregarded, low SAR deep-sea archives to research, which will lead to improved understanding of the global interaction between oceans and climate.

P-4631

Amino acid racemisation in foraminifera: testing for an intra-crystalline fraction and closed system behaviour

Lucy Wheeler¹, Kirsty Penkman¹, Roland Gehrels¹, Natasha Barlow², Hans Petter Sejrup³

¹University of York, York, United Kingdom, ²University of Leeds, Leeds, United Kingdom, ³University of Bergen, Bergen, Norway

A requirement for amino acid racemisation dating is closed-system behaviour of the protein fraction, which minimises external influences on racemisation rates and limits contamination and leaching of the native biomineral proteins. The intra-crystalline fraction of proteins (those occluded within the biomineral matrix) has the potential to act as a closed system during diagenesis and therefore produce more reliable age estimates.¹ Extensive research has been carried out to assess the suitability of a range of biominerals for AAR using this intra-crystalline approach (e.g. mollusc,² coral³).

Foraminifera have widespread applications as palaeoenvironmental indicators in Quaternary sea-level reconstructions; however, comparatively little is known about the behaviour of biomineral proteins in these protists and therefore their suitability for AAR. In this project, the intra-crystalline approach is extended to species of foraminifera widely used in palaeosea-level research. Bleaching experiments have been carried out on *Ammonia beccarii* and *Haynesina germanica* to isolate an intra-crystalline fraction of proteins, followed by high-temperature decomposition experiments determine the adherence of each species' intra-crystalline fraction to closed-system behaviour. The patterns of decomposition at diagenetic temperatures have been assessed for intra-crystalline amino acids in foraminifera using *Neogloboquadrina pachyderma* (*s*) from an independently dated core. This work will inform an assessment of the suitability of foraminifera as a substrate for AAR using the intra-crystalline approach.

Stratigraphic singularity: An earthquake located off Jersey triggered the mudflow preserving the only loess outcrop actually known under the seas

Jean-pierre Lefort¹, Paul Chambers², Guzel Danukalova³, Jean-Laurent Monnier⁴, John Renouf⁵, Evgenia Osipova³, David Aoustin⁶, François Pustoc'h⁶

¹University of Rennes 1, Campus de Beaulieu, Laboratoire d'Archéosciences (bât. 24-25), 74205 CS, 35042, Rennes, France, ²Jersey State, St Helier, Jersey, ³Academy of Sciences, Ufa, Russian Federation, ⁴University of Rennes 1, Rennes, France, ⁵Société Jersiaise, St Helier, Jersey, ⁶CNRS-CReAAH, Rennes, France

A five meters long core sample, retrieved in 2007 from the Havre de Lessay (France) (Latitude: 49°20993, Longitude: -1°788815) and located between Jersey and the Cotentin Peninsula (France) has been studied using different techniques (image processing, granulometry, petrography, malacology, palynology and tentative dating). Between the lower part and the top, the core is a yellowish loess, a black mud and a grey shelly formation. The basal formation, which displays a typical loess granulometry, is the only loess found anywhere in situ on the seabed worldwide. Elsewhere, this fragile sediment has been always washed out by the successive Quaternary transgressions. The overlying mud formation, which displays all the characteristics of a mudflow, sealed up the loess deposit. Because this core has been sampled on the rim of a submarine valley located in front of a major onshore geological disruption (the Saint-Germain-sur-Ay transcurrent shearing), clearly associated with an active seismic zone, it is likely that the protection of the loess deposit from erosion was initiated by an earthquake that triggered the overlying submarine mudflow.

P-4633

Recent advances in Western Ukrainian loess stratigraphy

Andryi Bogucki¹, Maria Łanczont²

¹Ivan Franko National University, Lviv, Ukraine, ²Maria Curie-Skłodowska University, Lublin, Poland

In the Ukrainian territory several areas with vast, thick loess covers are found. They belong to the European periglacial loess belt and are part of two geographical loess regions. The Central European region of dry loess formation extends from the Vistula River to the upper-middle Dnieper River. In the east it borders on the East European region of continental loess. At the end of the 1960s the stratigraphic division of loess-paleosol sequences (LPS) for Western Ukraine and the area from Middle Dnieper basin to Black Sea were worked out independently in the Lviv and Kiev centres, i.a. due to the difficulties in correlating LPS and divergent interpretations.

The original stratigraphic scheme of LPS in Western Ukraine was based on the main profiles of the Volhynian-Podilian Upland; age of the oldest distinguished loess layers corresponded to the Okanian (=Elsterian) glaciation. The paleosols, mainly interglacial, and additionally the horizons of permafrost deformation structures, characteristic for this area, were identified in specific stratigraphic situations and related to the main phases of permafrost development and degradation. Names of paleosols and cryogenic horizons were taken from stratotype profiles.

Further development of the Western Ukrainian loess stratigraphy was based on the research conducted in larger loess area including Transcarpathia, Pridnistrovian Podilia, East Carpathian Foreland, and adjacent Polish territories for comparison. These loess covers are a kind of bridge to the Middle Dnieper area; hence correct correlation of both regional schemes is possible. They were compared with the widely accepted in Europe today stratigraphic scheme of Chinese Loess Plateau, and with MIS stratigraphy. The LPS were related to the European division of the Quaternary.

Most of the new key and additional sections were studied using several methods (sedimentological, geochemical, paleomagnetic, isotopic (carbon, oxygen), paleopedological, paleontological, archaeological). Deposits were dated using the C¹⁴ and luminescence (TL, post-IRSL, OSL) methods. The results gave new significant data for paleoenvironmental reconstructions and stratigraphic correlations. Reliable age indicators identified in the Western Ukrainian loess-paleosol sequences are: Brunhes-Matuyama magnetic polarity reversal found in loess deposits on the Dnister and Tisza river high terraces; marker horizon of under-/intra-loess till, left by the Okanian ice sheet (MIS12), occurring within complete loess profiles of the Volhynia Upland and Upper Dnister basin; other geomagnetic excursions – Pringle Falls (MIS7), Blake (MIS5), Hilina Pali (MIS2). Pringle Falls event was found in the bipartite soil S2 with the older Middle Paleolithic artefacts, and the Blake event in the pedocomplex S1 with the younger Middle Paleolithic artefacts. Based on all data, the original version of the scheme was supplemented with the loess units older than MIS12, containing paleosol complexes of the Soltvyn (S5), Zahvizdja (S6-S8) and Kopani/Skala Podilska (S9) types. Stratigraphic division of the loess-paleosol units S2-L2-S1-L1 was detailed.

P-4634

Cross-Ukraine stratigraphical correlation in the Upper and Middle Pleistocene based on a multi-proxy approach

Natalia Gerasimenko

Taras Shevchenko National University of Kyiv, Kyiv, Ukraine

Problems of Pleistocene stratigraphic correlation are very apparent in the large Ukrainian loess-palaeosol region: various parts of which have different palaeoenvironmental backgrounds, dependent on climatic, orographic distinctions, and the distance from the continental ice sheets. For instance, in the north of Ukraine, the Bug loess (MIS 2) is the thickest (up to 15 m) and the most enriched in large silt, whereas to the south of 48°N, its thickness averages 2 m, increasing only in palaeodepressions. In the south, the Dnieper (Saalian) loess is the thickest (up to 20 m), and it has a homogenous large silt grain-size. Tyligul unit (Elsterian) is much thicker in the north than in the south, and Sula loess (Donian) has its maximum thickness in the east.

The Ukrainian loess region is subdivided into an area formerly covered by Dnieper glacial lobe, an area with the Elsterian glacial deposits, and an unglaciated area. Each of them include provinces – sixteen in total (Veklich et al., 1993). The best markers for stratigraphic correlation between them are: the M/B boundary, glacial deposits, age-indicative microfaunal complexes, and the pollen successions of the Eemian and Holsteinian. The other pollen, molluscs and large mammal assemblages, archaeological layers are courser tools, of use to identify larger time intervals of Pleistocene than the terrestrial correlatives of MIS.

Palaeosols are reliable for correlation between neighboring provinces, though changes in palaeocatena and the presence of welded soils cause uncertainties. Zonal changes of palaeosols are clearly visible in well-developed pedocomplexes, e.g. MIS 3 palaeosols are gleyed and leached of carbonates in the west and north, but they are Calcaric Cambisols in areas south of 47°. Luvisols of MIS 5e and Greyzems of MIS 5c are replaced in the south by leached Mollisols and Calcaric Mollisols, respectively. Upper Middle Pleistocene pedocomplexes in the north include soils of temperate climate, but south of 48° they have well developed rubified and argillic horizons, like those seen in Mediterranean soils. Early Middle Pleistocene soils are thick Vertisols and Luvisols to the north of 49°, but in the south of Ukraine they are Ferralic Cambisols and Ferrasols. Pollen data confirm palaeoenvironmental interpretations based on the palaeosol origins. The paleosols of the Middle Dniester valley, the Transcarpathian Lowland and the foothills of Crimean Mountains contain some pollen of thermophilous taxa, which is not typical for sites in the rest of Ukraine. The soil units of the Lower Middle Pleistocene include pollen of Neogene relics.

¹⁴C dating is a secure tool for correlation of MIS 3 soils, but despite that many OLS and TL-dates were obtained from older deposits, frequently their reliability is doubtful. Cross-Ukraine correlation of reference sites in the loess-palaeosols provinces, based on multiple proxies, are demonstrated in the presentation. Most of them are included in DATESTRA project.

P-4635

Upper/Late Pleistocene stratigraphy in the Kola Peninsula (N-W Russia): glacial and marine units

Olga Korsakova

Geological Institute of the Kola Science Centre of the Russian Academy of Sciences, Apatity, Russian Federation

Included the glaciomarine, glaciofluvial or glaciolacustrine depositional units and glacial tills, as well as the marine beds, sediment sequences are presented on the coastal areas and in the inner part of the Kola Peninsula. The combined finding of glacial and marine sediments in the sedimentary sequences allows the correlation of the main Upper/Late Pleistocene stratigraphic subdivisions in the Kola region. The stratigraphy hierarchical pattern can be apprehensible up to the group or supergroup, the stage, and Interglaciation-Glaciation in the lithostratigraphy, chronostratigraphy and climatostratigraphy, correspondently.

Correlated to the Late Pleistocene Subseries, the Mikulinsky (Eemian and Early Weichselian) Horizon and the Valdaisky (Mid and Late Weichselian) Supernorizon are the main lithostratigraphic units, which are corresponded to the Mikulinian Interglacial Complex and the Valdaian Glacial Complex in Russian climatostratigraphy. Marine Ponoï Beds and Strelna ones, corresponded to the members in the international lithostratigraphy hierarchical pattern, compose the entire Mikulinsky Horizon in the coastal sediment successions, and Ponoï Beds is the lower part of this Horizon in the inner Kola Peninsula. Both marine Beds compose the formation in rank. The lower boundary of this marine unit derives from lithology, spore-pollen proxies and diatoms and foraminifera data; there is no hiatus in transition zone of marine deposition succession since the marine inundation took place in the Kola Peninsula in previous deglaciation and was lasting in coastal areas during entire MIS 5. Upper parts of all referred sequences are deformed, and marine sediments are overlaid by glacial deposits with erosion.

Valdaisky Superhorizon (Valdaian Glacial Complex), which is a supergroup in the international lithostratigraphy, subdivides into Glacial Podporozhsky, Interstadial Leningradsky, and Glacial Ostashkovsky Horizons, not strongly correlated to the group in rank. The chronostratigraphic equivalent of the Horizons should be considered Podporozhian (early Mid Weichselian), Leningradian (late Mid Weichselian) and Ostashkovian (Late Weichselian) stages. Derived from sedimentology successions in the coastal and inner Kola Peninsula and different proxy environment indicators, large-scale deglaciation of land took place and the marine reservoir in the White Sea depression occurred here in the Last Glaciation during MIS 3. Corresponding deposits form the Leningradsky Horizon, underlaid and overlaid by tills or melt-water sediments, which represent the Glacial Podporozhsky Horizon and Ostashkovsky one. In coastal Kola Peninsula, the lithostratigraphy boundary between Glacial Podporozhsky Horizon and Interstadial Leningradsky one indicates the transition zone in the sediment succession with Mid Valdaian (Mid Weichselian) marine unit. Available 8 key sites from Kola Peninsula provide here the lithological, geochronological and various proxy data for Upper/Late Pleistocene regional stratigraphy.

This is a contribution to the DATESTRA project. The studies have been carried out within the framework of the GI KSC RAS research projects.

P-4636

New data on the structure and genesis of Quaternary perennially frozen sediments in Central Yakutia (Eastern Siberia)

Nikolai Torgovkin¹, Valentin Spektor¹, Nadezhda Bakulina², Georgii Maksimov¹, Igor Syromyatnikov¹, Vladimir Spektor¹

¹Melnikov Permafrost Institute Siberian Branch of the Russian Academy of Science, Yakutsk, Russian Federation,

²State Unitary Mining and Geological Enterprise of the Republic of Sakha (Yakutia) "Yakutskgeologiya", Yakutsk, Russian Federation

In the spring of 2018, on the watershed of the Lena and Amga rivers (Central Yakutia), we drilled a borehole to a depth of 100 m, and having encountered a full section of the Quaternary sediments bedding here. The complete sampling of frozen core was made to a depth of 94.5 m. Based on comprehensive studies, we identified five stratigraphic stages of the formation of Quaternary sediments, from top to bottom:

I. 0-2,65 m. Holocene soil of slope genesis.

II. 2.65-26.15 m. Ice complex (yedoma), represented by massive loams with schlieren cryostructure, containing ice-wedges.

III. 26.15-63.45 m. Lacustrine complex, formed by silt with horizontally and wavy-layering. Inclusions of freshwater shells and plant detritus are noted. Into the layer, thin separate 'closed' cracks filled with ice are encountered.

The significant difference in the cryostructure between yedoma and lacustrine sediments allows separating these complexes according by type of freezing. Besides having ice wedges, loam cryostructure enclosing advantageously thin- and mikroschlieren, indicating that discontinuous sedimentation mode with alternating subaqueous and subaerial conditions, and syngenetic type of accumulation were predominant. Stratigraphic position and $^{18}O/^{16}O$ analyses data allow us attributing yedoma to the Sartanian LatePleistocene horizon (MIS 2). Lacustrine sediments cryostructure is massive, which together with structural features, could indicate significant diagenetic fluctuations in the basin and epigenetic type of freezing. Thickness of lacustrine complex is the greatest (37.3 m), among the considered complexes, which confirms the earlier conclusions about distribution of the deep lake basin in Zyryan time (MIS 4).

IV. 63,45-78,9 m. Lacustrine -alluvial complex represented by interbedded sands and silts. This is a transitional layer between the Elginskaya and Mavrinskaya formations, revealed in the outcrops of the Mamontovaya Gora and the Bestyakhskaya terrace. Sediments were formed in large flowing water basin under more dynamic conditions than the lacustrine sediments overlying it. The character of sediments freezing is epigenetic. Based on the similarity of the lithological composition and stratigraphic position, we attribute this stratum to the end of the Mid-Pleistocene (MIS 8-6).

V. 78.9-94.5 m. Alluvial complex, represented by medium and coarse sands. The section ends by pebble horizon lying on bedrock. Sands correlate with the Bestyakhskaya formation bedding at the base of section of the Bestyakhskaya terrace. Underlying pebbles correlate with pebbles of the Elginskaya formation of Mamontovaya Gora. This allows us to relate this complex to the Tobolskiy horizon of the Mid- Pleistocene (MIS 9-11).

Pleistocene chronostratigraphy of the southeastern White Sea and adjacent areas (Arkhangelsk region, Russia)

Nataliya Zaretskaya^{1,2}, Olga Shilova³, Tatiana Repkina³

¹Geological Institute, RAS, Moscow, Russian Federation, ²Institute of Geography, RAS, Moscow, Russian Federation,

³Lomonosov Moscow State University, Moscow, Russian Federation

The White Sea which is an inner basin of the Arctic Ocean located in the Northwestern Russia is of high geological interest because of its binary structure: its northwestern half is located on the tectonically active Baltic crystalline shield, and the southeastern one is a part of the East European platform with developed sedimentary mantle and comprises the onshore areas of the Onezhski peninsula, Kuloi plateau and southern side of the Gorlo strait (Fig. 1). According the current Quaternary System subdivisions for European Russia (Zastrozhnov et al., 2018) it lies within the Northwestern subzone of Late Neopleistocene glaciations (W-Ia).

The Quaternary stratigraphy starts with Eemian which deposits are widespread both within the Gorlo strait and in the coastal zone (Demidov et al., 2007; Sobolev, 2008; Rybalko et al., 2017) and are mostly marine sands and silty sands with shells and shell detrital matter. The luminescent dating results are 160-110 kyr BP (Sobolev et al., 1995). In the coastal outcrops these deposits are presented by binary layer of dark-grey massive clays covered by light-grey sands, often directly overlain by LGM deposits.

The middle Weichselian interstadial deposits were identified in one section of Zimniy coast and are presented by sands and gravels interlayered with silts and loams. The origin is controversial: fluvial (Larsen et al., Demidov et al., 2006) or marine (Sobolev, 2008). One radiocarbon date is 27.9 ± 1.16 (shells), and TL dates are 55.8 ± 8 , 63.0 ± 11 and 71.0 ± 11 BP (Sobolev, 2008), OSL-dates are 77 ± 8 , 31 ± 3 and 19.9 ± 1.4 (Demidov et al., 2006).

Late Weichselian (LGM and deglaciation) tills are the most widespread in this area (Demidov et al., 2006; 2007; Rybalko et al., 2017), forming the gently undulating uplands with blanket bogs. This area was covered by last SIS glacier from 22 to 16-15 kyr BP (Hughes et al., 2015). The thickness of till layer varies from 1 to 8-9 m, and sometimes is underlain by the rhythmically interlayered sands and clays probably deposited in proglacial conditions of early LGM.

The deglaciation of this area left the well expressed marginal landforms; moraine ridges of Neva deglaciation stage (Older Dryas) are identified both in the coastal area (State..., 2012) and within the Gorlo strait (Sobolev, 2008; Rybalko et al., 2017). The Late Glacial – early Holocene basin deposits are found up to the height of 14-20 m a.s.l., and the Holocene marine (supported by diatom data) - up to 4-5 m a.s.l.; these are grayish or brownish-grey heavy silts and clays, usually covered by aeolian sands or peat and gyttja.

This work was supported by RFBR grants 17-05-00706 (chronostratigraphy) and 19-05-00966 (geomorphology, diatom analysis).

What was the rank of the Warthe cold period (Younger Saalian, MIS 6)? New facts from eastern Poland

Sławomir Terpiłowski¹, Tomasz Zieliński², Przemysław Mroczek¹, Paweł Zieliński¹, Irena Pidek¹, Piotr Czubla³, Stanisław Fedorowicz⁴

¹Faculty of Earth Sciences and Spatial Management, Maria Curie-Skłodowska University, Lublin, Poland, ²Institute of Geology, Adam Mickiewicz University, Poznań, Poland, ³Institute of Earth Science, Łódź University, Łódź, Poland,

⁴Department of Geomorphology and Quaternary Geology, University of Gdańsk, Gdańsk, Poland

In the present-day stratigraphic subdivision of Middle Pleistocene the Warthe cold period is in the rank of recessional stadial of Drenthe Glaciation, correlated with Marine Isotope Stage 6 (MIS 6), that follows the Schöningen Interglacial (MIS 7). We found a previously unknown sedimentary succession in eastern Poland, outcropping in the area of maximum extent of the Warthe ice sheet. Our study sheds a new light on stratigraphic significance of the aforesaid glacial period. The succession has been divided into four lithostratigraphical units: lower glaciofluvial deposits and basal till (unit A), fossil luvisol (unit B), periglacial horizon with involutions, frost wedge structures and deflation pavement (unit C), upper glaciofluvial deposits and flow till (terminoglacial fan – unit D). The studied units represent sedimentary record of two distinct cold periods connected with the advances of the youngest Saalian ice sheets in eastern Poland (unit A - Drenthe A; units C, D - Warthe). Warthe cold period has been documented by luminescence datings (approx. 134-170 ka) of sands infilling the frost wedges (unit C). These results comply with global climatic cooling during MIS 6. Two generations of cryogenic structures (involutions and frost wedge structures) and their frequency indicate a change of climatic conditions towards decrease of average annual temperature and humidity reduction. That indicates well-developed, continuous permafrost. This cold period was culminated by ice-contact sedimentation of marginal moraine (unit D). The soil with well-developed Bt horizon (unit B) derived from illuviation in conditions of mixed forest during long-lasting interglacial warming preceding the Warthe cold period – the Schöningen Interglacial (MIS 7). To conclude, the younger cold period of Saalian – the Warthian – should be regarded as an individual glaciation, similarly as Drenthian, which we suggest to locate as MIS 8 in the Quaternary stratigraphic chart.

Middle Pleistocene interglacial environmental changes inferred from aquatic microfossils at the paleolithic site of Schöningen, Germany

Kim Jasmin Krahn¹, Julien Pilgrim¹, Brigitte Urban², Mario Tucci², Antje Schwalb¹

¹Technische Universität Braunschweig, Institute of Geosystems and Bioindication, Braunschweig, Germany,

²Leuphana University Lüneburg, Institute of Ecology, Subject Area Landscape Change, Lüneburg, Germany

Although multi-proxy paleoclimatic data from Middle Pleistocene archeological sites are important to understand patterns of climate variability as well as prehistoric human adaptation, only few well-preserved records exist in Central Europe. The Lower Paleolithic sites in the open-cast mine of Schöningen, Northern Germany, have become internationally renowned because of their worldwide oldest wooden hunting weapons associated with exceptional preservation of remains of a diverse flora and fauna. The Middle Pleistocene paleolake sediments of the locally named Reinsdorf Interglacial, deposited between the Elsterian and Saalian glaciations and correlated at archaeological site Schöningen 13 II with MIS 9, provide a valuable environmental archive for investigating an interglacial transition into an early glacial phase. Diatoms and ostracods were analyzed for more detailed information about the characteristics of the paleolake development and thus smaller-scale climate fluctuations. The lake was characterized by brackish water within the oligo- to mesohaline range. Taxa preferences show deposition near the lakeshore, often associated with abundant aquatic plants. Calcium content was elevated with at least 18 mg Ca L⁻¹. Distinct changes in assemblages, concentrations and taxa dominances point to highly variable lake conditions throughout the terminating interglacial. Presence and absence of shallow water ostracods and abundances of benthic diatom taxa suggest that the paleolake was characterized by strongly fluctuating lake levels with repeating shallowing-upward cycles, probably climatically induced. High abundances of tychoplanktonic diatoms and ostracod taxa associated with streaming water and less brackish conditions in certain levels are indicative of a variable freshwater inflow from springs nearby. Average paleo-temperatures were reconstructed using the Mutual Ostracod Temperature Range method. Mean values varied between approx. +16 and +20 °C for July and approx. -11 and +1 °C for January. Highest numbers and best preservation of ostracod shells were found not in sediments representing full interglacial conditions but during a later phase. This climate oscillation at the transition into the following glacial period led again to more favorable conditions for aquatic organisms. The youngest part of the sequence was void of ostracods hinting at desiccation of the site and preceding climate deterioration during the early glacial. Our findings highlight the relevance of Schöningen for understanding Central European interglacial climate dynamics.

Unravelling chronology and geochemical signatures of Mid-Pleistocene periodic palaeolakes from NW Poland, Central Europe

Artur Sobczyk¹, Ryszard Krzysztof Borówka², Renata Stachowicz-Rybka³, Anna Hrynowiecka⁴, Adam Kotowski⁵, Krzysztof Stefaniak⁵

¹Institute of Geological Sciences, University of Wrocław, Wrocław, Poland, ²Geology and Paleogeography Unit, Faculty of Geosciences, University of Szczecin, Szczecin, Poland, ³W. Szafer Institute of Botany, Polish Academy of Sciences, Krakow, Poland, ⁴Polish Geological Institute - National Research Institute, Marine Geology Branch, Gdansk, Poland, ⁵Department of Paleozoology, Institute of Environmental Biology, University of Wrocław, Wrocław, Poland

We performed detailed multiproxy analyses of 11 m thick lacustrine sediments sections from the two superimposed Pleistocene lakes from NW Poland. Lakes deposits geochemical, palynological and macrofossils analyses have been supplemented with optically stimulated luminescence and radiocarbon datings. Analysed sections represent a unique record of Mid-Pleistocene climatic changes in Central Europe associated with the Scandinavian Ice Sheet oscillations. According to the OSL dating results, the onset of lower lake formation coincides with the recession of the Late-Saalian (MIS6) ice-sheet from NW Poland (OSL 141.4±3.0 ka). As a result, hilly and hummocky landscape originated, wherein local hollows had been fed by the Ca-rich groundwater and surface outwash. Climate change from cold to warm conditions during the Eemian Interglacial (MIS 5e), resulted in limnic cycle onset and succession of thermophilic plants in the basin area. Existence of first (lower) lake ceased with a peat horizon overlaid by sands and sandy silts, to be linked with Early Weichselian glaciation (OSL 109.9±2.5 ka). In the upper part of lower paleolake, the nearly complete skeleton of rhinoceros *Stephanorhinus kirchbergensis* (Jäger, 1839) has been excavated. Second (upper) paleolake formed in superimposed position during the Early Weichselian (MIS 5d-b) glaciation, and uppermost section of lacustrine organic matter (peat horizon) profile, revealed Middle Pleniglacial (MIS 3/2) radiocarbon ages in the range of ~41-32 ka cal BP associated with interstadial conditions (Hengelo – Denekamp Interstadials). During the Last Glacial Maximum (MIS 2), Scandinavian Ice Sheet has overridden the area of analysed palaeolakes reaching its maximum position around Leszno, ca. 150 km to the south. If ones assumed a normal *post-mortem* position of rhinoceros skeleton preceding burial processes, ice-sheet overriding fossilised lacustrine sequence could be at least partly responsible for on-site observed *Stephanorhinus kirchbergensis* skeleton disarticulation.

Input to the stratigraphy of MIS 12-6 in eastern Europe, based on record from the site Rechitsa in western Belarus

Barbara Woronko¹, Leszek Marks^{1,2}, Alexandr Karabanov³, Jerzy Nitychoruk⁴, Maksim Bahdasarau⁵, Tatyana Rylova³, Joanna Rychel², Łukasz Zbucki⁴, Mikalai Hrachanik⁶, Aleksandra Majecka¹, Katarzyna Pochocka-Szwarc², Tomasz Krzywicki², Łukasz Nowacki², Aksana Hradunova⁵

¹Warsaw University, Faculty of Geology, Żwirki i Wigury 93, 02-089 Warsaw, Poland, ²Polish Geological Institute – National Research Institute, Rakowiecka 4, 00-975 Warsaw, Poland, ³Institute for Nature Management, National Academy of Sciences of Belarus, Minsk, Belarus, ⁴Pope John Paul 2nd State School of Higher Education, Faculty of Economics and Technical Sciences, Biała Podlaska, Poland, ⁵Brest State University, Faculty of Natural Sciences, Brest, Belarus, ⁶Brest State University, Faculty of Natural Sciences, Brest, Poland

The site Rechitsa in western Belarus is located in the end morainal zone of the Warta/Sozh Stadial of the Odranian Glaciation (Saalian, MIS 6). It is a big outcrop in which the Quaternary sands and gravels are excavated. This site is extremely important to reconstruct the late Middle Pleistocene environment in central Europe. Referring to a regional palaeogeography, the sequence starts with sand of the late Berezinian (Elsterian; MIS 12) braided river that is overlain by peat of the Alexandrian Interglacial (Holsteinian; MIS 11). The interglacial sequence terminates in peaty gyttja that comprises pollen spectra of a pine-birch forest with substantial participation of steppe vegetation. The overlying sequence is composed of peat and gyttja interbeds reflecting varying lake water levels, in turn dependent on mutual relation of temperature, precipitation and evaporation. The sequence terminates with clay, the top of which was eroded and a channel was cut. At the base of this channel, just above the erosive contact with the clays, rip-up casts of a gyttja deposit are present that is not preserved in situ. They are overlain by a thin (0.15-0.20 m) layer of peat, the pollen spectra which indicates predominance of pine-birch forest with steppe elements (*Pinus-Betula*-NAP) including 40% of *Artemisia* and 10-15% of *Betula nana*. The peat is overlain with brown massive clay with organic material, pollen spectra of which suggests an open vegetation with *Juniperus*, but successively suggesting a progressive cooling. It is overlain by massive decalcified clay without organic matter and with isolated gravels to 0.2 m in diameter that are explained as dropstones deposited from floating lake shore ice. In the top of clay there are two involution horizons and aeolian cover sands. The afore-mentioned series is cut by immense ice wedges with primary infilling, OSL-dated at 210-220 ka BP. Their magnitude (2.0 and 3.5 m long and 0.6 – 0.8 m wide at the top) is unusual in this part of Europe and it suggests to have been developed either during a single long and severe periglacial episode, or in a few shorter but equally severe glacial episodes. This last option seems more probable, because aliquots of the OSL-dated quartz grains in sandy infillings of the ice wedges indicated several sets of ages including 284-272, 219, 199-187, 169-164 and 138 ka BP. Based on sedimentological context and temperature and vegetation curves, the most probable is that the last time the wedges opened at least twice, during MIS 8 and 6 i.e. corresponding to the first and third ages. The research project was funded by the National Science Centre in Poland (decision no. DEC-2013/09/B/ST10/02040).

P-4801

Dating fault gouges and Quaternary sediments in the Wangsan fault, southeastern Korea

Albert Chang-sik Cheong¹, Jeong-Heon Choi¹, Chang-Bock Im²

¹Korea Basic Science Institute, Cheongju, Korea, Republic of, ²Korea Institute of Nuclear Safety, Daejeon, Korea, Republic of

Geochronological data provide a fundamental basis for assessing hazard risks of the fault. Quaternary faults near the Wangsan Fault System, southeastern Korea, have attracted much attention because they are close to the nuclear power plants and heavy industrial complexes that have been constructed since the early 1970s. We here summarize Rb-Sr and optically stimulated luminescence (OSL) ages of fault gouges and fluvial sediments from a remarkable thrust fault exposed on the bluff of a river terrace near the Wangsan village. Both unconsolidated sediments and the basement andesite are cut by the fault with a vertical slip of 16 m. The net displacement along the fault plane is estimated as 28 m. A 40–120 cm thick, light gray and brown fault gouge layer consists of quartz (~40%), feldspar (~35%), illite and smectite with minor kaolinite. Acid (1N hydrochloric acid)-leaching experiments for the fine (< 0.2 μ m) fractions of two gouge samples yielded reproducible isotope dilution thermal ionization mass spectrometric Rb-Sr ages (14.0 ± 0.3 Ma and 13.5 ± 0.3 Ma). These ages are consistent with the K-Ar result (14.8 ± 1.3 Ma) obtained for the comparable size fraction (0.35–0.05 μ m) of the gouge, and interpreted as representing the time of faulting and subsequent hydrothermal alteration. Taken together with the published electron spin resonance (ESR) ages of the gouge (~550 ka), it is concluded that the Wangsan fault was formed in the Middle Miocene and reactivated in the Middle Pleistocene. The Rb-Sr and ESR ages, however, do not represent the timing of the last fault movement because it is evident that the fault rocks were not generated in unconsolidated sediments near the surface. Five sediment samples were selected for OSL dating to constrain the upper limit for the time of surface faulting. Three dates from the footwall block, ranging from 90 ka to 54 ka, were stratigraphically consistent, and two dates from the hanging wall block (81 ± 5 ka and 82 ± 5 ka) were in good agreement with each other. The OSL dating reveals that the fluvial sediments cut by the Wangsan fault were deposited in the Late Pleistocene with an average accumulation rate of ~0.04 mm/y, and the last fault activity occurred sometime after 54 ka. This research was supported by a grant (2017-MOIS31-006) from the Research and Development of Active fault of Korea Peninsula funded by the Korean Ministry of the Interior and Safety (MOIS).

Teotihuacan ancient culture depressed by a megaearthquake associated to the seismic Guerrero gap recorded in Cacahumilpa Cave and EAEs (Mexico)

Raúl Pérez-López¹, Miguel A. Rodríguez-Pascua¹, Jorge L. Giner-Robles², Javier Elez³, María A. Perucha¹, Pablo G. Silva³, Elvira Roquero⁴

¹IGME - Geological Survey of Spain, Madrid, Spain, ²Universidad Autónoma de Madrid, Madrid, Spain, ³Universidad de Salamanca, Escuela Politécnica Superior, Avila, Spain, ⁴E.T.S.I. Agrónomos, Universidad Politécnica de Madrid, Madrid, Spain

Teotihuacan was one of the more blossom cultures in the Mesoamerica pre-Hispanic times, located in the central part of Mexico. The archaeological remains are one of the most famous tourist places in our days. During his highest splendid time (Classic Period, ca 600 CE yr.), close to 200.000 people lived in an urban city with monumental buildings. The city was arranged in one main street of 2 km, oriented N15°E (Avenida de los Muertos), with impressive religious buildings like the Sun Pyramid, one of the greatest pyramid in America, the Moon pyramid at the north and the Feathered Snake Pyramid (the Citadel), at the south part of the city. The city was a dominant center point of the Mesoamerican culture between the years 125 and 650 CE. In the year 650 CE (Epiclassic period), a dramatic decrease of the urban population was noted by several authors and archaeologists. Finally, the city was totally abandoned sometime before the Aztec culture rose as dominant (c.a. 800 CE). A systematic analysis of the main pyramids shows several Earthquake Archaeological Effects (EAEs) affecting the south staircase of the Sun Pyramid, with reinforcement of the E-W sides and high damage affecting the original south staircase of the Feathered Snake Pyramid. All of these building damages appears to be coeval between the years 600 and 650 CE. Furthermore, a speleoseismic analysis of the Cacahuamilpa cave shows multiple coseismic stalagmite and stalactite oriented collapses, cave located at Tasco city (130 km away from Teotihuacan). Numerical dating of these sismothems suggests that the speleothems collapse and tilting occurred between the year 463±50 and 1064 ±20 yrs. CE, according to diverse authors. To check our proposal, we produced a ShakeMap for an Mw 8.1 to Mw 8.4 earthquake, with a theoretical epicenter located at the Guerrero seismic gap segment of the pacific subduction zone (388 Km from Teotihuacan, N210°E direction), simulating a rupture between 150 to 292 Km of reverse faulting of this segment of the Middle American Trench (MAT). Calculated seismic ground accelerations for these theoretical events can explain both the cave damage at Tasco and building damage at Teotihuacan (0.32 g; VIII ESI-07). Therefore, we consider the possibility that a strong earthquake (Mw>8) associated to the Guerrero segment could be the responsible for the great population decline and subsequent abandonment of the ancient Teotihuacan. In this way, there is the possibility to link strong seismic activity with outstanding “cultural reliefs” occurred in Mesoamerica. This proposal does not conflict with either of the existing theories for the Teotihuacan abrupt collapse (droughts, revolutions, volcanic eruptions, etc.), because the sudden overlapping of natural disasters would increase famine episodes, internal warfares and community unrests for brief periods of time.

P-4803

A Worldwide and Unified Database of Surface Ruptures (SURE) for Fault Displacement Hazard Analyses

Stéphane Baize¹, Alexandra Sarmiento², Fiiia Nurminen³, Timothy Dawson⁴, Takashi Azuma⁵, Paolo Boncio³, Johann Champenois⁶, Francesca Cinti⁷, Riccardo Civico⁷, Carlos Costa⁸, Luca Guerrieri⁹, Etienne Marti¹⁰, James McCalpin¹¹, Koji Okumura¹², Oona Scotti¹, Makoto Takao¹³, Pilar Villamor¹⁴

¹IRSN, Fontenay-aux-Roses, France, ²UCLA, Los Angeles, USA, ³University of Chieti, Chieti, Italy, ⁴CGS, San Mateo, USA, ⁵AIST, Tsukuba, Japan, ⁶CEA, Bruyères-le-Chatel, France, ⁷INGV, Rome, Italy, ⁸University San Luis, San Luis, Argentina, ⁹ISPRA, Rome, Italy, ¹⁰University La Sorbonne, Paris, France, ¹¹Geohaz, Crestone, USA, ¹²University Hiroshima, Hiroshima, Japan, ¹³TEPCO, Tokyo, Japan, ¹⁴GNS Science, Wellington, Japan

Fault Displacement Hazard Assessment is based on empirical relationships which are established using historic earthquake fault ruptures. These relationships evaluate the likelihood of co-seismic surface slip considering on-fault (i.e. along the primary earthquake fault) and off-fault (i.e. distributed surface rupture off the primary rupture) ruptures, for given earthquake magnitude and distance to fault. Moreover, they allow to predict the amount of fault slip at and close to the active fault of concern. Applications of this approach include land use planning, structural design of infrastructure and critical facilities located on or close to an active fault.

To date, the current equations are based on sparsely populated datasets, including a limited number of pre-2000 events. In 2015, an international effort started to constitute a worldwide and unified surface co-seismic displacements database (SURE) to improve further fault displacements estimations, in the framework of the INQUA International Focus Group EGSHaz. To date, two workshops have been held to start discussions on how to build such a database. Outcomes from these discussions are (1) the first step should be to unify the existing datasets; (2) the future database will include recent cases which deformation have been captured and measured with modern techniques; (3) new parameters, relevant to properly describe the rupture (such as surface geology and location of rupture with respect to primary fault complexities) will also be included.

This contribution will present the status of the SURE database and will delineate some perspectives to improve the hazard assessment related to surface faulting. The database encompasses 41 earthquakes from magnitude 5 to 7.9, with more than 6 thousands slip measurements and 45 thousands of rupture segments. Twenty earthquake cases are from Japan, 13 from the USA, 2 from Mexico, 1 from New Zealand, Kazakhstan / Kyrgystan, Italy, Ecuador, Turkey and Argentina. Twenty three earthquakes are strike-slip faulting events, eleven are normal or normal-oblique, and eight are reverse faulting.

To pursue the momentum, the initial and common effort needs to be continued and coordinated; and the maintenance and life of the database must be guaranteed. We stress that this effort must remain based on a large and open community of earthquake geologists to create a free and open access database.

P-4804

Use of the ESI-07 Scale for generation of seismic scenarios in Spain: from ancient earthquakes to future simulated shake exercises

Pablo G. Silva¹, Raúl Pérez-López², Javier Elez¹, Jorge L. Giner-Robles³, Miguel A. Rodríguez-Pascua², Elvira Roquero⁴, M. Ángeles Perucha², Teresa Bardají⁵

¹Dpt. Geology, University of Salamanca, Ávila/Salamanca, Spain, ²Instituto Geológico y Minero de España (IGME), Madrid, Spain, ³Dpt. Geology & Geochemistry, Universidad Autónoma de Madrid, Madrid, Spain, ⁴Dpt. Pedology, Universidad Politécnica Madrid, Madrid, Spain, ⁵Dpt. Geology & Geography, University of Alcalá de Henares, Alcalá de Henares (Madrid), Spain

The combination of macroseismic data-points from the environmental earthquake effects (ESI-07) and building damage (EMS-98), leads to the refinement of seismic scenarios for instrumental and historical earthquakes. In particular, seismic information from Earthquake Environmental Effects (EEEs) allows to multiply, sometimes by ten (x 10), the number of macroseismic data-points, especially in non-populated zones, which allows improving identification of historic to ancient epicentres located away from old urban areas. In Spain, the 2nd edition of the Catalogue of Earthquake Environmental Effects (to be published in 2019 by the Geological Survey of Spain, IGME) provides hybrid EMS-ESI macroseismic maps for most of the strong historical and instrumental earthquakes with intensities \geq VIII EMS-98 (c. 70 events). In most of the cases (especially after the 17th Century), the incorporation of multiple ESI-07 macroseismic data resulted in a better identification of both: (1) the probable seismic sources; and (2) the participation of secondary earthquake geological effects in the resulting damage scenarios. In this contribution we present data on the AD 1764 Estubeny (Valencia) and the AD 1862 Huércal-Overa (Almería) earthquakes occurred in different sectors of the Spanish Betic Cordillera, the more seismically active zone of the Iberian Peninsula. The obtained macroseismic scenarios are converted in seismic acceleration (PGA) maps on the basis of standard ground motion prediction equations (GMPE) and specific algorithms for seismic amplification. On the other hand, routines learned from the generation of seismic scenarios (ShakeMaps) developed for instrumental and historical earthquake in Spain have been implemented for the generation of earthquake simulation exercises. The collaboration among the Salamanca University (USAL), the Geological Survey of Spain (IGME) and the “*Unidad Militar de Emergencias*” (UME) of the Spanish Army, leads to the generation of future earthquake scenarios by means of the lessons learned of ancient earthquakes applying methodologies similar to those used by the USGS ShakeMap Program. Recent “earthquake drills” in densely populated areas of the Guadalquivir basin (Sevilla, 2016) and the Lorca-Alhama de Murcia Fault (Librilla, 2018), were based on seismic scenarios provided by the USAL and managed by the IGME, considering the highest emergency levels considered in Spain (Level 3). The main goal of this research is the generation of scientific maps to be used by civil and military authorities during the management of natural disasters as earthquakes, giving a real vision about what we can expect during large earthquakes (\geq 6.0 Mw) affecting wide areas within Spain. Research funded by the MINECO-FEDER Spanish research projects CGL2015-67169-P (QTETC-SPAIN-USAL)

P-4805

Neotectonic Environment and Geodynamic Significance in South Korea: An Overview

Youngbeom Cheon¹, Min-Cheol Kim², Moon Son²

¹Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of, ²Pusan National University, Busan, Korea, Republic of

The Korean peninsula is situated within the eastern part of the Eurasia plate, and has long been regarded as a tectonically stable region. Since 1990s, increasing number of researches have reported the evidences, which are against this conventional view through historical (MMI \geq VIII) and modern instrumental ($\geq M_w$ 4.0) earthquake records. Further, more than 60 Quaternary fault outcrops were also newly observed along the major inherited fault zones in SE Korea (e.g. Yangsan Fault System, Ulsan Fault, Yeonil Tectonic Line, Ocheon Fault System). The conspicuous features of the Quaternary faults are: (1) attitudes similar to those of adjacent major faults (generally NNW–SSE- to NNE–SSW-strikes), (2) dominantly top-to-the west reverse fault geometries with upward decreasing dip pattern, (3) strike-slip with reverse component or reverse-slip kinematics, and (4) reactivations under ENE–WSW to E–W compressional stress field. Based on majority of the observed Quaternary fault outcrops and resultant crustal uplift as well as high rates of microseismic activities, the NNW–SSE-striking Ulsan Fault and the Yeonil Tectonic Line (in Gyeongju–Ulsan areas), which were acted as western principal displacement zone of the Miocene crustal deformation in the Korean peninsula, are interpreted as ones of the most active faults under the Neotectonic stress field. However, on 12th September 2016, the M_w 5.8 earthquake occurred in Gyeongju-city, which is the largest ever instrumental earthquake in the southern Korean peninsula since the first instrumental monitoring in 1978. This earthquake is interpreted to have occurred by the reactivation of a subsurface subsidiary fault of the NNE–SSW-striking Yangsan Fault. In addition, in 15th November 2017, another earthquake shock with M_w 5.4 due to reactivation of the other NNE–SSW-striking fault hit the Pohang-city, which is \sim 30–40 km to the northeast of Gyeongju-city. The geodynamic setting that causes the present-day stress regime in the Korean peninsula is a combined result of the convergence of Eurasian, Pacific, and Philippine Sea plates, as well as far-field stress induced by India-Eurasia collision and continuous northward movement of the India plate. It has been interpreted that the current stress regime in the Korean peninsula have initiated with the change of the Pacific Plate motion during 5–3.2 Ma.

At present, the historical and instrumental records of earthquakes in Korean peninsula are not enough, and full understanding of the recurrence history and magnitudes detected by observed Quaternary faults has been limited so far. Therefore, more advanced approaches for studying the active faults and concomitant rupture processes are required. In particular, recent advances in numerical dating, such as luminescence, Be^{10} , C^{14} , Al^{26} dating methods, are expected to play important roles for the reconstruction of the Quaternary fault activities in South Korea.

Environmental Effects and ESI-07 intensity of the September 8, 2017, Mw 8.2 Tehuantepec-earthquake: geological signature of a large intraslab event

María Magdalena Velázquez-Bucio¹, Alessandro Maria Michetti², Kervin Chunga³, Sabina Porfido^{4,5}, Francesca Ferrario², Franz Livio², Víctor H. Garduño-Monroy⁶

¹UNAM, Morelia, Mexico, ²Università dell'Insubria, Dipartimento di Scienza e Alta Tecnologia, Como, Italy,

³Universidad Estatal Península Santa Elena UPSE, Facultad de Ciencias de la Ingeniería, Santa Elena, Ecuador, ⁴CNR-ISA, Avellino, Italy, ⁵INGV-Osservatorio vesuviano, Napoli, Italy, ⁶UMSNH - INICIT, Morelia, Mexico

The September 8, 2017, Mw 8.2 earthquake with epicenter in the Gulf of Tehuantepec offshore, 133 km Southwest of Pijijiapan, Oaxaca, Mexico, generated considerable environmental effects in a vast region including central-southern Mexico and Guatemala. Immediately after the event, we carried out field reconnaissance surveys of the geological phenomena induced by the event. In the following months, we analyzed and interpreted additional data made available by the National Geological Survey of Mexico and other sources, and those published in the literature meanwhile. This allowed us to compile the first database of the earthquake-induced environmental effects and ESI-07 macroseismic field for an event due to slab bending and rupture. In fact, the Tehuantepec event represents an intraslab earthquake characterized by a hypocentral depth of 45.9 km, and a focal mechanism indicating a WNW-trending, subvertical, normal fault.

The total area affected by secondary effects is in the order of 54.000 km². Intensity of VII to IX_{ESI-07} has been assigned in the Gulf of Tehuantepec region. In the epicentral area, coseismic coastal subsidence up to 0.5 m has been documented at Salina Cruz and Juchitán, Oaxaca (figure 1). Oceanic tsunami reached Puerto Chiapas (run-up of 3.4 m above tide level), Salina Cruz (1.89 m), and Huatulco (1.37 m; MNSS). Intensity of X_{ESI-07} has been assigned to the epicentral area and IX_{ESI-07} to this coastal area. VIII_{ESI-07} is assigned to Cañón del Sumidero and Tuxtla Gutiérrez city, ground effects included landslides and rockfalls up to 10⁴ m³. In beachfront areas, cracks on alluvial soils reached 40 cm of width and 1.40 m of depth (figure 2). A value VII_{ESI-07} is assigned to Tuxtla Gutiérrez and Juchitán, the most notable ground effects were lateral spreading with up to 10 cm wide longitudinal fractures in paved roads and 20 cm wide in riverbanks. In Tuxtla Gutiérrez city, rock falls and landslides up to 10² m³ occurred. Lateral spreading and longitudinal and transversal fractures up to 10 cm wide are observed along paved roads in Juchitán, Oaxaca.

Figure 1. Tectonic subsidence, IX_{ESI-07}. Area of restaurants flooded by sea water. Juchitán, Oaxaca.

Figure 2. Cracking in natural soil road, VIII_{ESI-07}. Salina Cruz, Oaxaca.

The attenuation of ESI-07 intensity was more pronounced to the ESE than to the opposite direction, in agreement with rupture directivity deduced from instrumental data. The application of ESI-07 scale will provide data for the generation of a new intensity map and will allow its comparison with published macroseismic data based on traditional intensity scales (MM, EMS). Such map will contain reliable information according to the distribution and size of damage in the natural environment, as a scenario to take into account in future hazard and seismic risk studies in the country.

Analysis of geomorphology and tectonolineaments related with earthquakes around Gyeongju, Korea

Chung-Ryul Ryoo

Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

Gyeongju is located in the junction area of the Yangsan and Ulsan faults in the southeastern Korea. The Yangsan Fault have a N-S or NNE-SSW directions, and the Ulsan Fault have a NNW-SSE direction around Gyeongju. Recently, two important earthquakes in Korea occurred in 2016 (Mw 5.8) and 2017 (Mw 5.4) in the vicinity of the Gyeongju city. We analysed the geomorphology and tectonolineaments to well understand the relationship with seismotectonic environment and seismic damage zones around Gyeongju, Korea. Several active faults around Gyeongju have a N-S strike dipping to the east and are closely related with westward convex lineament, showing top-to-the-west movements. And also, the eastern margin of the Tertiary extensional basins are mainly reactivated, damaged, evolved and developed as active faults showing westward convex lineament pattern. We also discuss an intracontinental seismotectonic environments around Gyeongju, which is not related with continental collision effect from Himalaya-Tibet but with subduction effect from Pacific.

P-4808

Stereopaired morphometric protection index red relief image maps (Stereo MPI-RRIMs): effective DEM visualization for interpreting and mapping tectonic geomorphic features

Heitaro Kaneda¹, Tatsuro Chiba²

¹Chiba University, Chiba, Japan, ²Asia Air Survey Co. Ltd., Kawasaki, Japan

We propose stereopaired morphometric protection index red relief image maps (Stereo MPI-RRIMs) for effective visualization of high-resolution digital elevation models (DEMs) to interpret and map small tectonic geomorphic features along active faults. Stereo MPI-RRIMs resolve problems of an original red relief image map (RRIM) in active fault studies and allow simultaneous expression of all of the three basic topographic parameters of elevation, slope, and convexity and concavity with minimal degradation of original data quality. Although stereographic viewing may require some practice and/or supporting devices, this is a big advantage over the most often used DEM visualization of shaded relief maps and slope maps, both of which only represent one aspect of 3D morphology. We show that Stereo MPI-RRIMs vividly visualize various tectonic geomorphic features and even errors from DEM production processing, thereby maximizing the potential of the digital topographic data for active fault studies. We argue that those who use DEMs need to pay more attention to DEM visualization, and our proposed method, along with our simple calculation programs, would aid in more complete interpretation and mapping of small tectonic geomorphic features.

P-4809

Environmental effects accompanying the Mw 7.3, November 12, 2017, Sarpol-e-Zahab earthquake: observations from the Iran border and preliminary ESI2007 intensity

Hamideh Amini¹, Alessandro Maria Michetti², Morteza Fattahi¹

¹University of Tehran, Tehran, Iran, Islamic Republic of, ²Università dell'Insubria, Como, Italy

The Mw 7.3 earthquake occurred in the region of Iran-Iraq border on Sunday, November 12, 2017, is the largest instrumental and historical seismic event recorded around this border, and was felt over an area of more than 800,000 km². According to the Iran legal medicine report, until 2017.12.12 about 579 people were killed, most of them were in Sarpol-e-Zahab with 518 killed and about 12000 people injured.

No unequivocal surface faulting has been mapped. The affected zone of this strong seismic event contains the Mountain Front Fault and High Zagros Fault of main Zagros structures both in strike of NW-SE which located closer to each other in the NW. Heavy engineering damages and numerous related environmental phenomena were caused by this earthquake. According to the several reported environmental effects, essentially from the Iran side of the epicentral area, in this study we assess the macroseismic intensity field. Considering the observed landslides, rock-falls, liquefaction, ground features and other effects, maximum intensity value of this earthquake based on ESI 07 intensity scale proceeds to the value X near to Sarpol-e-Zahab city. Two more effective effects were observed by landslides (Fig. 1) and rock-falls (Fig. 2).

Figure 1. Mela Kabood- Gorchi Bashi landslides (in the north of Sarpol-e-Zahab); we assess X ESI 07 intensity at this site.

Figure 2. Rock fall on the way of Baba-Yadegar to Ban-e-Zarde (in the north of Sarpol-e-Zahab); we assessed ESI 07 = VIII at this site.

The other largest earthquakes of this region are two historical events occurred in 958 AD and 1150 AD, both with reported magnitude 6.4; then, more investigation is needed to find relevant information of the region's seismicity and seismic hazard. In fact, the analysis of the 2017 Sarpol-e-Zahab earthquake macroseismic information and ground effects will allow a better understanding of source parameters of strong historical events in the region.

Research of active tectonic changes in Korea using In situ Cosmogenic radionuclides

Yire Choj, KyeongJa Kim

Korea institute of geoscience and mineral resources, Daejeon, Korea, Republic of

Since the Gyeongju (Sep.12.2016, M_w 5.8) and the Pohang (Nov.15.2017, M_w 5.4) earthquake in the Korean peninsula in recent years, the need for research on active faults considering the characteristics of seismic and geological characteristics of Korea has been emphasized.

In order to activate the research to track the active tectonic changes in Korea, this paper want to discuss how to apply the information such as surface exposure dating, depth-profile dating, and burial dating that can be derived about active tectonic processes, utilizing concentrations of in situ produced cosmogenic radionuclides ^{10}Be (half-life = 1.38 Ma), ^{26}Al (half-life = 0.7 Ma) and ^{14}C (half-life= 5.7 ka) in a variety of tectonic change. The main purpose of this study is to determine the displacement rate and recurrence interval of the fault through the age dating of the quaternary deposit which was cut by faults existing in Korea. Ultimately, it can be used as a key index to identify the recurrence model of large scale earthquake occurred in intraplate area. This paper summarize the methodology and concept to research active tectonics on the Korean Peninsula using multiple cosmogenic nuclides and discusses the matters to be considered when applying these research methods in Korea. We hope that the technique of measuring in situ cosmogenic radionuclides holds promise for quantitative studies of processes and time-scales in a wide range of active tectonic problems.

A possible change of Holocene paleoearthquake recurrence patterns along the Lucaowan – Shibaocheng segment of the eastern Altyn Tagh fault, China

Guihua Chen, Kang Li, Xun Zeng, Rongzhang Zheng
Institute of Geology, China Earthquake Administration, Beijing, China

Surface-rupturing paleoearthquakes provide centennial to millennial scale records of active faulting for major seismogenic faults. As the fast slipping northern boundary fault, the left-lateral Altyn Tagh fault was poorly understood on its paleoseismological behavior. Although some results were published recently for the central segment, few studies were known for the eastern and western segments. We excavated a 22-meter-long and 3.5-meter-deep trench on an offset alluvial fan across the Lucaowan – Shibaocheng segment of the eastern Altyn Tagh fault near Hongliuxia Village. Eight to twelve sequences of alluvial deposits were exposed within the fault zone in the trench walls. The alluvial sequences consisted of a sandy gravel layer in the lower part and a fine sand layer in the upper part. At least seven surface-rupturing events are identified from offset deposition units since 6500 Cal BP. The last three events occurred during the last 4000 years within the upper half meter deposit, while the earlier four events recorded within the 1.5 meters deposit between 4600 to 6500 Cal BP. The average recurrence interval for the last three events is obviously longer than that for the earlier four events. This result implies a possible change of paleoearthquake recurrence patterns during the Holocene along the Lucaowan – Shibaocheng segment of the eastern Altyn Tagh fault.

P-4812

Surface deformation features associated with MW=5.4 Pohang earthquake, SE Korea, 2017

Kwangmin Jin, Hong-Jin Lee

Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

The Korean Peninsula has been historically considered to be tectonically stable compared with neighbouring countries (e.g. China, Japan, Taiwan), since it is located within the Eurasian intracontinental region. However, quite recently, two moderate earthquakes hit Gyeongju ($M_w=5.8$; September 12, 2016) and Pohang ($M_w=5.4$; November 15, 2017) areas in southeast Korea, those are the largest earthquakes in South Korea since the modern instrumental recording period. The Pohang earthquake occurred in the northern part of Pohang city with a very shallow depth (~ 4 km). According to the focal mechanism, it triggered by the reverse fault movement with minor strike-slip component. However, surface ruptures associated with the earthquake have not been reported. This is despite some buildings, roads, bridge, and wall being moderately or severely damaged as a result of sudden ground shaking associated with the earthquake. Although the surface fault have not been developed, various types of surface deformation features were broadly developed. We immediately conducted field investigation on surface deformation features, such as ground cracks, ground failure, rock falls, uplift of buildings, and liquefaction, etc. Moreover, we traced and measured the damaged elements on cracks of road and ground, failure of ground and slope, uplift of buildings. Based on the field data, we tried to predict to subsurface deformation features associated with the earthquake. Finally, we suggest that surface deformation features of the Pohang earthquake were coincided with reactivation of subsurface pre-existing high-angle of reverse fault.

P-4813

The movement history of the southern part of the Yangsan Fault Zone, Gyeongsang Basin, Korea

Ji-Hoon Kang¹, Chung-Ryul Ryoo²

¹Department of Earth and Environmental Sciences, Andong National University, Andong, Korea, Republic of,

²Geology Division, Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

The Yangsan Fault Zone (YFZ) was developed into the NNE trend in the Gyeongsang Basin, the southeastern part of the Korean Peninsula, and the Quaternary faults have been reported in the YFZ up to recently. This study suggests that the tectonic movement of the southern part of YFZ can be explained at least by two different strike-slip movements, named as D1 and D2, and then two different dip-slip movements, named as D3 and D4. (1) D1: a sinistral strike-slip movement, which caused the bedding of sedimentary rocks to be high-angled toward the main fault of YFZ, formed the (E)NE trending open fold in the earlier phase and the (N)NE trending tight fold in the later phase. (2) D2: a dextral strike-slip movement, which was marked by the slipping of the high-angled beddings as fault surfaces, formed the predominant sub-horizontal slickenlines and sub-vertical slickensides and the main fault rocks of YFZ. The second order R and R' faultings and X faulting occurred in the earlier and later phases, respectively, and formed the sigmoidal drag folds accompanied with these movements. (3) D3: a conjugate reverse-slip movement slipped along fault surfaces which trend (E)NE and moderately dip (S)SE or (N)NW. The slickenlines, which plunge in the dip direction of fault surfaces, overprint the previous sub-horizontal slickenlines. The fault is characterized by S-C fabrics, which were superimposed on the D2 fault gouges, and fault surfaces, which show ramp and flat geometry, and formed the asymmetric and drag folds and collapse structures accompanied with it. The D3 dispersed the orientation of the main fault surface of YFZ. (4) D4: a Quaternary reverse-slip movement offset the Quaternary deposit, and formed S-C fabrics on it. The D4 fault surfaces are developed in the extensions of the D3 fault surfaces of basement rocks, like the other Quaternary faults within YFZ. It indicates that these faults were formed under the same compression of (N)NW-(S)SE direction. And after that, the active faults are assumed to occur in the Korean Peninsula under the compression of ENE-WSW direction.

Database of the paleoseismological surveys on active faults in Japan

Takashi Azuma

Geological Survey of Japan/AIST, Tsukuba, Japan

Geological Survey of Japan/AIST has opened the Active Fault Database of Japan since 2005. This database contains results of paleoseismological surveys on active faults in Japan, which were published in scientific journals and surveys reports. Active fault traces in this database are divided to "behavioral segment" based on both of the faulting events and geometry of them. Several segments close to each other make "fault system" that could generate large earthquakes with multiple ruptures.

Current version of the database includes 583 behavioral segments and 320 fault systems. Each behavioral segment is evaluated in length, trend, dip, slip-rate, timing of the last faulting event, average recurrence interval, ratio of elapsed time and 30-years-probability of the future faulting event. For calculation of 30-years-probability, time-dependent model is used for behavioral segments of which both of a recurrence interval and age of the last faulting event are known, whereas Poisson model is used for them of which only a recurrence interval is known.

Recurrence interval is one of the important paleoseismological data to calculate the ratio of elapsed time and the 30-years-probability. However, only 63 behavioral segments were known there recurrence intervals based on paleoseismological surveys. And, for 33 behavioral segments, recurrence intervals are estimated by the ages of more than 3 faulting events, whereas recurrence intervals for the other 30 segments are calculated based on the ages of only 2 faulting events. Furthermore, for other 135 segments, average recurrence intervals are calculated by their slip-rate and the amount of slip per event. The age of the last faulting event are another important paleoseismological data. In the Active Fault Database of Japan, those of 208 behavioral segments are contained. The age of most recent events on 47 behavioral segments are related to historical earthquakes recorded in documents.

Geomorphic and paleoseismic investigation along the central part of the Ulsan Fault at Singye-ri, Gyeongju, SE Korea

Su-Ho Jeong, Sambit Prasanajit Naik, Young-Seog Kim
Pukyong National University, Busan, Korea, Republic of

The Ulsan Fault is the one of the major active fault in SE Korean Peninsula. The NNW-SSE trending Ulsan Fault is a reverse dominant oblique slip fault dipping to the east and extends ~50 km on land. Along the central part of the Ulsan Fault, especially Singye-ri area, several sub-parallel faults and dome-shaped hills are developed. To understand the topographic formation process and propagation process in the central part of the Ulsan Fault, detailed geomorphic analysis using remote sensing data and paleoseismic investigation were carried out.

First of all, we deciphered the old aerial photo and DEM (Digital Elevation Model) produced by 1:5,000 digital map. From the analyses, several lineaments, deformed alluvial fans, and back-tilted surfaces were identified. Extracted lineaments are well matched with the slope changing positions where induced to develop the back-tilted surfaces. Along this zone, we could not observe any clear evidence of river erosion. indicating dominance of tectonic deformation in the mechanism of these geomorphic features. Second, on the basis of aforementioned data, we investigated all streams flowing perpendicular to the fault. During the fieldwork, we found several fore-thrust dipping to the east and back-thrust dipping to the west. The locations of these faults are well-matched with lineament and slope transition zone. Both fore- and back-thrust displaced Quaternary layers indicating Quaternary activity. For further detailed study, we have collected OSL and 14C samples. After obtaining age data, we could understand the formation process of back-tilted surface and propagation of central part of the Ulsan Fault.

Luminescence dating of terrestrial sediments in Quaternary faults along the Yangsan and Ulsan Faults, South Korea

Jeong-Heon Choi¹, Tae-Ho Lee¹, Young-Seog Kim², Moon Son³, Albert Chang-sik Cheong¹

¹Korea Basic Science Institute, Cheongju, Korea, Republic of, ²Pukyong National University, Busan, Korea, Republic of,

³Pusan National University, Busan, Korea, Republic of

The Korean peninsula, located in the eastern margin of the Eurasian plate, has long been regarded as a tectonically stable region. However, since the early 1990s when luminescence dating emerged as one of the useful tools for Quaternary dating, a growing number of chronological evidence has revealed that not a few faults in the Korean peninsula, particularly in its southeastern part, were active during the Quaternary (Choi et al., 2003a, b). In addition, in the last few years, two consecutive earthquakes occurred in southeastern Korea, one in Gyeongju (M_L 5.8, 12 Sep. 2016) and another in Pohang (M_L 5.4, 15 Nov. 2017), which have drawn keen national-wide attention to seismic safety of Korea. Recently, along the Yangsan and Ulsan Faults (SE part of the peninsula), unconsolidated terrestrial sediments were found to be cut by two age-unknown faults (Byeog-Gye and Cheon-Gun faults), thus establishing chronology of these sediments is expected to provide essential information to reconstruct the history of the fault movements. To figure out the depositional ages of the sediments, we applied luminescence dating methods using various signals in quartz and feldspars; these are conventional optically stimulated luminescence (OSL), thermally transferred OSL (TT-OSL) and isothermal thermoluminescence (ITL) signals for quartz and post infrared-infrared stimulated luminescence (pIR-IRSL) signals for K-rich feldspars. For both Byeog-Gye and Cheon-Gun sites, with the measurement protocols and materials that passed through several suitability tests, we obtained luminescence ages of ~ 60–100 ka for sediments cut by the faults. Also, it appears that both faults are covered by the late Holocene (Meghalayan Stage) sediments (~ 2–3 ka). These age constraints argue against the conventional view that the Korean peninsula has been tectonically stable during the Quaternary.

Dual polarimetric GPR survey for investigation of quaternary seismic faults

Takao Kobayashi, Jin-Hyuck Choi, Seung Ryol Lee

Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, Republic of

A quaternary seismic fault holds records of seismic history of the area. Mapping and studying quaternary seismic faults of an area provide us important information for evaluating potential hazards of the area. Geophysical exploration techniques are practical method to investigate faults. Ground Penetrating Radar (GPR) is one of such geophysical exploration tools. A GPR transmits radar pulses (electromagnetic waves) into the subsurface to receive echo pulses that are reflected from objects. Analyzing received echoes, one can obtain information about subsurface structure.

GPR has long since been put in the field of fault study, and the results have been reported in literatures. A quaternary fault, however, has turned out to be rather a difficult target for GPR for two reasons. Firstly, the difference of dielectric constant of materials over the fault face is very small, which makes a radar echo from the boundary very weak. Secondly, the fault face in most cases is a vertical boundary rather than a horizontal one hence much of incident GPR pulse energy is deflected to directions off the surface, which makes the received echo even weaker. The problem has been managed by applying signal processing technique to the measurement data. However, one has to know that some processing such as filtering process can spoil the target signal whereas deconvolution process, which is practiced to enhance the target signal, could introduce false information into the processed data.

In this paper, we propose dual polarimetric GPR measurement as an alternative technique to manage the problem. The proposed technique carries out 2-D GPR survey on the ground surface twice using two polarizations which are orthogonal to each other (single polarization in a 2-D survey). This technique produces two polarization measurements data at every measurement point in the survey area. Vertical boundary does not return strong coherent radar echoes but weak incoherent scattering echoes whereas subsurface objects that are larger than the scale of wavelength of GPR pulse returns strong coherent echoes which mask weak scattering echoes. We take difference of two measurements to cancel the strong coherent echoes. Weak scattered echoes from fault face might be spoiled by this operation to some degrees, but, echoes thanks to its incoherent nature, the degree of being spoiled is much smaller than that for the case of coherent echoes.

We have so far examined this technique by applying to a liquefaction vestige which was found after the M5.2 earthquake that had taken place on 14, November in 2017 in South Korea. A 100 MHz GPR was used in the test. The effect of technique was confirmed by improved GPR image of the thin vertical flow pass of ground water.

Late Holocene shoreline deformations along the Gökova Bay, SW Turkey

Cengiz Yıldırım¹, Murat Ersen Aksoy², Orkan Özcan¹, Peter Salvatore³, Mehmet İşiler⁴, Volkan Özbey⁴, Attila Çiner¹, Mehmet Akif Sarıkaya¹, Turhan Doğan⁵, Erhan İlkmen⁵

¹Eurasia Institute of Earth Sciences, Istanbul Technical University, İstanbul, Turkey, ²Department of Geological Engineering, Muğla Sıtkı Koçman University, Muğla, Turkey, ³Yeşilköy, İstanbul, Turkey, ⁴Department of Geomatics Engineerings, Faculty of Civil Engineering, Istanbul Technical University, İstanbul, Turkey, ⁵Earth and Marine Sciences Institute, TUBITAK Marmara Research Center, Kocaeli, Turkey

Gökova Bay is located in the south Aegean Sea and is one of the most seismically active regions in Western Turkey. One of the challenging aspects of the seismic hazard assessments in the region is the offshore faults. There is almost no information about their paleoseismic activities. In contribution, we carried out fieldwork along the shorelines of the bay and strive to identify the geomorphic and sedimentological markers of modern and historical coseismic deformations. We started from Bodrum area (the largest coastal touristic centre) right after the 21 July 2017 Bodrum-Cos (Mw: 6.6) Earthquake. We found co-seismically uplifted (20 cm) tidal-notches associated with this earthquake together with up to 80 cm a.s.l. uplifted beach deposits on Karaada Island (1 km South of Bodrum). Radiocarbon (¹⁴C) ages from uplifted beach deposits yield 2800±30 yr BP (uncalibrated) indicating late Holocene seismic activity. There are also geomorphic markers of historical coseismic uplift along the southern and northern shoreline of the bay. We could not find datable material from the southern shores but the presence of uplifted tidal notches at 40 cm to 120 cm higher than modern sea level was ample. Nevertheless, tidal notches are higher along the northern shores of the bay. We identified at least 5 levels of tidal notches, which are at 20 cm to 170 cm higher than modern sea level. Radiocarbon (¹⁴C) age of a lithophaga fragment from 100 cm high tidal notch yielded 2314±32 yr BP (uncalibrated). Although there are no other age data from higher and lower levels for the time being we plan further research on the area. This contribution provides first evidence of the presence of coseismically uplifted shorelines along the Turkish coasts of the Aegean Sea. It also demonstrates the presence of active faults very close to the shoreline that are capable of producing large earthquakes and might be important for the regional seismic hazard. This project is supported by TUBITAK 1002 Program (Project No: 118Y116) and Istanbul Technical University Research Fund (Project No. TGA-2018-411184).

Archaeoseismic evidence for a Late Roman earthquake in Ceuta (northern Africa)

Klaus Reicherter¹, Dario C. Bernal², Fernando Villada Paredes³, Alexander von Scheele¹, Jose Luis Portillo Sotelo², Jose Alberto Retamosa Gámez²

¹Inst. of Neotectonics and Natural Hazards, RWTH Aachen University, Aachen, Germany, ²Área de Arqueología, Departamento de Historia, Geografía y Filosofía, Universidad de Cádiz, Cádiz, Spain, ³Ciudad Autónoma de Ceuta Ángulo de San Pablo, Ceuta, Spain

We present the first archaeoseismic evidence for earthquake damages in Northern Africa, in Roman buildings in the Spanish city of Ceuta. Strong earthquakes above a Richter magnitude of M 5.5 usually leave traces on the Earth's surface along a fault, which are mapped and evaluated. In addition, there are other earthquake effects, such as soil liquefaction or mass movements, e.g. landslide, which can also occur away from the fault. This does not necessarily include collapsed buildings, so-called archaeoseismological studies. This requires very detailed knowledge of the buildings, their history and architecture and any structural modifications or changes in use over time and cooperation with archaeologists and other professionals. In Ceuta, we have almost no large outcrops and access to geological features and structures. In the 1540s the Portuguese invaders began building the Royal Walls including bastions, like the Baluarte de la Bandera. The bastion is built on Arabic and Roman remains dating back to the first century AD. In the excavations of the fortress, many open cracks in the masonry and foundation could be documented. The cracks are often traceable over several meters and rotated Roman walls of a tower constructed very late second AD/early third century AD (*terminus post quem*) in an anti-clockwise sense. Most probably, an impulsive event led to the tearing of the bedrock and rotation of the wall in the foundation. The well-known building history of the fortress and its predecessor buildings and dates suggest a "late Roman" destruction phase in the second half of the 7th century (younger than 650 AD; *terminus ad quem*), documented in several places. We present T-LiDAR scans and an assessment of the structural damage. The historical earthquake catalogues do not contain a strong event at the wake of the Dark Ages. The causative fault may be situated at along the nearby contact of Alpujarride and Malaguide complexes in Ceuta peninsula, that may have been reactivated. However, we cannot exclude a far-field earthquake within the geodynamical context of the Straits of Gibraltar.

P-4820

Far-field effects induced by the 2016 Oct. 30th Central Italy earthquake on Roma historical monuments: the Necropoli Ostiense case study

Daniele Spizzichino¹, Gabriele Leoni¹, Luca Maria Puzzilli¹, Luca Guerrieri¹, Marina Marcelli², Cristina Carta²

¹ISPRA, Roma, Italy, ²Sovrintendenza Capitolina ai Beni Culturali, Roma, Italy

The 2016 October 30th Norcia earthquake has been the largest main shock (Mw 6.5) of a seismic sequence that affected Central Italy since 2016 August 24th, causing more than 300 casualties and very large damage in Amatrice and surrounding villages (MCS intensities up to X-XI).

The event was clearly felt all around in Central Italy and even in Rome, at a linear distance of about 130 km, where it caused locally damages, especially to historical buildings, and threatening the stability of some infrastructures. In a few hours almost 200 surveys were conducted with the aim to verify effects (mainly fissures and cracks) on both historic and modern buildings. Strongest damages were concentrated mostly in the southern area of the city centre: in particular, the San Paolo basilica was closed to verify local instabilities, after the opening of cracks and fall of cornice's pieces. Similar damages were also observed on other relevant historical and artistic monuments (e.g. Porta Portese gate, Sant'Ivo alla Sapienza church and San Lorenzo and Santa Maria Maggiore basilicas).

Immediately after the earthquake, ISPRA experts in cooperation with local archeological superintendence authorities were asked to implement a damage assessment in the Necropoli Ostiense archaeological site, located next to the San Paolo basilica. This is the best preserved part of a vast necropolis, flanking the eastern side of the ancient via Ostiensis, within the alluvial plain of Tiber river and it lays at the foot of a 20 meters high cliff, made with pyroclastic deposits.

The whole archaeological site was affected by a set of N-S trending parallel cracks presumably induced by the earthquake. In order to characterize with great detail this site in terms of geology and stratigraphy, an active seismic survey was carried out in the archaeological site, by using the surface-waves method, aimed at the characterization of alluvial deposits in terms of shear waves velocity (V_s), that is a parameter directly related to stiffness of buried material. After a preliminary survey (November 2016), according to the above evidences and to the original hypothesis that the observed crack pattern are co-seismic effects induced by the seismic shaking, a simple manual crack gauge network on 5 main discontinuities was implemented and installed. The general stability of the cracks seems to confirm the hypothesis of a single shock due to the earthquake's dynamic input. The relationship between the Necropoli and the neighboring Tiber's valley has been also investigated. Further geophysical surveys will allow to better define the interaction between archeological structures and underground setting.

These actions are needed to characterize the impact of strong earthquakes from Central Apennines on cultural heritage in Roma in order to identify proper mitigation measures.

P-4821

Cone penetrating testing and continuous coring combine to infer a mid-term plate-boundary slip rate for the Imperial Fault, California

Thomas Rockwell¹, Yann Klinger², Drake Singleton¹, Yuval Levy¹, Koji Okumura³

¹San Diego State University, San Diego, USA, ²Institut de Physique du Globe, Paris, France, ³University of Hiroshima, Hiroshima, Japan

We collected cone-penetrometer (CPT) soundings and continuous cores to extend the subsidence record for a sag depression along the high-slip section of the 1940 Imperial fault rupture where 6 m of right-lateral slip was documented. The Imperial fault is the main plate boundary fault at the international border with Mexico and has been interpreted in the past to accommodate up to 40 mm/yr of plate boundary shear. The site is a 20 m-wide releasing step along the rupture, and sustained about 90 cm of subsidence in the 1940 earthquake. Previous paleoseismic work at the site has demonstrated that earlier earthquakes in ca 1726 and 1500 produced nearly identical amounts of vertical subsidence in the sag suggesting that they also likely sustained a similar amount of dextral slip. In contrast, two other interpreted earthquakes produced 0-6 cm of subsidence and were interpreted to be the result of moderate earthquakes, as occurred in 1979.

Two cores and 26 CPTs were acquired across the sag that penetrated a succession of lake and deltaic deposits to ~25 m depth: the sediments west of the fault date to about 4500 years at the base of the core whereas in the sag itself, the sediments are about 2-2.2 ka at 25 m depth. Thus, the sag records about 8 m of vertical subsidence in the past 2.2 ka, which suggests the occurrence of about 9 events if the 1940 and 1726 events are used as a guide. This results in an average recurrence interval for such events of about 230 years (considering the ~80 year open interval). If each of these larger events was produced by a similar amount of strike-slip as in 1940, then this implies a slip rate of about 26 mm/yr, which is consistent with recent InSAR and GPS studies that suggest a lower rate with additional slip on faults to the west.

P-4822

Surface Ruptures Following The 26 December 2018, Mw4.9, Mt. Etna Earthquake, Sicily (Italy)

EMERGEO WG

Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

The Mw4.9, Mt. Etna earthquake occurred on 26/12/2018 at a depth of about 1 km (<http://cnt.rm.ingv.it>). The event struck the southeastern sector of the volcanic area producing severe damage in several towns. The earthquake was likely induced by the magmatic dike intrusion of Mt. Etna accompanied by deformation of the volcanic edifice and thus generating the stress redistribution in the surrounding faults. The Mw4.9 causative fault is the Fiandaca fault (FF), belonging to the Timpe tectonic system in the eastern flank of the Mt. Etna (Fig. 1).

The FF is NW-SE oriented and turns in ~NS direction in the southern portion. The fault is locally characterized by aseismic slip and in the past by coseismic surface ruptures.

The EMERGEO group (geological emergency group of the Istituto Nazionale di Geofisica e Vulcanologia) promptly activated to map the coseismic ruptures along the FF. The survey is presently ongoing. About 1000 points of measurements relative to geometry and kinematics of the ruptures have been collected so far (Fig. 1).

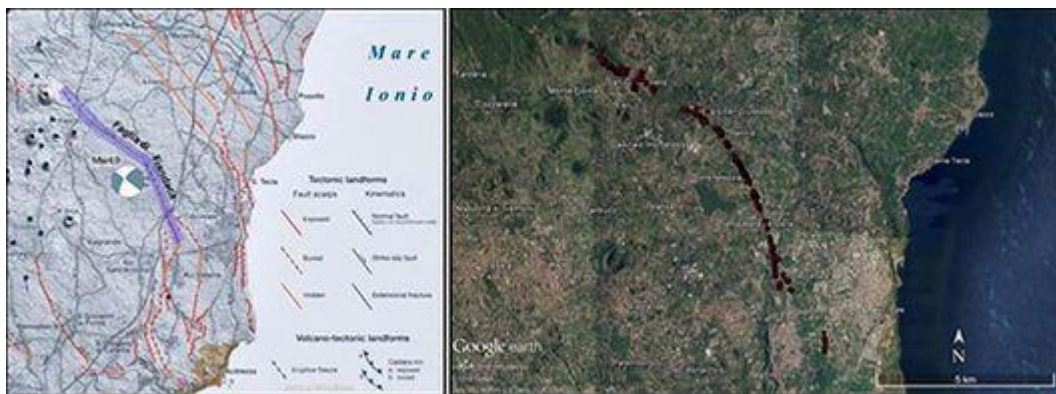

Fig. 1 – Left: Active faults in the south-easternmost flank of the Mt. Etna (Azzaro *et al.*, 2012). Light blue band includes the area of coseismic ruptures surveyed by EMERGEO WG along the Fiandaca fault. The TDMT solution of the event is placed at the epicentral location (<http://cnt.rm.ingv.it>). Right: Points of measurements (red circles) collected by Emergeo WG (from 26/12/2018 to 5/01/2019).

We documented significant surface faulting for a minimum extent of 7 km. The ground ruptures are aligned and continuous along the FF, displacing coherent and incoherent deposits and anthropic materials (Fig. 2). They exhibit right lateral transtension, with values of slip also of 30 cm. The main deformation zone is tens of meter wide and is composed by sub-parallel rupture traces in a left-stepping en echelon arrangement. Where present, ruptures occur in coincidence to the long-term expression of the fault, that is generally expressed as a topographic inflection. Intense damage at buildings is localized over and close to the ground rupture “line”.

The integration of the geological data with seismological and geodetic data will lead to an accurate comprehension of the seismic process. Given the accurate mapping of the ruptures, the 2018 Mt. Etna earthquake represents a

fundamental case to analyze the hazard associated to ground displacement along the faults in Mt. Etna area, and to increase our knowledge on surface faulting process in volcano-tectonic environments.

Fig. 2 – Coseismic ruptures of the Mw4.9 event.

Structural architecture and glacitectonic evolution of the Mud Buttes cupola hill complex, southern Alberta, Canada

Emrys Phillips¹, David Evans², Nigel Atkinson³

¹British Geological Survey, Edinburgh, United Kingdom, ²Durham University, Durham, United Kingdom, ³Alberta Geological Survey, Edmonton, Canada

The Mud Buttes in southern Alberta (Canada) is a large, arcuate cupola hill composed of intensely folded and thrust sandstones, siltstones and mudstones of the Cretaceous Belly River Formation. It forms one of a number of glacitectonic compressional structures (e.g. Neutral Hills) which occur within a geomorphologically complex area separating the strongly streamlined trunks of the former Central Alberta and Maskwa palaeo-ice streams. Glacitectonism responsible for the development of the internally complex Mud Buttes landform occurred at the margin of the Prospect Valley glacier lobe of the Laurentide Ice Sheet. Analysis of the deformation structures reveals that construction of this landform occurred in response to at least two phases of south-directed ice sheet advance separated by a period of retreat. The first phase led to the formation of a forward propagating imbricate thrust stack leading to polyphase deformation of the Belly River Formation. D1 thrusting led to the detachment of thrust-bound slices of bedrock which were accreted to the base of the developing imbricate stack. This process resulted in the structurally higher and older thrust-slices being progressively “back-rotated” (tilted), accompanied by D2 thrusting and folding. Further thrusting during D3 was restricted to the core of the Mud Buttes as the deforming sequence accommodated further compression imposed by the advancing ice. Minor oscillations of the ice margin led to localised brittle-ductile shearing (D4) of the bedrock immediately adjacent to the ice contact part of the thrust stack. The second ice advance led to the accretion of a relatively simple thrust and folded sequence seen on the northern side of Mud Buttes. The resulting glacitectonic landform was subsequently overridden by ice advancing from the north-northwest.

The potential of periglacial slope deposits for chronological studies on glacial sediments in the Central Spanish Pyrenees

Florian Hirsch, Thomas Raab

Brandenburg University of Technology Cottbus-Senftenberg, Geopedology and Landscape Development, Cottbus, Germany

Due to the diamictic character and the complex depositional environment of glacial deposits chronological analyses on these deposits are often problematic. The post-LGM reshaping of glacial sediments in a periglacial environment often resulted in the formation of so-called periglacial slope deposits (PSD) that are mainly characterized by solifluction and the aeolian admixture of silt. Our study presents findings from glacial sediments in the Central Spanish Pyrenees that were associated with an MIS 3 glaciation. The presence of periglacial deposits that have OSL ages between 14 ka to 11 ka raise doubts about the MIS 3 age of the glacial deposits. According to the state of knowledge, the glacial advances in the Eastern Pyrenees were synchronous with the global LGM during the Late Pleistocene (MIS 2), but the glacial advances in the Central Spanish Pyrenees at MIS 3 were asynchronous with the global LGM. Whereas in the Eastern Pyrenees the glacial advances are dated in several well agreeing studies by surface exposure dating of boulders from lateral or terminal moraines, the asynchrony of the Central Spanish Pyrenees was postulated mainly by OSL dating on glacial and fluvial sediments and on radiocarbon dating of pollen from lacustrine deposits. We therefore applied a combined approach of geomorphological, sedimentological and pedological investigations to reconstruct the Late Quaternary landscape development under a special consideration of periglacial deposits in the Aragon- and Gallego Valley of the Central Spanish Pyrenees. Our study reveals that in both valleys the Pre-Holocene geomorphodynamics on the Late glacial deposits show clear analogies with findings from Pleistocene periglacial landscapes in Central Europe. For MIS 4 and early MIS 3 periglacial processes are proven by loess deposition and formation of solifluction sediments. The glacial sediments, which were dated in earlier studies into mid MIS 3 and counted so far as prove for the asynchronous LGM of the Central Spanish Pyrenees, are covered by periglacial deposits of Late glacial age (14 ka to 11 ka). Because we can clearly differentiate further phases of geomorphodynamics during the Holocene with truncated soil profiles and the correlate sediments of soil erosion next to undisturbed soils in periglacial sediments with a Late glacial age, we challenge the thesis of an asynchronous LGM in the Central Spanish Pyrenees and advocate a synchronous LGM in the Gallego- and Aragon valley analog to the Eastern Pyrenees.

P-4825

Erosion landscape on the East European plain, formed in periglacial conditions and its recent analog at the Yamal peninsula

Aleksey Sidorchuk, Andrei Entin
Moscow State University, Moscow, Russian Federation

One of the most interesting features on the East European Plain is the net of dry valleys and hollows. Dense vegetation usually covers their bottoms and slopes, so the modern erosion here is negligible in the pristine conditions. Coring in these valleys showed the features and deposits of at least two erosion events, first during late MIS-6 and the second during late MIS-2. The both periods were characterized by periglacial conditions with low air temperatures and deep permafrost, as well as very high surface runoff. The structure of these systems of dry valleys and hollows is well described with power-law magnitude-frequency relationships, close to determinations of the fractal theory. These power-law relationships don't act only near and within the belt of no erosion, where probability distribution functions of morphometric characteristics takes another form.

The same type of the erosion landscape is typical for the Arctic regions with the modern periglacial conditions, especially for Yamal, Gydan and Tazovskiy peninsulars. The size, density and structure of such valleys and gullies is quite similar to those on the East European Plain, but these features are active there (especially in the conditions of natural or anthropogenic vegetation cover deterioration). Therefore, the landscape and hydrological conditions at the modern belts of no erosion in Arctic, can be used to reconstruct the same characteristics of the erosion landscape in former periglacial conditions, first of all, typical values of the critical velocities of erosion initiation. Gully erosion and thermoerosion model was used to find the most suitable values of these critical velocities, which can explain the structure and density of dry valleys systems on the East European Plain.

This study was developed under RFBR grant 18-05-60147 "Extreme hydrometeorological phenomena in the Kara Sea and the Arctic coast"

P-4826

Pleistocene Periglacial Slope Deposits (PPSD) in the mid-latitudes - Is a trans-regional genetic classification reasonable?

Thomas Raab¹, Florian Hirsch¹, Patrick Drohan²

¹Brandenburg University of Technology Cottbus-Senftenberg, Geopedology and Landscape Development, Cottbus, Germany, ²The Pennsylvania State University, State College, USA

Pleistocene Periglacial Slope Deposits (PPSDs) are very common in the mid-latitudes and fundamentally control the distribution and properties of the soil's parent material. The main distribution areas of PPSDs are regions more or less close (tens to hundreds of kilometres) to the ice limits of the Last Glacial Maximum (LGM) where permafrost conditions during Quaternary cold periods have favoured the formation of slope sediments by solifluction, cryoturbation and eolian processes. In mainland Europe this area stretches over hundreds of kilometres from the Weichselian ice-margin in the North European Lowland to the Central European low mountain ranges. This "periglacial corridor" between the LGM of the Scandinavian Ice Sheet (SIS) and the Alpine Piedmont Glaciation (APG) has been subject of PPSD studies for more than 50 years, and the basic concept of PPSD stratigraphy has been established starting with the description of type localities in central Germany by Semmel in 1964 and Schilling & Wiefel in 1962. In North America the effect of Late Quaternary periglacial processes on soil is increasingly acknowledged but stratigraphic PPSD concepts based on facies description that consider the environmental conditions of PPSD formation (e.g. clast fabric orientation as a matter of gelifluction, increased silt+clay content resulting from eolian admixture) have rarely been applied. A genetic taxonomy of PPSDs comparable to the one that has been used in Germany for many years is entirely missing in mapping units of Pedology and Quaternary geology. Instead of a genetic taxonomy of PPSDs an effective classification is applied based on facies-neutral properties (mainly textural and lithological parameters), and sediments of periglacial origin are mostly called colluvium. Unfortunately, the term colluvium has different meanings in North America and Europe creating further confusion in discussions. Though there are obvious terminological differences, relicts of periglacial dynamics have actually been very well known for many areas in North America and especially for the Appalachian Highlands and Interior Highlands south of the maximum extent of the Late Wisconsin Laurentian Ice Sheet (LIS), e.g. in central Pennsylvania. This contribution seeks to close a gap between North America and Europe regarding the knowledge of PPSDs and the usage of a genetic PPSD classification. We intend to start a discussion on a coordinated transcontinental approach which is needed to achieve a harmonized PPSD taxonomy. Main questions for this international research are: (i) what findings from the NE USA match with results from PPSD studies in Central Europe, (ii) is the German PPSD taxonomy suitable for a proper classification of PPSDs in NE USA, (iii) what could an international PPSD taxonomy look like and is a genetic classification feasible?

P-4827

Reconstruction of high- and low-drag alpine glaciers in the Little Ice Age: implications for palaeoclimatic inferences from former glaciers

Martin Kirkbride¹, Ramon Pellitero-Ondicol², Michael Brown¹

¹University of Dundee, Dundee, United Kingdom, ²Universidad Nacional de Educacion a Distancia, Madrid, Spain

Basal shear stress represents the driving stress required to overcome frictional resistance to glacier flow. Modelled reconstructions of former glaciers conventionally use a value of 100 kPa^{-1} based on the yield stress of perfectly plastic ice. This allows construction of longitudinal profiles from which topographic maps of glacier surfaces are used to calculate hypsometry and equilibrium line altitudes (ELAs). We test the universality of the 100 kPa^{-1} yield stress by reconstructing longitudinal basal shear stress profiles from glaciers in the western Alps based on their Little Ice Age (LIA) extents. Glacier retreat from LIA maximum terminal moraines (c. 1820-1860) has created forelands of well-preserved subglacial and ice-marginal landforms. Landform-based reconstructions are checked against the cartographic representations of glaciers in the 1862 Carte d'État Majeur. Ten glacier forelands are used to reconstruct LIA maximum glaciers and cross-sectional form ratios, from which basal shear stress (τ_b) profiles are calculated empirically for former ablation zones. These reveal that few glaciers conform to the conventional τ_b of 100 kPa . We find that glaciers resting on till beds averaged $59 \pm 29 \text{ kPa}^{-1}$, and glaciers on scoured rock beds averaged $151 \pm 72 \text{ kPa}^{-1}$, while two glaciers with mixed till and bedrock beds had mean τ_b of 113 kPa^{-1} and 145 kPa^{-1} . At one glacier overburden stress was calculated from laboratory oedometer testing of a till block, which implied a lower shear stress than calculated from geomorphological evidence.

The spread of values indicates that basal shear stress accumulates to overcome those bed elements imparting the greatest resistance to ice flow. The implication for glacier reconstruction is that an appropriate shear stress should be used to model a glacier long profile where geomorphological evidence of former bed conditions is preserved. We then examine the sensitivity of reconstructed ELAs of Younger Dryas age glaciers to basal shear stresses ranging from $\tau_b = 50 \text{ kPa}^{-1}$ to 150 kPa^{-1} . We find that the effect on ELA and palaeoclimatic reconstruction is potentially significant, but only if a uniform bed resistance is applied to the entire long profile. More realistic iterations suggest ELA is not critically sensitive to shear stress differences in the lower glacier. In the field it has proved hard to determine how extensive former till beds were in the alpine environment, due to rapid post-depositional reworking of frost-susceptible basal tills. We suspect that such low-drag bed conditions have been widely underestimated in existing reconstructions.

P-4828

Glacial vs. periglacial forming in Central Germany during the Pleistocene – examples from the Hohburg Mountains and the Rhoen Mountains

Christian Opp

University of Marburg, Marburg, Germany

After Otto Martin Torell's speech in Berlin 1875, it became accepted, that the Pleistocene Scandinavian glaciation had covered large parts of the Central European Lowland and some of the highland mountain areas. 31 years before Torell's speech, Bernhard von Cotta, Carl Friedrich Naumann, and Adolph von Morlot had already described independently both glacial and periglacial traces in the Hohburg Mountains, a transaction site northeast of Leipzig, located between the German Highlands and the North-German Lowland. But Charles Lyell and Albert Heim, who had already studied glacial traces in the Swiss Alps, still declined the glacial traces of the Hohburg Mountains in 1874 as purely periglacial features. Later on and until today, the glaciation of the Hohburg Mountains during the Saalian glaciation became recognized as well as the periglacial forming during the Weichselian glaciation. Results of geomorphological field survey and both field and laboratory analyses of the sediments prove the glacial and periglacial forming of the Hohburg Mountains.

Some authors (c.f. Liedtke 1981, Rother 1995, Raab 1999) presented clear evidence of the mountain glaciation of the Black Forest, Bavarian Forest and Harz Mountains during the Pleistocene. Until now the autonomous glaciation of the Ore Mountains and of the Rhoen is declined by most of the authors. But others, c.f. Härtung, described the relief forms as of both glacial and periglacial origin in different locations of the Rhoen Mountains throughout the 20th century's literature. Geomorphological field surveys and both field and laboratory analyses of these sediments, conducted during the last two decades, showed no glacial forming features. However, the largest and mightiest fossil rock glacier and block accumulation in Germany was identified in the Rhoen Mountains. The Schafstein rock glacier is a clear evidence of a strong periglacial influence of the Rhoen Mountains during the Pleistocene. Results of its characterization (cf. block sizes, block roundness), refraction seismic profiles, temperature measurements between the blocks and drone based IR camera measurements will be presented.

P-4829

Schmidt hammer exposure-age dating of (peri-) glacial landforms thanks to R-values calibration by historical data in the Southern Swiss Alps

Cristian Scapoza¹, Christian Ambrosi¹, Chantal Del Siro², Christophe Lambiel²

¹Institute of Earth Sciences, University of Applied Sciences and Arts of Southern Switzerland, Canobbio, Switzerland,

²Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland

Within the framework of scientific researches related to geomorphoclimatical evolution of the Alps during Lateglacial and Holocene, only few studies were carried out on periglacial sedimentary terrains. In order to reconstitute the palaeoenvironmental history of the alpine periglacial domain, this research has focused on the morphostratigraphy of periglacial and glacial landforms of the Splügenpass region (transnational pass between Switzerland and Italy) and of the upper part of Val Scaradra (north-eastern part of the Ticino Canton).

The surface dating was performed with the analysis of Schmidt hammer rebound values (R-values). The joint utilisation of palaeogeographical method, allowing the reconstruction of past glacier and rock glacier extensions, and the definition of age-calibration curves of R-values on historical constructions and thanks to historical cartography, allowed Schmidt hammer exposure-age dating (SHD) and the definition of relative chronologies with high temporal resolution.

In the Splügenpass region, Schmidt hammer R-values measured on metagranite porphyr were calibrated thanks to two historical retaining walls for a mule track, attributed respectively to the Roman Epoch (1.65 ka cal BP) and to the Late Middle Ages (0.7 ka cal BP). Thanks to SHD, it was possible to establish a chronology of the Lateglacial glacier retreat and to date rock glaciers and talus slopes development. The results show that Splügenpass was ice free since 15.8 ± 2.6 ka cal BP, whereas the Splügenpass rock glacier started its formation during the Lateglacial Interstadial (the minimal age of the front is of 12.6 ± 2.6 ka cal BP).

In the upper Val Scaradra, R-values were measured on large boulders of the proglacial area of the Scaradra glacier composed by micaschists and paragneisses. From a Younger Dryas lateral moraine to the glacier portal, several terminal moraines were studied by SHD in order to determine the glacier fluctuation during the Holocene. Schmidt hammer R-values were calibrated thanks to historical topographic maps of the area: (1) the original relief for the Dufour Map (Topographical Map of Switzerland, sheet OA 443, Feuille XIX. Sect. 2, 1:50'000) cartographed by Hermann Siegfried in 1854; (2) the editions of the Sheet 504/Olivone of the Siegfried Map (Topographical Atlas of Switzerland, 1:50'000; the first edition is from 1872) and; (3) the editions of the Sheet 1253/Olivone of the National Map of Switzerland 1:25'000 (the first edition is from 1966).

The SHD age-calibration based on historical surfaces of known age highlights a non-linear behaviour of surface weathering from the Lateglacial to the Late Holocene. These investigations will also improve the knowledge of the potential use of SHD for numerical-age dating in alpine geomorphological studies, a field of research that is currently rapidly developing and that can be an alternative to Cosmogenic Nuclides dating in the understanding of complex glacial-periglacial-paraglacial landsystems.

P-4830

Lichenometry of wandering blocks approaching the landslide surface velocity

Raúl Perez-Lopez, Gerardo Herrera, Roberto Sarro, Juan C. García-Davalillo, Marta Bejar-Pizarro, Rosa M. Mateos, José A. Fernández-Merodo
IGME - Geological Survey of Spain, Madrid, Spain

Landslides, creep slow movements and rockfalls have been widely studied from modern times by using remote sensing, which goes back up to 20 years by using GPS and INSAR and almost 100 years by using aerial photographs. The use of ancient maps and even old paintings from the 19th century allow going back up to 200 years. In this work, we introduce the use of lichenometry of wandering blocks to estimate the velocity of a landslide located at El Portalet (Central Pyrenees, Spain), by using these blocks (decametric size and limestone lithology) as time and spatial markers. To do this, we have used lichenometry to estimate the age of the blocks and determinate the runout distance traveled by the blocks detached from the source area, by geomorphologic markers. We have obtained the annual growth rate (GR) of the calcicolous lichen specie *Aspicilia calcarea* (Hoffm.) from cemeteries, historical buildings and infrastructures for the last 300 yrs. A lineal GR value of 0.45 mm/yr has been estimated. The oldest block was dated in 600 CE \pm 40 yr. and the modern one in 1750 CE \pm 5 yr. The analysis of aerial orthophotos and field work of the study zone reveals two N- and S-oriented chutes in which wandering blocks were located: the North path (NP) and the South path (SP). The inventory map had been carried out taking in account the wandering blocks disseminated close to 1 km in length from the source area. The lichenometry analysis yields that the block surface velocity varies from 0.3 m/yr to =0.97 m/yr for the NP and 0.2 to 0.88 m/yr for the SP. However, the behavior of both chutes is opposite. Whereas the NP accelerates during warm climate periods and decelerates in the cold ones, on the contrary, the SP velocity decelerated during Medieval Warm Period and accelerated during the Little Ice Age (LIA). Estimations of the block wandering during the Industrial Era are approximated. INSAR and GPS velocity during the last 20 yrs. shows 0.2 m/yr. Clinometers and thermometers in boreholes indicate that during the last 20 years no permafrost was detected. Instead, the rupture plane for the landslide was estimated between 13 and 14 m depth and even 25 m depth for the SP. Differential behavior of both landslides seems to be related with the presence of water, the flux-direction and the presence of natural obstacles at the foot of the landslide.

P-4831

3D mapping and geological subsurface modelling in Helsinki metropolitan area, Finland

Emilia Kosonen, Niko Putkinen, Antti Ojala, Noora Kähkölä, Maarit Saesma, Ossi Ikävalko, Hilikka Kallio, Jukka-Pekka Palmu, Teemu Lindqvist
Geological Survey of Finland, Espoo, Finland

Ongoing urbanization has caused profound changes in land use and construction in larger cities and increased a need for detailed 3D models for specific purposes, such as construction suitability, environmental assessments offshore infrastructure. Helsinki metropolitan area (land 770.35 km²) consist of crystalline bedrock superimposed by Quaternary deposits of glacial, glaciofluvial and glacialmarine in origin. One third of the land area is covered with fine-grained (clayey) sediments with thickness varying from 1 to 35 m. The Helsinki metropolitan area was deglaciated circa 13 000 years ago and the area has undergone lacustrine and brackish marine stages, along with other Baltic Sea basin (BSB) shoreline cities. The metropolitan area emerged from BSB 8000-2000 years ago, and the areas glacioisostatic land uplift is still about 2 mm per year relative to sea level. The urban land cover expansion is increasingly focusing on areas with fine-grained soft and unconsolidated sediments with poorer ground conditions. The need for comprehensive understanding of the engineering geological properties and 3D geometry of these fine-grained superficial deposits has increased.

The present study was carried out in collaboration with the Helsinki metropolitan area cities (Helsinki, Vantaa and Espoo) and Geological Survey of Finland. The combined use of Quaternary maps, LiDAR digital elevation models (DEM) and site-specific geophysical and sediment core investigations together with cities geological maps and geotechnical investigations provide a basis for high-resolution digital terrain characterization and 3D sediment mapping; an integrated approach by the Geological Survey of Finland. This study focuses on the distribution and characteristics of fine-grained deposits and on mapping underlying permeable glaciofluvial sand and gravel deposits and their hydrological parameters.

The fine-grained sediment case studies displayed that deposits (clay basins) consist of two different types of fine-grained units, postglacial lacustrine silty clays and sulphate-bearing brackish water muds, with different engineering-geological properties. These units are separated by an undulating erosional surface (unconformity). This unconformity is of high engineering geological significance, because the overlying organic-rich brackish water mud has a poorer bearing capacity and higher abundance of sulphide minerals. The present study provides a basis for characterization and classification of basin fill deposits by using their lithology, surface geometry, sediment thickness, lateral continuity and basin characteristics. The goal is to provide models on e.g. the distribution of greenish-grey brackish water mud and the appearance and continuity of clay-covered aquifers.

P-4832

Challenges in assessing land systems and slope stability from a glaciated volcano: the Mount Meager Massif (BC, Canada)

Marco Giardino¹, Gioachino Roberti^{2,3}, Stefano Freschi¹, Luigi Perotti¹, Brent Ward³, Pierre Friele⁴

¹University of Torino, NatRisk, Earth Science, Torino, Italy, ²Minerva Intelligence Inc., Vancouver, Canada, ³Canadian Centre for Natural Hazards, Burnaby, Canada, ⁴Cordilleran Geoscience, Squamish, Canada

Mount Meager is a glaciated volcanic massif located in SW British Columbia, Canada. Within an area of about 225 km², the massifs shows both modern and ancient glacial and periglacial landforms, as well as landslides characterized by high frequency and magnitude. Many studies have focused on present and past landslide activity at Mount Meager, but only few studies have investigated the role of recent deglaciation on slope stability. According to the GLIMS world Glacier Database Mount Meager Massif supports 32 alpine glaciers. No detailed studies have focused on the Mount Meager present glacier morphology and activity, nor on the effects of regional glaciation on Mount Meager volcanic activity. In this study we approached the present glacier morphology and activity at Mount Meager volcano, as well as landslide events by identifying physiographic land types, reflecting both lithology, structural and geomorphological constrains.

We applied an historical approach to digital interpretation of over 500 airphotos of the Mount Meager massif, creating 8 subset of images from 1947-2006. By using SfM software we provided high-resolution orthophotos (0.42-1.13 m/pixel) and tested the cartographic suitability of the historical datasets by comparison with a Lidar DTM acquired in 2015-2016. We performed interpretation of Lidar and orthophotos and identified landform components of Mount Meager Massif: glacier outlines, moraines, landslides deposits, scarps, and fractures. Geomorphic parameters were assessed: glacier front position from 1951 to 2016, and relative retreat of front position in 2016; glacier length and basin area; headwall height and aspect of cirque; elevations of glacial accumulation zone. The historical approach allowed interpretation of glacier fluctuations: even if with different parameters and activity, glaciers at Mount Meager Massif are generally retreating. Total cumulated retreat is about 8 km² and retreat is about 20% with respect to the 1951 glacier extension.

We recognized mutual conditions posed by present and past glaciations and hydrothermal activity to present-day volcanic massif stability and glacier morphology. We developed a conceptual model to explain the high landslide frequency and the glacial activity at Mount Meager: rocks are fractured and altered by interaction with past ice sheets and today's glaciers are mostly debris-covered and sit in collapse scars from large landslides. Climate-related deglaciation of volcanic mountains not only cause changes in ice cover, but affects regional and local hydrology, slope stability, sediment supply, hydrothermal circulations, leading to short-term and long-term consequences on the overall relief geomorphology.

P-4833

Constraining the glacial history and relict landscapes of the Cheshire Plain and south-west Pennines: ice-marginal limits, landsystems and geotechnical implications.

Angie Turner¹, Richard Waller¹, Ian Stimpson¹, Guido Meinhold¹, Jon Lee², Emrys Phillips³

¹University of Keele, Stoke-on-Trent, United Kingdom, ²British Geological Survey, Nottingham, United Kingdom,

³British Geological Survey, Edinburgh, United Kingdom

In Great Britain, numerous attempts have been made to constrain the maximum extent of the late Devensian British-Irish ice-sheet (BIIS) through the mapping of distinctive ice-marginal landforms such as end moraines and lateral meltwater channels. However, in the south-west Pennines, where the geomorphological signatures are unclear, significant uncertainty remains regarding the location of the ice margin with numerous ice limits for the Late Glacial Maximum (LGM) having been proposed by various authors.

In these circumstances, till geochemistry provides an alternative approach that can be used to determine former ice limits and ice-flow directions. This approach is routinely used in Antarctica for example to determine provenance, ice-flow patterns and paleoclimate conditions. Within the context of the UK however, the boundaries between late Devensian tills and those belonging to the Mid Pleistocene are not mapped with any certainty. In addition, little work has been undertaken on the tills found within inland locations due to the lack of natural exposures, with most work to date focussing on coastal sections. As a consequence, data concerning the location, consistency, age and depth of inland tills remains sparse, leading to great uncertainty regarding variations in local ground conditions. Ice-marginal landsystems are associated with significant spatial heterogeneities in this regard, with the associated variations in the geotechnical properties of near-surface materials posing significant engineering challenges.

This poster presentation forms part of a broader PhD project that will assess the extent to which clast provenance analysis and till geochemistry can assist in the identification of former ice limits in inland locations where the geomorphological signatures are absent or unclear. The results of preliminary analyses on samples obtained from cores along a 80km transect that traverses a former Late Devensian ice limit within the Cheshire Plain will be presented. In addition, these preliminary results are compared with an easterly transect extending into the Peak District (an area of Pre-Devensian tills) in order to assess the degree of variability in relation to both the local geology, age and ice-sheet configuration.

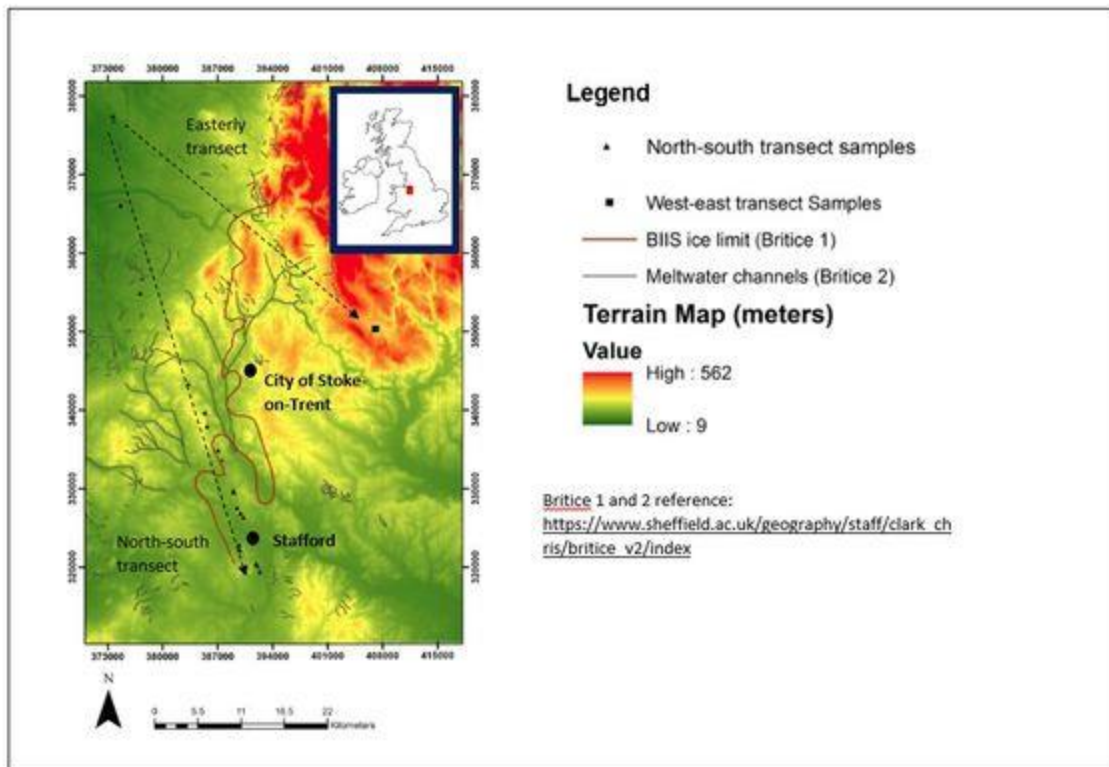

Figure 1. Sample transects and ground core locations in the Cheshire Plain and south-west Pennines.

P-4834

The impact of climate cooling on the evolution of the Middle and Late Pleistocene sedimentary environments in Central Europe

Paweł Zieliński¹, Robert Jan Sokołowski², Barbara Woronko³, Lidiya Dubis⁴

¹Department of Geoecology and Palaeogeography, Maria Curie-Skłodowska University in Lublin, Lublin, Poland,

²Institute of Oceanography, University of Gdansk, Gdynia, Poland, ³Faculty of Geology, University of Warsaw, Warsaw, Poland, ⁴Catholic University of Lublin, Lublin, Poland

One of the most interesting areas where the cyclicity of climate changes is clearly pronounced is Central Europe. This area has been affected by both successive Scandinavian Ice Sheet (SIS) transgressions and the development of various terrestrial environments in periods between these transgressions. Despite the fact that periods of cooling the climate without the direct presence of an ice-sheet occupy about 70-80% of the time, the knowledge about them is the least well-known.

During long periods of the climate cooling, the area of Central Europe experienced repeated aggradation of permafrost. The timeframe of permafrost presence and its type is well recognized for the Weichselian Glaciation. However, information about the presence of permafrost from before Eemian Interglacial is few.

Selection of key areas is determined by location in the periglacial zone in cold periods of the Middle and Late Pleistocene. On this assumption, it covers Central Europe – the Central- European Lowland, i.e. Poland, east part of Germany and the west part of Ukraine. Thereby, research will cover over 1500 km latitudinal extension area. Such a large area requires an indication of test areas, where deposits of two the most typical sedimentary environments existing in the periglacial zone – fluvial and aeolian will be documented.

The main goal of the project is the reconstruction of fluvial and aeolian depositional environments in cold climate phases of the Middle and Late Pleistocene in Central Europe:

- Determination of the conditions of functioning of the fluvial and aeolian environments in cold periods of the Middle and Late Pleistocene in the studied area.
- The reconstruction of the type of permafrost, number of phases and their ages, the rate of the permafrost aggradation and degradation in the studied period, and the correlation of cryogenic horizons with Marine Isotope Stages (MIS).
- Characteristics of local conditions affecting the development of permafrost, as well as the determination of the textural and structural features of the sediments and obtaining which of them were determined by local and regional factors.
- Reconstruction of climate changes (thermal-humid and air circulation) in Central Europe in the Middle and Late Pleistocene, with particular emphasis on the features of climate continentality.
- The development of a sampling method from sandy wedges, enabling the study of their age variability (overlapping of successive generations of wedges).
- The modification of the morphoscopic method aimed at the reconstruction of various sedimentary environments and the order of their interaction on shaping the grain surface of the quartz sand fraction.

Periglacial alluvial fan activity over the last 100 ka: insights from a study of the Eerbeek fan (The Netherlands)

Willem Viveen¹, Jeroen Schoorl², Jakob Wallinga², Sanne Palstra³, Johannes Van der Plicht³

¹Grupo de Investigación en Geología Sedimentaria, Departamento de Ingeniería, Pontificia Universidad Católica del Perú, Lima, Peru, ²Land Dynamics Group, Wageningen University, Wageningen, Netherlands, ³Rijksuniversiteit Groningen, Groningen, Netherlands

Periglacial fans are common in NW Europe, but in the literature little attention has been given to their formation in relation to climate variations over a full glacial-interglacial cycle. We have reconstructed the evolution of a periglacial alluvial fan in the Netherlands over the past 100 ka by combining the reconstructed 3-D, stratigraphic architecture of the fan with age control of 38 samples from two sediment cores by means of optically stimulated luminescence (OSL) and ¹⁴C methods. The reconstruction shows evidence of distinct phases of clastic alluvial fan aggradation, organic accumulation (peat units) and aeolian deposition. We interpret climatic changes, and in particular the existence of permafrost in combination with vegetation absence and sufficient water availability, as the driver for fan activity, as sediment transport by running water will only occur when infiltration is hampered by a permafrost layer. The age control provides a correlation with major Marine Isotope Stage transitions during the last glacial period, and shifts in the depocentre position from more proximal to distal locations reveal the build-up history of the fan. Fan aggradation rate calculations show a general increase from MIS 5d towards MIS 3, and after that a decrease towards the Holocene (MIS 1). The lower activity during MIS 2 is probably related to further aridification and the limited presence of a seasonally thawing top layer during permafrost conditions.

Surge-induced streaming of Two Medicine Glacier, Rocky Mountains, Montana, USA in response to climate warming, topography and a weak bed

Nick Eyles, [Shane Sookhan](#), Lina Arbelaez-Moreno
University of Toronto, Toronto, Canada

During the final stages of late Wisconsin glaciation after 14,500 ybp, ice from the Northern Rocky Mountain Ice Cap (NRMIC: 150,000 km²) flowed through narrow passes in the continental divide along the crest of the Rocky Mountains and terminated as outlet glaciers on the interior plains of eastern Montana. The Two Medicine Glacier was the largest forming a ~ 2000 km² piedmont lobe comparable in size to today's Malaspina Glacier of southern Alaska. The geomorphology of its well-exposed bed east of present-day Glacier National Park is exceptional compared to other lobes and shows 50 km-long flow sets of megascale glacial lineations cut into soft bentonite-rich Cretaceous shales and identifying a former ice stream. Streamlined landforms are fringed by arcuate belts of uncontrolled hummocky moraine composed of thick (< 10 m) clay-rich clast-poor till produced by subglacial erosion of subglacial bedforms and downstream advection of remolded shale. The Two Medicine Ice Stream (TMIS) is the only paleo-ice stream so far recognized in the eastern Rocky Mountains of Montana and was likely triggered by regional climate warming, enhanced accumulation and basal melting of the eastern NRMIC and downstream surging during regional deglaciation prior to c. 12,000 ybp when mountain passes became ice free. Ice streaming was facilitated by topographic forcing of confluent outlet glaciers and their flow out onto the Interior Plains across a weak bed of easily-remolded shales rich in swelling clays.

Holocene retreat of Jakobshavn Isbræ

Karita Kajanto¹, Helene Seroussi², Basile de Fleurian¹, Kerim Nisancioglu^{1,3}

¹Department of Earth Science, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway, ²Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA, ³Centre for Earth Evolution and Dynamics, University of Oslo, Oslo, Norway

Marine terminating glaciers, such as Jakobshavn Isbræ in West Greenland, are complex systems driven by a combination of changes in oceanic and atmospheric climate. The recent retreat and speedup of Jakobshavn Isbræ is mainly attributed to oceanic warming, while the general retreat of the Greenland ice sheet since the last glacial maximum is attributed to changes in surface mass balance. However, the relative impact of atmospheric and oceanic forcing on marine terminating glaciers of the Greenland ice sheet, and the corresponding time scales of the response remain unknown. We use a thermo-mechanical 3D ice sheet model to study the retreat history of Jakobshavn Isbræ during the Holocene (9500 BP to present) and compare it with available observational data.

The glacier retreat is simulated with the Ice Sheet System Model (ISSM) in a thermo-mechanically coupled 3D setup. The resolution is enhanced in areas with complicated topography and fast flowing ice. The model is run forward with different oceanic forcings starting from a recorded margin position at 9500 a BP. The simulated evolution of the front is compared to known geomorphological evidence, such as moraines and dated boulders.

The results show that the retreat in the fjord is strongly dependent on the bathymetry of the fjord. Furthermore, our results suggest that while surface mass balance dominates the retreat of the land based sections of the glacier, the fast flowing ice stream in the fjord is dominated by oceanic forcing and the dynamic response of the marine terminating front. Thus, our results indicate that the evolution of the land based and marine based ice in the area of Jakobshavn are driven by different external forcings, and that it is critical to resolve the detailed fjord topography.

P-4838

Ice sheet extent and deglaciation on the continental shelf offshore of northeast Greenland during the LGM

Colm Ó Cofaigh¹, S. Louise Callard¹, Jerry M. Lloyd¹, Dave H. Roberts¹, Boris Dorschel², Torsten Kanzow²
¹Durham University, Durham, United Kingdom, ²Alfred Wegener Institute, Bremerhaven, Germany

The Northeast Greenland Ice Stream is a key sector of the Greenland Ice Sheet because it controls ice flux into the NE Atlantic and it holds a sea-level equivalent of ~ 1.4 m. Recent ice shelf loss and grounding line retreat post 2010 suggest that the ice stream and this sector of the Greenland Ice Sheet are starting to respond to atmospheric/oceanic change. The aim of the project 'NEGIS' is to reconstruct the past behaviour of the Northeast Greenland Ice Stream from the LGM to the late Holocene including the past sensitivity of the ice stream to oceanographic and atmospheric forcing. The project adopts a combined approach of terrestrial and marine geological data collection which will be used to calibrate and validate numerical ice sheet models that can predict ice stream-shelf dynamics over centennial to millennial timescales. This presentation focuses on the offshore component from the continental shelf and upper slope, focusing mainly on new marine geophysical data and sediment cores collected from mid-outer Westwind and Norske Troughs, two major cross-shelf bathymetric troughs. These bathymetric troughs acted as pathways for offshore-directed ice flow across the wide NE Greenland continental shelf during the last glacial cycle. Data collection took place during two research cruises of the RV Polarstern in 2016 and 2017. The seafloor geomorphological and acoustic data reveal a range of flow parallel and flow transverse landforms in both troughs. Well-developed mega-scale glacial lineations and drumlins record former streaming flow towards the outer shelf/shelf edge. The geophysical data also imaged flow transverse landforms such as moraines and grounding-zone wedges which record episodic grounding line retreat inshore from the shelf edge/outer shelf during deglaciation. Beyond the shelf edge of Norske Trough the continental slope is characterised by glacial debris flows typical of submarine slopes offshore of shelf-edge terminating palaeo-ice streams. Sediment cores from the troughs recovered over-consolidated subglacial tills overlain by deglacial stratified glacial marine sediments recording advance and retreat of the ice stream. Radiocarbon dating of deglacial sediments in these cores indicate that deglaciation of the ice stream from the shelf edge of Norske and Westwind troughs was underway by c. 19.2-19.7 ka cal BP. Collectively these data indicate that the Northeast Ice Stream was grounded to the shelf edge and imply a much more extensive Greenland Ice Sheet in this sector during the LGM than has hitherto been demonstrated.

P-4839

Interactions between meltwater drainage, bed erosion and ice dynamics beneath terrestrial ice streams: insights from a new experimental modelling approach.

Edouard Ravier¹, Thomas Lelandais¹, Olivier Bourgeois², Stéphane Pochat³, Régis Mourgues¹

¹Le Mans Université - Geosciences Department, LE MANS, France, ²LPG, Nantes, France, ³LPG, Nantes, France

The interactions between subglacial drainage, bed erosion and basal sliding govern past and modern ice stream activities, thus controlling the evolution of ice sheet dynamics and mass balance. Complex landform assemblages beneath palaeo-ice stream are the result of these interactions although timing and characteristics of subglacial processes, inferred from geomorphological and sedimentological analyses, remain often poorly-constrained. If both palaeoglaciological studies and numerical modelling have provided a tantalizing glimpse on subglacial processes occurring at ice stream beds, we here present a new analog modelling approach. This approach has been underestimated in glacial sciences while having the potential to circumvent the challenge of numerically modelling interactions between ice stream dynamics, subglacial drainage and bed processes.

The subglacial bed and the ice are respectively simulated with a layer of fine sand and a layer of silicon putty. Meltwater production is simulated with a punctual injection of water within the experimental subglacial bed. The formation of subglacial drainage landforms was monitored through time, and their shapes were analyzed from digital elevation models obtained by stereo-photogrammetry. The ice dynamics was also monitored using the temporal displacement of markers placed at three different levels of the silicon putty. This initial experimental setup, developed over the past three years, has shown promising results. We managed to address the temporal relationships between (1) meltwater pocket storage/drainage (2) meltwater subglacial drainage types, (3) temporal evolution of subglacial meltwater drainage efficiency, (4) tunnel valley formation and (5) ice stream dynamics. Experimental results highlight that distributed subglacial drainage such as transient water pocket migration can trigger ice flow acceleration similar to an ice stream. The subsequent distributed-channelized transition occurring when the water pocket reaches the ice margin initiate tunnel valleys formation. Thereafter, ice stream dynamics is mainly controlled by the ability of tunnel valleys to drain all meltwater leading to modifications of ice streams directions, geometries and velocities. Ultimately, when the tunnel valleys system become efficient, ice streams can enter a stagnation phase. These experimental results reconcile several natural observations in modern ice sheets and provide some temporal constraints on the spatial coexistence of tunnel valleys and palaeo-ice streams.

Recently, significant modifications have been carried out on the initial experimental setup; we tripled its size, we added 12 meltwater injection points to simulate more complex meltwater storage and drainage patterns and we developed a new analog subglacial bed. Indeed, an analog subglacial till (scaled to natural till) has been developed in the lab using permeability and mechanical tests. We also show you some of the preliminary results of this updated experimental setup together with the new array of subglacial landforms we are able to reproduce beneath experimental ice streams (Glacial lineations, flutes, moraines).

P-4840

Mineral dispersal trains as products of hard-bedded ice streams in northern Canada

Roger Paulen¹, Chris Stokes², Beth McClenaghan¹

¹Geological Survey of Canada, Ottawa, Canada, ²Durham University, Durham, United Kingdom

The identification of glacial dispersal landforms and sedimentary deposits formed by fast-flowing glaciers was important to the earliest recognition of palaeo-ice streams of the Laurentide Ice Sheet in the 1970 and 1980s. The spectacular continental-scale Dubawnt dispersal train in northern Canada was one of the first to be identified as the product of a high glacial flow rate. Subsequently, dispersal plumes of Paleozoic carbonate rocks imprinted on Precambrian Canadian Shield terrain in northern Canada were interpreted to be products of ice streams.

Smaller glacial dispersal trains emanating from point sources within larger palaeo-ice stream trunk flows have also been identified. The Strange Lake glacial dispersal train in northern Quebec and Labrador, is a remarkably linear ribbon defined by till geochemistry and airborne gamma-ray data that extends >60 km down-ice (northeast) from a mineralized rare earth element-rich peralkaline intrusion. This dispersal train formed within one of several ice streams that operated over a hard bed near the center of the Labrador Dome of the Laurentide Ice Sheet. Further north, a kimberlite indicator mineral-rich dispersal train (referred to as the Tremblay Corridor) extends 65 km down-ice (northwest) from a cluster of kimberlite intrusions on northern Melville Peninsula, Nunavut. This glacial dispersal train was also formed over a hard bed by the Gulf of Boothia Ice Stream, which originated from the Foxe Dome of the Laurentide Ice Sheet.

The geomorphic imprint of ice streams over hard-bed, higher relief areas tends to be less obvious because of thinner till cover and an absence of diagnostic geomorphic features such as shear margin moraines. Despite the relatively thin till cover in the Strange Lake, Labrador area, and on the northern Melville Peninsula, the extremely high concentrations of mineralized (exotic) debris within the till 10s of kilometres down-ice from their sources is quite remarkable. Typically, under normal ice flow conditions in areas of hard-beds on the Canadian Shield, dispersal trains formed by erosive ice are diluted over relatively short distances (<5 km) down-ice. The long (10s of km) dispersal trains of till with distinct chemical and/or mineralogical compositions, coupled with obvious erosive/depositional corridors of streamlined landforms, provide a means of identifying hard-bedded ice streams elsewhere in northern Canada.

P-4841

The Cabot Lake ice-stream: a hard-bedded palaeo-ice-stream near the Ancestral Labrador ice-divide of the Laurentide Ice Sheet's Quebec-Labrador Dome.

Jessey Rice¹, Martin Ross¹, Roger Paulen²

¹University of Waterloo, Waterloo, Canada, ²Geological Survey of Canada, Ottawa, Canada

The Cabot Lake ice-stream (CLIS) is a previously unidentified east-trending ice-stream on the Canadian Shield that provides evidence for rapid basal-flow acceleration in close proximity to an ice-divide. The CLIS is located near the central-eastern border of Quebec and Newfoundland and Labrador, between two much larger ice-stream corridors. The CLIS is situated south of the Kogaluk River Ice-Stream near Strange Lake (IS #185 of Margold et al. 2015), and north of the unnamed ice-stream in the Smallwood Reservoir (herein referred to as the Smallwood ice-stream). The CLIS occupies a lowland region in the headwaters of the George River and is bounded on its onset zone and terminus by large bedrock upland regions: the Paleoproterozoic De Pas Batholith at its onset in the west and the Neoproterozoic granite and orthogneiss at its terminus in the east. The CLIS is 40 km wide at its onset, with a classic converging flow pattern and sharp lateral margins that narrows to 20 km wide near its terminus, where it abruptly ends at an intrusive bedrock upland region. The CLIS contains over 1000 streamlined landforms, many with elongation ratios of 12:1 or greater. The CLIS was relatively short-lived, given its extent, and following the ice streaming, the system shutdown with sluggish, topographically-controlled ice-flow to the northeast, which explains the high degree of preservation of the landforms and lack of a time-transgressive land system that would result from gradual glaciological changes. This younger northeastern ice-flow was oblique to the eastern-trending CLIS bedforms, as indicated by striations on nearby bedrock highlands and moderate reworking of some of the MSGs.

This ice-stream operated near a migrating dispersal saddle of the Laurentide Ice Sheet's Quebec-Labrador dome in central-eastern Quebec. The CLIS' proximity to this ice-divide suggests that ice-streams were active toward the centre of the ice-sheet during late-stage deglaciation. The timing and duration of the ice-stream remain undefined; however, it shares a similar longitude to the Happy Valley-Goose Bay ice-stream to the south (IS #186 of Margold et al. 2015), another short ice-stream that is thought to have been active at about 8.9 cal ka BP. The location of the CLIS in such close proximity to an ice-divide, in conjunction with the other ice-streams operating simultaneously along the eastern margin of the retreating Laurentide Ice Sheet (e.g., Kogaluk River, Smallwood, and Happy Valley-Goose Bay ice-streams) indicate these ice-streams had an important impact on the transportation of glacial sediments away from core-regions of the ice dispersal-centre and possibly influenced the westward migration of the ice-divide during deglaciation.

P-4842

Iceberg scouring in terrestrial eastern Sweden and implications for deglacial history

Christian Öhrling¹, Gustaf Peterson^{1,2}, Gustav Sohlenius¹, Henrik Mikko¹

¹Department of Physical Planning, Geological Survey of Sweden, Uppsala, Sweden, ²Department of Earth Sciences, Gothenburg University, Göteborg, Sweden

During mapping on detailed elevation models in eastern Sweden, large areas with morphologically chaotic till surfaces have been detected below the highest coastline. We interpreted these areas being formed as the result of iceberg scouring.

The mapping was conducted on LiDAR derived elevation models in a GIS environment. Units for these features will be incorporated in a future national glacial geomorphological database developed by the Geological Survey of Sweden to make these data openly accessible.

The mounds are circular to elongated with crater-like rims, often cross-cutting. Sizes are from semi-circular mounds of few meters up to elongated mounds more than 1 km long and 50 m across. Based on the morphology we interpret these as iceberg plough marks and pits formed by floating icebergs scouring the sea bottom. Previously, iceberg activity has been interpreted in this area based on deposits of sedimentary material which should have its provenance in the Bothnian Sea. Our study support that calving icebergs most probably was produced by and derived from the Bothnian Ice Stream.

This is, as far as we know, the first reported observations of iceberg scouring in Swedish modern terrestrial environments. Moreover, it should be noted that while screening other parts of Sweden we have also found iceberg pits in paleo-ice lakes in central Sweden and also a few mounds in south eastern Sweden.

The new finding of iceberg-grounding activity is significant for interpretations of surficial deposits and possibly an important piece to the puzzle of the Fennoscandian Ice Sheet history, for example: 1) the varve chronology from terrestrial areas displays a uniform ice-margin retreat, while the Bothnian Sea record presents an ice streaming behavior. Such an environment would produce an abundance of icebergs – this mapping clearly shows that this was the case. 2) In physical planning it is important to know where sediments have melted out from ice-beargs, as it must be considered that fine sediments might be found further down in the stratigraphy, even if there is diamicton on the surface. 3) Iceberg-scouring events are significant for paleo-environmental reconstructions at all scales, since the needed glaciological and oceanic conditions indicate past climate-ocean interactions.

P-4843

Are bedrock mega-grooves formed through ice streaming?

Mihaela Newton, Chris R Stokes, Dave H Roberts, Dave JA Evans
Department of Geography Durham University, Durham, United Kingdom

Mega-grooves are assemblages of straight and parallel troughs 100s of meters long, thought to have formed through erosion in bedrock, beneath Quaternary ice sheets. The mechanisms and palaeoglacial conditions of mega-groove formation are still to be elucidated, but most studies published in the past decades favour the hypothesis of formation through intense and focused abrasion beneath fast-flowing ice in the onset zones of ice streaming. However, the evidence for a link between mega-grooves and ice streaming is often poorly constrained and ice streaming may not be a necessary condition for groove formation. Indeed, it is likely that the duration of ice flow is also important (e.g. re-excavation through repeat glaciations), along with bedrock susceptibility to erosion. In this paper we present recent landform mapping from several sites across the world, which suggest that the mega-groove patterns as bedrock bedforms differ to those characteristic to zones of ice-streaming onset. Thus, overall, mega-grooves are parallel and sometimes even slightly divergent in planform, in the down-ice flow direction, whereas bedrock bedforms in ice-streaming onset zones have a clearly defined convergent pattern. Also, empirical observations in Assynt, Scotland in conjunction with detailed mapping on high-resolution aerial imagery identified three groove assemblages with different orientations. Two of these correspond to sets of geological fractures aligned at an angle to palaeo-ice flow direction. The third set consists of grooves and ridges aligned parallel to the palaeo-ice flow direction and also to the bedrock strike. This last group give the landscape its characteristic streamlined aspect due to their large number, length, and continuity for 100s of meters, and have been previously interpreted as the result of ice streaming. However, the presence of cross-cutting groove assemblages, and the fact that all grooves and ridges occur in close connection with geological structural lines, point to a landscape of areal scouring, likely throughout multiple glaciations, rather than streamlining through fast ice flow.

P-4844

A conceptual framework for the spatial and chronological variations in the intensity of glacial flow within the Boothia-Lancaster ice stream.

Tommy Tremblay¹, Michel Lamothe²

¹Canada-Nunavut Geoscience Office, Iqaluit, Canada, ²Université du Québec à Montréal, Montréal, Canada

The history of ice flow within the Boothia-Lancaster Ice stream (BLIS) area relates to numerous datasets and important concepts, which, however sparse and geochronologically uncertain, indicates several successive ice flow patterns. Based on spatial features and chronological/stratigraphic aspects on land and underwater for the BLIS, it is possible to suggest conceptual correlations with the offshore IRD stratigraphy in Baffin Bay. The concepts of time and space involved are based on 1. Ice flow paths variations in time; 2. Glacial erosion history; 3. Stratigraphic data from which one deduces presence or absence of ice. In turn, the synthesis of those concepts could be useful for the modelling of the ice sheet behaviour.

New Arctic DEM, high definition satellite observations, multibeam echosounder, pebble counts in till, TCN analysis, stratigraphic units geochronology, field-based glaciodynamical observations and field striations measurements, help to understand in greater details the history of ice flow. Glaciodynamical mapping highlights extensive cold-based zones on several plateaus surrounding the BLIS, with important TCN inheritance measured in bedrock and till/regolith samples. A ternary diagram with relative importance of erosional factors helps to illustrate the transition between cold-based and warm-based zones. Pebbles transport half-distances are used to understand the contrast between various glaciodynamical settings. Submarine glacial geomorphology from multibeam echosounder indicate subglacial ice flow all through the Lancaster Sound, Gulf of Boothia and Committee Bay axis.

Fluctuations in the intensity of BLIS activity during the last glaciation is indicated from striae chronology on Boothia Peninsula, and recent data from the Keewatin (Hodder et al., 2016) indicates possible switch in ice flow intensity reaching as far as the Keewatin ice divide. Possible ice flow paths variations in time, however not strictly dated, can be conceptualized. During deglaciation, highly contrasted glacial geomorphology results from marked differences in ice retreat rates between the west and the eastern side of the BLIS.

Stratigraphy for pre-LGM events on Boothia Peninsula and Bylot Island indicates that ice cover and marine invasions can be traced before MIS2. Pre-LGM stratigraphic units, previously only dated with ages on shells at >35 to >41 ¹⁴C ka (AMS) and with amino acid dating, are currently being dated with IRSL. On Boothia Peninsula, the Paisley River IRSL preliminary dates yield ages between 80 ka and 150 ka.

P-4845

New data about the Kileshino section - as the important section for understanding the LGM position on the Valday Upland (Russia)

Natalia Karpukhina¹, Evgeny Konstantinov¹, Andrey Panin^{1,2}, Valentina Pisareva¹, Inna Zyuganova¹, Andrey Zakharov¹, Dmitry Baranov²

¹Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation, ²Lomonosov Moscow State University, Moscow, Russian Federation

Stratigraphic investigations of sections with organic deposits of the Mikulinian Interglacial (MIS 5e) or Early - Middle Weichselian ages (MIS 5b - MIS 3) are a reliable method for assessing the development of the Late Valdai (Weichselian) glaciation. The Kileshino section is one of the key sections for studying the Last Glacial Maximum (LGM) position in the central part of the Valday Upland. Investigations of the section were started in the late 50s XX century. Most researchers try to correlate peat observed in the section with the Mikulinian Interglacial (MIS 5e). Also, some researchers were able to detect the layer of till which covers organogenic deposits in the section; others did not find any till. The uncertainty in the section structure does not allow to reasonably show the LGM boundary in the central part of the Valday Upland.

In 2017 detailed investigations of the section in village Kileshino were carried out for the purpose of revision. The section opened the valley side of the r. Sizhina. On the base of visual structure observations, grain size, loss on ignition at 550 and 900 C, magnetic susceptibility, pollen, paleocarpology and 14C analyzes were distinguished stratigraphic horizons: alluvial deposits of the Late Valdai Age (0–2,86 m); floodplain facies of alluvial deposits of the Early Valdai Age (2,86-5,3 m); lacustrine-peat deposits of the Mikulinian Interglacial (5,3-7,0 m); lacustrine and limnoglacial sediments of the Late Moscow age (7,0-13,40 m). The stratigraphy of section allows making a correlation between boreholes along the profile line through the key section. It needs for understanding the bed position of organogenic deposits. Analysis of the profile shows that till represented by loams with the inclusion of carbonate and crystalline rocks debris, were found at the upper parts of interfluves and some boreholes. It suggests that organo-mineral deposits which studied in the section were formed in the depression between hills of the Late Moscow age. In the Late Valdai (MIS 2) the ice cover could hardly spread to the south from the section.

This research is supported by the Russian Science Foundation, project no. 17-17-01289.

P-4846

Low-temperature permafrost and absence of ice-sheet relics – new data in respect to Northwestern Siberia's environment during the Pleistocene cryochrones

Vladimir Sheinkman^{1,2,3}, Vladimir Melnikov^{1,2,3}

¹Tyumen Industrial University, Tyumen, Russian Federation, ²Tyumen State University, Tyumen, Russian Federation,

³Earth's Cryosphere Institute, SB RAS, Tyumen, Russian Federation

Development of permafrost in Northwestern Siberia has been a fact that is beyond any doubt. Permafrost occupies a vast area here both at present and over the Pleistocene. At that, there is numerous evidence of very strong rock freezing formed at that area. Permafrost changed in thickness, its area fluctuated in size, but it always formed here as the main environmental attribute. Some researchers, nevertheless, suppose presence of ice sheets in Northwestern Siberia during the Pleistocene cryochrones, though to explain the combined development, at the same time and at the same area, of giant glaciers and well-expressed permafrost phenomena is impossible. In any case, at the base of ice sheets frozen grounds have to transform, whereas surface deposits occur in the region as unaffected original forms in a state of fair preservation. They reflect undergoing through only active freezing at the background of mostly river self-development resulted in different forms. Some of those forms rated, at times, as glacial relics, are not of glacial origin, and no evidence of ice sheets occurs here.

The base to suppose an ice sheet in Northwestern Siberia is distribution of stony material north of the Middle Ob' River where a low upland (less than 300 m a. s. l.) stretched along the sub-latitudinal direction and named the Siberian Uval is situated. When to look at the map, the upland likes to a moraine ridge; however, it is only in the form. Overall, the Siberian Uval represents a system of typical river terraces with a height of cliffs up to 35-40 m, and such indicator of former strong freezing as pseudomorphs after polygonal ice wedges occurs in their bodies. According to the dating carried out by different ways, the wedges at the top of the terraces formed during MIS-2, and during the cold phase of MIS-5 in the central part of the terraces. Their top deposits resemble loess-like sediments, but they contain fresh water aquatic microfossils and bear features of floodplain alluvium (see our other abstract). As to the stony material, it mostly represents basaltic fragments carried away from the right-hand bank of the Yenisei River. The terrace deposits are mostly composed of sandy alluvium, whereas the stony material is much dispersed debris embedded in sandy deposits. To our mind, it is a result of river ice-floe drift typical for self-development of many rivers in Siberia – even at present, Yenisei, during the ice drift time, can rich 30-m raising of water level, whereas thickness of ice floes can rich 2 m. It is quite enough to capture boulders by ice floes and to move them over not high water divides near the Siberian Uval. All of that confirms non-glaciated development of the studied area.

P-4847

Loess-like deposits at the top of the high river terraces of Northwestern Siberia: floodplain alluvium or eolian sediments?

Vladimir Sheinkman^{1,2,3}, Sergey Sedov^{1,2,3}

¹Tyumen Industrial University, Tyumen, Russian Federation, ²Tyumen State University, Tyumen, Russian Federation,

³Earth's Cryosphere Institute, SB RAS, Tyumen, Russian Federation

Accumulation of loessic sediments is usually observed to the south of the margins of the Pleistocene glaciers. Within the Arctic and Subarctic zones, loess-like sediments are spread in the regions which were not covered by glaciers during the Pleistocene cryochrones. Some researchers considered Northwestern Siberia as an area of development of the Pleistocene glaciations which to the west merged with the North-European ice sheet (Grossvald, Hughes, 2002). Recently alternative concepts supposing much more modest spread of the ice sheets in Northern Eurasia were developed. Within these hypotheses West Siberia was completely free of the ice cover (Sheinkman, 2016; Sheinkman et al., 2017). At that, the paleoecological scenario supposes for West Siberia wide development of extra-arid cold ecosystems in the Late Glacial and Last Glacial Maximum (Velichko et al. 2011). Such a scenario implies activation of eolian processes which could give rise to loess accumulation.

During our study of the Quaternary sequences in the upper and middle reaches of the rivers running down from the Siberian Uval (a not high upland at the right-hand bank of the Middle Ob' River), we encountered in many exposures of the high (at a relative height of 15-20 to 35-40 m) river terraces the layers of loamy sediments that capped extensive sandy alluvial sequences. The most profound and well developed superficial loamy stratum has been found in the top exposure of the terraces. The loams consisted predominantly of silt fractions, were not laminated evidently, and showed well-developed cryogenic structure. They were severely affected by the pseudomorphs after middle-size polygonal ice wedges often outlined by thin paleosols. Set of ¹⁴C determinations produced from the paleosols the ages between 10 and 20 ka BP. It attributes the loam accumulation and its cryogenic transformation to MIS-2 (the Sartan cryochrone, in Siberian schemes). So, interpretation of the loams as the floodplain alluvium met firstly certain difficulties because in this case evident thin rhythmic lamination is expected. Therefore, the alternative hypothesis of eolian accumulation of these loess-like sediments and simultaneous impact of cryogenic processes in the cold and dry landscapes was developed – which fits into the “Glacial desert model” (Velichko et al., 2011).

Nevertheless, micromorphological studies of the considered loamy deposits revealed typical features of floodplain sediments. These are: a) well-expressed microlamination, b) occurrence of organic plant fragments oriented parallel to the lamination, c) iron hypocoatings along the layers – an indicator of gleying, d) relics of fresh water aquatic microfossils – diatoms, sponge spicules. So, we suggest these facts evidence in favour of floodplain alluvium origin of the loamy sediments although incorporation of the windblown material is still not excluded. Within the floodplain hypothesis, recent tectonic uplift should be considered to explain the elevated present day position of the loams

P-4848

Late-Glacial paraglacial drainage system inferred from palaeolakes buried under the aeolian sand

Petras Šinkūnas, Nikita Dobrotin, Eugenija Rudnickaitė, Andrej Spiridonov
Institute of Geosciences, Vilnius University, Vilnius, Lithuania

On a distal part of the outwash plain in the several sites of Ūla River valley, South East Lithuania, the organogenic sediments (gyttja) are found at the different depth buried under the lacustrine and aeolian sand. The Late-Glacial is indicated as the sedimentation time by the results of a palaeobotanical analysis, ^{14}C and OSL dating. During the earlier studies, the origin of palaeolakes was always interpreted as glaciokarst with the subsequent postglacial sedimentation in kettle-hole lakes. Correspondingly, the area of the outwash plain was interpreted to be covered by ice during the Last Glacial Maximum and boundary of the ice sheet passing along the distal outline of the outwash. The results of a new site study and the reinvestigation of old sites supplemented with LIDAR models and ground-penetrating radar data show the existence of the paraglacial drainage system, which was late mostly covered by aeolian dunes. The moving dunes apparently dammed the surface runoff and formed the lakes inside the valleys of the drainage system. The sediment sequence structure shows the lake sedimentation interchange with the aeolian one until the lakes were filled with sand and buried completely. The study results also let to consider the position of the Last Glacial Maximum boundary up to half a hundred kilometres northwestwards. This research was funded by a grant (No. S-LL-18-2) from the Research Council of Lithuania.

Surface morphological types and spatial distribution of fan-shaped landforms in the Arctic based on examples from Svalbard, Iceland, and Greenland

Aleksandra Tomczyk, Marek Ewertowski

Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznan, Poland

Landforms, which shape reassemble fans and cones, are a characteristic element of many mountain landscapes in the Arctic. In this research, we focus on small fans that developed along steep mountainsides as a result of paraglacial adjustment of topography, and which varied greatly in geomorphology and processes. We distinguished: colluvial fans - mainly formed by rockfalls and snow avalanches, alluvial fans that are dominated by debris flows, and alluvial fans that are dominated by fluvial flows. The primary purpose of this study is to provide a context for a further examination of the variability in fan shape and morphology by documenting their spatial distribution across the selected area of Svalbard (central part of Spitsbergen Island), Iceland (SE fringe of Vatnajökull) and Greenland (Zackenber area and S Disco Island).

The geomorphological features of surface morphology of fans were identified based on analysis of orthoimages (high-resolution satellite imagery and aerial photographs) combined with visualisations of DEM (shading relief with different azimuth angles of the light source) and maps of slope gradient, aspect and curvatures. Additional field geomorphological mapping and ground checking were carried out during fieldworks. Three main types of fans' surface morphology were mapped: colluvial fans, debris-flow-dominated fans, fluvial-flow-dominated fans. A classification of the surface morphology of fans was developed based on their geomorphic expression and traces of dominating processes. For example, the presence of braided channel networks on the fan's surface indicated that its morphology had been transformed mainly by fluvial-flows rather than debris-flows. The abundance of levees and lobes indicated domination of debris flows, whereas a relatively uniform surface with traces of avalanches and sporadic debris-flow channels was classified as colluvial fans. The main morphometric and morphological features of the fans and their catchments have been collected, including: fan and catchment area, relief, length, width, elevation (the lowest point at the fan toe, apex, and the highest point of the catchment boundary), fan mean plan and profile curvatures, distance from the ice margin, and fan relation to neighbouring fans.

Colluvial fans were the smallest and steepest, whereas debris-flow-dominated and alluvial-flow-dominated fans were significantly larger and characterised by a gentler slope. Moreover, the catchments of colluvial fans were much smaller in comparison to the large catchments of fluvial-flow-dominated fans. Other morphometric properties of both fans and catchments also differed according to type. The collected data will be used for further in-depth analysis of the relationship between the surface morphology of fans, dominant processes, morphometric variables and time passed since deglaciation.

Research in Svalbard and Iceland was founded by the Polish National Science Centre, Poland (2016/21/B/ST10/01353). Greenland research in Zackenber and Arctic Station received funding from INTERACT under the European Union H2020 Grant Agreement No.730938, project numbers: 119 and 232 [ArcticFan]

P-4850

Paleocryogenesis in the periglacial area of the West Siberian Plain

Sergey Korkin, Elena Korkina

NIZHNEVARTOVSK STATE UNIVERSITY, NIZHNEVARTOVSK, Russian Federation

Below are some of the results of the study of geodynamic processes and paleocryogenesis in periglacial zone of the West Siberian plain. Sedimentary strata revealing elevated terraced surface, within the middle course of the Ob basin, can be classified into two types: 1) sedimentary strata with traces of cryometamorphic deformations; 2) sedimentary strata with the inclusion of boulder-pebble material. The study area belongs to the zone of island permafrost and intergelisol of the Arctic region and is located within 60 – 62 Parallels of Northern latitude. Appearance paleocryogenic deformations, their Genesis and sedimentation conditions in stratigraphic sequences of the middle course of the Ob is a debatable issue. Accumulation and formation of sedimentary strata occurred in the Neopleistocene time. The change of sedimentation is subject to interstage and interstadial periods. A manifestation of intense paleocryogenesis occurs during the Upper Pleistocene period. The studied sequences of the Ob valley accommodate various types of vein structures that differ in size and structure. The general trend for the studied sequences is the lower tier represented by sandy rocks with layers of iron hydroxides.

The generalizing trend of sequences is:

The second tier (at a depth of 10 – 12 m) stratigraphically lies above the first tier, represented by ice-subsoil veins. Large wedge-shaped ice-subsoil veins are fixed in the sequence of Kir'yas, smaller are fixed in the sequence of Agan's Uval.

The wedge-shaped pseudomorphs are filled by bluish gley loam (except in the sequence of Kir'yas) and banded argillite with a border of iron hydroxides.

The third tier (at a depth of 8 – 10 m), formed above the tier with wedge-shaped pseudomorphs, is represented by humus-gley paleosols with water-accumulative characteristics, the age of which correlates with MIS 3 and is 43.871 cal. BP for the Kir'yas sequence, for Agan's Uval sequence 27.300 years cal. BP.

The fourth tier (at a depth of 6 – 8 m) are presented pseudomorphs, crushed by loamy-sandy rocks.

The fifth tier (at a depth of 1 – 6 m) for the sequences of Kir'yas and Agan's Uval is represented by loess – like loam, a sequence of Mega is represented by lake-alluvial sandy loam.

This process is almost exclusively due to the elementary ice veins that fill the frost cracks.

The consequence of such genesis of veins is their correct wedge-shaped form, distinct vertical banding and clear contacts with the host rocks. Cooling, aridization of climate, in comparison with the previous epochs, led to a reduction in the level of the sea basin, which became an obstacle to the development of glaciation in the north of the West Siberian plain and this contributed to the intensive freezing of rocks. The development of paleocryogenesis and epigenetic ice in particular contributed to the wet conditions and developed extensive lake-marsh complexes.

Geomorphology, facies variability and large-scale depositional architecture of ice-marginal deltas in glacial lake basins: a synthesis

Jutta Winsemann¹, Jörg Lang¹, Ulrich Polom², Markus Loewer², Jan Igel², Lukas Pollock³, Christian Brandes¹

¹Institut für Geologie, LUH Hannover, Hannover, Germany, ²LIAG, Hannover, Germany, ³BGR, Hannover, Germany

During the Middle Pleistocene glaciations ice sheets repeatedly blocked the main river-drainage pathways in northern central Europe and led to the formation of extensive ice-dammed lakes along the southwestern margins of the Fennoscandian ice sheets. During deglaciation the lakes commonly increased in size and eventually drained successively towards the west and northwest. Catastrophic lake-drainage events occurred when large overspill channels were suddenly opened.

This study presents a synthesis of ice-marginal deltas controlled by rapid lake-level change. The integration of digital elevation models, outcrop, borehole, ground-penetrating radar (GPR) and high-resolution shear-wave seismic data allow to assess the role of rapid base-level change on delta morphology, sedimentary facies and the larger-scale depositional architecture and provide information about the distinct types of deltaic facies and geometries generated under different lake-level trends.

The exposed delta sediments record mainly the phase of lake-level highstand and subsequent lake drainage. The stair-stepped profiles of the delta systems reflect the progressive basinward lobe deposition during forced regression when the lakes successively drained. Depending on the rate and magnitude of lake-level fall, fan-shaped, lobate or more digitate tongue-like delta morphologies developed. Deposits of the stair-stepped transgressive delta bodies are buried, downlapped and onlapped by the younger forced regressive deposits.

The delta styles comprise both Gilbert-type deltas and shoal-water deltas. The sedimentary facies of the steep Gilbert-type delta foresets include a wide range of gravity-flow deposits. Delta deposits of the forced-regressive phase are commonly dominated by coarse-grained debris-flow deposits, indicating strong upslope erosion and cannibalization of older delta deposits. Deposits of supercritical turbidity currents are particularly common in sand-rich Gilbert-type deltas that formed during slow lake-level rise and highstand. Foreset beds consist typically of laterally and vertically stacked deposits of antidunes and cyclic steps. The trigger mechanisms for these supercritical turbidity currents were both hyperpycnal meltwater flows and slope-failure events.

Shoal-water deltas formed at low water depths during both slow lake-level rise and forced regression. Deposition occurred from tractional flows. Transgressive mouthbars form laterally extensive sand-rich delta bodies with a digitate, multi-tongue morphology. In contrast, forced regressive gravelly shoal-water deltas show a high dispersion of flow directions and form laterally overlapping delta lobes.

Deformation structures within the forced regressive ice-marginal deltas are mainly extensional features, including normal faults, small graben or half-graben structures and shear-deformation bands, which are related to i) gravitational delta tectonics; ii) post-glacial faulting during glacial-isostatic adjustment and iii) crestal-collapse above salt domes. In some cases, a neotectonic component cannot be ruled out. Dead-ice melting did not play a major role in the formation of normal faults.

Lake Seliger (Valdai upland, Russia): hydrological history after deglaciation

Evgeny Konstantinov¹, Andrey Panin^{1,2}, Natalia Karpukhina¹, Andrey Zakharov¹, Svetlana Bricheva³

¹Institute of Geography RAS, Moscow, Russian Federation, ²Faculty of geography Lomonosov Moscow State University, Moscow, Russian Federation, ³Faculty of geology Lomonosov Moscow State University, Moscow, Russian Federation

Lake Seliger is a system of 24 semi-isolated bays (so-called Plyosy), which stretch for 60 km from north to south on the Valdai Upland. This territory is the main watershed of the East European Plain, which divides the river runoff between the basins of the Caspian and Baltic Seas. The Valdai Upland is in the margin zone of the last glaciation. This area has a typical post-glacial landscape with marginal moraines, kamas, eskers and kettle holes. The Valdai Upland gave the name to the last glacial epoch in the Russian geological systematic - the Valdai glaciation. Traditionally, the Lake Seliger is considered relict lake, which remained after degradation of a huge proglacial lake. But bottom sediments and topography previously have not been studied in sufficient detail.

In winter of 2018, the bottom sediments of Lake Seliger were drilled from ice. Drilling was carried out on 5 profiles in the southern part of the lake. Bathymetric and GPR work was also carried out for all profiles. In total, 14 boreholes were drilled. Received and delivered to the laboratory 43 m of cores. For samples from reference cores, the loss on ignition, the magnetic susceptibility and the particle size distribution were determined. 15 radiocarbon dates were obtained.

In all boreholes at the bottom of the lake, 2-3-meter, and in some cases 6-meter lake mud, have been discovered. The upper part of the mud has a dark gray color due to enrichment with organic matter (30-60%). This is the Holocene sapropel (gyttja). The lower layers of mud in many boreholes have a light gray or blue-gray color, because they contain little organic matter (3-10%). This is a sign of formation in a cold climate - at the end of the last glacial epoch. Everywhere under the mud coarse sands occur. It is deposits of a fairly fast water flow. Many bays of the lake have an elongated and meandering shape and it looks like flooded river valleys. The topography of the bottom of these bays also indicates the fluvial origin.

Based on the study of sediments and topography of the bottom and shores of the lake, the following conclusions were made:

1. Lake Seliger is a flooded system of river valleys which appeared after the retreat of the last glacier.
2. The transformation of the river system into the lake took place gradually at the end of the Late Pleistocene, during the Belling-Allred interstadial (about 14.5–12.5 ky BP).
3. The likely reason for the transformation of the river system into the lake system is the differential glacio-isostatic movements of the earth's crust which changed the surface topography.

The construction of a new varve thickness time series from glacial Lake Agassiz

Andy Breckenridge¹, Thomas Lowell², Nigel Wattrus³, Dorothy Peteet⁴, Nathaniel Norris², Andrew Dennison³, Michael Moretto¹

¹University of Wisconsin-Superior, Superior, USA, ²University of Cincinnati, Cincinnati, USA, ³University of Minnesota Duluth, Duluth, USA, ⁴Lamont-Doherty Earth Observatory, New York City, USA

A new varve time series is being constructed using lake sediments from the former Lake Agassiz basin in northern Minnesota and Ontario (United States/Canada). Our goals are to reconstruct both ice margin retreat and glacial Lake Agassiz lake levels across the period spanning the Bølling-Allerød and Younger Dryas (YD). This is the first annually resolved record from North America that details ice margin dynamics and meltwater supply from the LIS through these dynamic climate periods; therefore, this project offers the opportunity to determine the LIS response to abrupt climatic shifts. In addition, by combining the ice margin positions, tracked by varves, with a lake level record, developed from sediment cores and seismic reflection data, the hypothesis that glacial Lake Agassiz drainage triggered the YD will be tested.

Here we report on 12 cores recovered so far, which all have varves, and correlate to records described by Antevs (1951) from Steep Rock Lake and Rittenhouse (1933) from Lake Wabigoon. We expect to add data from five more sites this year. Our youngest (most northern) and oldest (most southern) series of varves cross-correlate well, but the intervening record is complicated by non-varved sections, which we attribute to lake level drops associated with ice retreat opening new, lower elevation outlets for Lake Agassiz. This interpretation is supported by abrupt contacts between varved and non-varved sections, and unconformable surfaces and associated gravity flows visible in seismic reflection data.

The thickest (and presumably longest-lasting) non-varved, lowstand section is the youngest. The lowstand ends ca. 11,500 cal yr BP, at around the YD/Holocene transition. This lowstand is well-documented elsewhere in Lake Agassiz sediments and referred to as the Moorhead Low. Our reconstructions suggest that Lake Agassiz drained to the Arctic Ocean during this lowstand, because ice covered every potential eastern outlet to the Atlantic Ocean that would have been sufficiently low enough in elevation to create the lowstand. There are two, older, non-varved sections that likely resulted from earlier drawdown events. Multiple lowstands in Lake Agassiz have been suggested, but in recent literature, only one lowstand is typically emphasized. Neither the timing, nor ice margin positions for these older drawdown events are currently well constrained.

By targeting lower elevation or more isostatically depressed sites, we should be able to recover varves that span the non-varved sections, which are critical for determining the timing and durations of the lowstands. Varves spanning part of the Moorhead Low document that the lowstand lasted at least 750 years (from 12,250 to 11,500 cal yr BP).

Proglacial lakes at the southeastern edge of the last Scandinavian Ice Sheet: *sic et non*

Nataliya Zaretskaya^{1,2}, Andrei Panin^{2,3}, Natalia Karpukhina², Anna Utkina³

¹Geological Institute, RAS, Moscow, Russian Federation, ²Institute of Geography, RAS, Moscow, Russian Federation,

³Lomonosov Moscow State University, Moscow, Russian Federation

The southeastern flank of the last Scandinavian Ice Sheet extended over the territory of Northwestern Russia, occupying the White Sea and the downstream part of the Severnaya Dvina (SD) River catchment (Svendsen et al., 2004), and thus the proglacial lakes must have been formed in the SD valley and its large tributaries Vychegda and Vaga (Fig. 1).

The idea of the LGM proglacial lake formation in the Severnaya Dvina and Pechora drainage systems was first proposed by Krasnov (1948) and then developed by Kvasov (1975). In the last decades, analysis of digital elevation models allowed to propose new LGM limits advancing farther east- and southeastwards into the valleys of Vychegda and Vaga rivers (Lysa et al., 2011; 2014; Fredin et al., 2012; Larsen et al., 2013).

Our chronostratigraphic studies of natural outcrops and river valley morphology in the SD catchment area have led us to the reconstruction of two separate proglacial lakes in Vychegda and Vaga valleys in the LGM.

In the Vychegda valley, we examined the morphological features mapped by Fredin et al. (2012) and Larsen et al. (2013) as terminal moraines that dammed the proglacial lake. According to our observations, the moraine is characterized by dense erosion network, and the breakthrough reach of Vychegda contains a staircase of relatively high terraces with alluvial bottom and aeolian cap (Zaretskaya et al., 2018). Preliminary OSL-age of higher terraces at around MIS 5 allows to propose the MIS 6 age for the moraine ridge. Vychegda MIS2 terraces are of alluvial origin with traces of ice wedge casts in the sandy layers of LGM age (Zaretskaya et al., 2014; Zaretskaya et al., in press) and do not contain specific proglacial lake sediments such as varved clays. Accumulation of this terrace had probably been promoted by the backwater effect from the proglacial lake forming downstream. The only section with well-expressed LGM-related varved-like deposits is located in the middle reaches of SD. This coincides with the reconstructions of the LGM limits just upstream the Vaga confluence (Svendsen et al., 2004).

Another situation is observed in the Vaga valley. We identified the well-expressed grayish varved clays within Vaga fluvial system with maximum thickness of 10 m. Thickness of sand and silt layers varies significantly, which indicates the unstable hydrodynamic regime characteristic for proglacial lakes within river valleys; that is a large and deep ice-dammed Vaga lake was forming during the LGM.

The proglacial lake expansion east- and southeastwards was probably limited by glacioisostatic forebulge crossing these river systems during the LGM. The absolute height of water level could reach 80 m a.s.l.

The studies of LGM glacial boundary are supported by RSF, project 17-17-01289, the chronostratigraphy was supported by RFBR grant 17-05-00706.

Paleoenvironmental potential of newly-formed proglacial lakes (Calluqueo Lake, Chile)

Loïc Piret¹, Sebastien Bertrand¹, Fernando Torrejón²

¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium, ²EULA-Chile Center, University of Concepción, Concepción, Chile

Proglacial lakes are widely recognised in the glacio-sedimentological community to hold accurate and high resolution records of glacier variability. However, the modern literature on proglacial lake sedimentation contains conflicting interpretations about the exact signature of glacier mass balance variations in proglacial sediments. The goal of our project is therefore to better understand how glacier variability is recorded in lake sediments. To do so, we study sediment records from glaciers in Chilean Patagonia, and compare our results to historical documentary evidence and information from satellite images. Here, we focus on Calluqueo Glacier, the largest ice mass (45.3 km²) of Monte San Lorenzo (48°S). Although a 3 km long and 1 km wide lake currently exists in front of the glacier, historical images show that in 1941 the glacier still covered the entire lake basin. It rapidly retreated between 1941 and 1985, when it became land-based. Unfortunately, information about the exact position of the ice front between 1941 and 1985 is currently lacking or too vague to interpret. Nowadays, Calluqueo Lake is divided in two sub-basins separated by a rocky sill. The sub-basins are connected via a relatively narrow (240 m) and shallow (40 m) channel, and the lake is bordered by a thick lateral moraine that contains large boulders. Our bathymetrical survey revealed that the largest and most proximal basin reached a maximum depth of 220 m, whereas the smaller distal basin reaches a depth of 50 m. Van Veen grab sampling showed that sediment was limited to the small distal basin although the entire lake has been ice free for at least three decades. The deepest proximal basin did not contain any material samplable with a grab sampler. Four short (7 – 27 cm) sediment cores, which appear to be laminated based on X-ray computed tomography images, were collected from the distal basin. Core chronologies are not yet available, but our observations suggest that the first ~30 years of the glacier's retreat are not represented in the sediments of Calluqueo Lake. We hypothesize that fine-grained sediments that are discharged into the lake immediately after its formation first start accumulating between the large boulders that compose the ablation moraine on the lake floor. These sediments only start forming a continuous stratigraphic record after the coarse moraine deposits are buried under fine-grained particles. Additionally, sediment deposition may be reduced due to fine particles by-passing the lake as a result of the temperature-related density gradient in the water column. Regardless of the explanation, our results imply that the first years/decades of Calluqueo Glacier's retreat were not recorded in the sediments of its proglacial lake, which potentially restricts the use of proglacial lake sediments to reconstruct the early stages of glacier retreat.

Sedimentary evidence for a Younger Dryas ice-dammed lake in the Gaick, Scotland

Benjamin Chandler¹, Sven Lukas², Clare Boston¹

¹Department of Geography, University of Portsmouth, Portsmouth, United Kingdom, ²Department of Geology, Lund University, Lund, Sweden

Ice-marginal and proglacial glaciolacustrine sediment-landform assemblages are important geological archives, potentially providing valuable information on the style and dynamics of former glaciers. In this contribution, we present the results of sedimentological and structural-geological investigations of an assemblage of glaciolacustrine deposits identified at the northern end of a contemporary lake in the Gaick, Scotland. This sediment-landform assemblage is crucial to elucidating the extent and style of glaciation in this area, where it has long been 'generally accepted' that the most recent glacial phase was one of extensive plateau icefield glaciation during the Younger Dryas (~12.9–11.7 ka). According to this model, the valley containing the glaciolacustrine deposits would have been submerged by ice during the Younger Dryas, but we have found no geomorphological or sedimentary evidence for this configuration. Instead, our sedimentological investigations have revealed glaciolacustrine sediment-landform assemblages (a glaciotectionised grounding-line fan and a Gilbert-type delta) that document the lowering of an ice-dammed lake, which we infer to have existed during the Younger Dryas based on morphostratigraphy. The sedimentary and morphostratigraphic evidence for this ice-dammed lake and the associated glacier limits therefore contradicts the widely-accepted model of Younger Dryas glaciation in the Gaick. Thus, these findings have important implications for our understanding of glacial events in this area of the Central Grampians, Scotland.

P-4858

Assessing the ages of the Moorhead and Emerson phases of Lake Agassiz and their temporal connection to the Younger Dryas

Joseph Young, Alberto Reyes, Duane Froese
University of Alberta, Edmonton, Canada

The low-water Moorhead Phase of glacial Lake Agassiz has been attributed to a rapid ~ 90 m drawdown in lake level contemporaneous with the onset of the Younger Dryas cold reversal ca. 12.9 cal yr BP. We examine the radiocarbon dates associated with the Moorhead and subsequent high-water Emerson Phases in the Lake Agassiz basin. We apply manual and statistical filters to vet the radiocarbon dataset, resulting in the exclusion of about one third of existing dates. A Bayesian radiocarbon calibration model applied to the filtered dataset yields modeled age ranges for the onset and demise of each lake phase. Notably, the modelled age range for the onset of the Moorhead phase post-dates the initiation of the Younger Dryas. The dataset and model do not necessarily preclude freshwater flux from Lake Agassiz drawdown during the Moorhead phase as the trigger for the Younger Dryas cold reversal, but they do indicate that this interpretation relies on only a few low-precision radiocarbon dates that are identified statistically as outliers. The lingering uncertainty in the radiocarbon chronology for Lake Agassiz, despite rigorous filtering and application of a Bayesian calibration model, strongly suggests that additional high-quality radiocarbon dates from clear depositional settings in the Lake Agassiz basin are required to further constrain lake level histories and linkages to abrupt deglacial climate change.

P-4859

Tracing the final deglaciation of the Scandinavian Ice Sheet in northwestern Sweden - ice-dammed lakes and a catastrophic glacial-lake outburst flood

Carl Regnéll

University of Bergen, Bergen, Norway, Bjerknes Centre for Climate Research, Bergen, Norway

This study presents geomorphological evidence indicating final deglaciation of the last Scandinavian Ice Sheet remnants east of the Scandinavian mountain range, northwestern Sweden, in contrast with the prevailing view of final deglaciation in the higher mountains of Sarek. High resolution (LiDAR) terrain models were used to map out a large number of previously undocumented paleoshorelines within the northern Scandinavian mountain range. The distribution of these paleoshorelines indicates a larger system of ice-dammed lakes than previously thought. Using cross-cutting relations and the altitudes of bedrock thresholds the relative ages of the different lake-stages was obtained and used to trace the ice-sheet retreat in the area. Similar to the deglaciation further to the north and south, the distribution and pattern of the ice-dammed lake deposits in this area suggests an eastward retreating ice-sheet, which dammed up lakes towards the mountains in the west.

In addition, this study presents geomorphological evidences, in the form of mega deposits and extensive erosive features, of a catastrophic glacial lake outburst flood along the Pite River valley. These features, including erosive lines found up to 50 m above present day river level, can be traced continuously for ~130 km from the mountain range and ending at the early Holocene Ancylus lake level. Based on cross-cutting relations to early Holocene raised shorelines from the Ancylus lake the age of the flood is constrained to c. 9.9-9.8 cal. ka BP.

P-4860

Rostov lowland (Yaroslavl region, Russia) - was there a gulf of proglacial lake?

Evgeny Konstantinov¹, Natalia Karpukhina¹, Vladimir Belyaev², Andrey Zakharov¹

¹Institute of geography RAS, Moscow, Russian Federation, ²Lomonosov Moscow state university, Moscow, Russian Federation

Rostov lowland is a middle size depression (550 km², 60-80 m deep) which situated about 170 km to the NE from Moscow. The lowland is surrounded by moraine hills of Saalian glaciation. About 10% of area of the lowland is occupied by Lake Nero. On the west bank of Lake Nero the city of Rostov is located - one of the oldest cities in Russia, founded in 862. The modern lake level is 93 m asl. From the Lake Nero flows out the Kotorosol River. The Kotorosol River flows into the Volga River near the city of Yaroslavl. On the slopes of the Rostov lowlands are situated 5-6 lake terraces. There is a discussion about the age of the terraces and the reasons of lake level fluctuations. According to Kvasov (1975) at the end of the Late Pleistocene the level of lake rose to 145 m asl and the lake had a connection with the huge system of proglacial lakes. According to Aleshinskaya and Gunova (1997), the level of Lake Nero in the late Weichselian epoch did not exceed 110 m asl and highest terraces was formed in late Saalian epoch. In many ways, this discussion is due to the weak use of dating methods in older works.

We investigated the topography of the terrace complex of the Rostov lowlands. On the basis of SRTM we identified areas with well-defined terraces. Using DGPS the height of the terraces on the eastern side of the basin was fixed: T1 - 94-95 m asl, T2 - 102-104 m asl, T3 - 108-109 m asl, T4 - 123-125 m asl, T5 - 130-134 m asl, T6 - 145 m asl. 11 boreholes were drilled on the terraces of the eastern side of the basin. A series of radiocarbon dates from terraces has been obtained. The dating results indicate that the level of Lake Nero in the Late Weichselian did not exceed 110 m asl, which refutes the model of Kvasov (1975). The terrace of 110 m is also well marked on the sides of other adjacent basins - Yaroslavl, Kostroma, Galich. This suggests the existence of a single interconnected system of glacial lakes in the Late Valdai on the territory of the Yaroslavl Volga region.

An alternative view of the Anglian/Elsterian (MIS 12) glaciation of southeastern England

Harold Langford

Department of Geography, Birkbeck University of London, London, United Kingdom

Anglian/Elsterian (marine oxygen isotope stage (MIS) 12) glaciation of East Anglia has been debated for more than 150 years. Most favour a subglacial origin for the spectacularly deformed chalk-rich diamictons (CRDs) and associated sediments of the North Norfolk coast, although for the most part the CRDs are clearly waterlain. This presentation pieces together evidence from the Peterborough area with observations along the North Norfolk coast, between Weybourne and Trimmingham, in order to provide a plausible account of the Anglian glaciation of East Anglia in the context of a proglacial lake occupying the southern North Sea basin. Two subaqueous diamictic facies deposited in a proglacial lake depositional environment, as evidenced by the conspicuous presence of dropstones, dominate the Anglian sequence on the North Norfolk coast: Happisburgh diamicton (HD) and Bacton Green diamicton (BGD). The former has either folded Chalk bedrock or Chalk rafts of varying size, which are present only to the east of Sheringham. Chalk was sourced offshore from the north by erosion of a Chalk headland on the north bank of the W–E trending Ancaster river. The BGD has an influx of ferruginous fines, large pockets of sand and gravel and, to the west of Sheringham, of extremely chalk-rich diamictons. Sand and gravel appear to be sourced from a glacial portal to the north of Britons Lane/Sheringham. Extremely chalk-rich diamictons deposited by cohesive flow were probably sourced from an ice lobe associated with the Blakeney esker to the west; the ice lobe was responsible for the extensive erosion of Chalk between Weybourne and Huntingdon and represents the only demonstrable incidence of Anglian subaerial glacial overriding of East Anglia. The HD represents a deeper water setting, up to 62 m OD at Briton's Lane, relative to the BGD. Proglacial lake development extended westwards upstream in the Ancaster river catchment as demonstrated by evidence for lacustrine, deltaic and subaqueous slide and grain-flow deposits in the Peterborough area, where a deeper water phase reached up to about 70 m OD. At Norman Cross a succeeding shallower phase is recorded up to 30 m OD. The abundant evidence for subaqueous deposition of CRDs and associated sediments along the North Norfolk coast and in the Peterborough area indicates that the proglacial lake occupying the southern North Sea basin was more extensive than is normally portrayed. Recognition of the two proglacial-lake phases suggests that the two-stage opening of the Dover Strait could have occurred in MIS 12. Destruction of a Chalk headland to the north of the present North Norfolk coast supports the presence of an Ancaster river, which has implications for reconstructions of Anglian ice advances and limits, as well as the pre-Anglian drainage network of East Anglia.

P-4862

Detailed sedimentological analysis of a new 3000 varve year record from Chilean Patagonia

Joshua H. Pike, Adrian P. Palmer, Varyl R. Thorndycraft, Jacob M. Bendle, Ian P. Matthews

Centre for Quaternary Research, Department of Geography, Royal Holloway, University of London, Egham, United Kingdom

High resolution sedimentary archives, such as glaciolacustrine varve sequences formed in proglacial lakes, offer the potential for detailed reconstructions of past glacier dynamics. Specifically, a glaciolacustrine varved sequence can be utilised to investigate, at an annual resolution, the rates and/or duration of change during deglaciation of a former glacial basin. However, to robustly utilise these high resolution palaeoenvironmental archives, there is a need to understand the processes of sediment deposition.

Typically, glaciolacustrine varves are composed of two main sediment components: a coarse sediment component (very fine sand and silt) deposited during the melt season, and a fine component (very fine silt and clay) deposited during the non-melt season. At the macroscale, the couplets may appear simple, but when viewed at the microscale, the couplets may exhibit a complex range of sedimentary structures entering the proglacial environment, which can originate from the glacial margin, nival melt, precipitation and slump deposits.

We presents new varve data obtained from field exposures in Chile Chico (-46.53°S, -71.73°W) in the Lago General Carrera (Chile)/Buenos Aires (Argentina) basin in central Patagonia. Here, an ice-contact proglacial lake formed during the recession of an ice lobe of the former Patagonian Ice Sheet from its local Last Glacial Maximum position. The remodelled ages for the Fenix I moraine (i.e. the youngest of the Fenix complex and innermost before wider glacier retreat) is $18,778 \pm 615$ to $18,086 \pm 214$. Sequences of laminated glaciolacustrine sediment accumulated in the palaeolake and have subsequently been exposed following lake drainage. We report on the geomorphic and sedimentological context which defines glaciolacustrine evolution at Chile Chico, present the results of detailed macro- and micro-facies analyses of the sediments recovered, and develop a process model for the formation of melt season and non-melt season components that suggest a varved origin. Using these new data, we construct a ~3000-year duration varve thickness record for Chile Chico that post-dates (<17 ka BP) the Fenix Chico Master Varve Chronology.

P-4863

Paleolake Riada, Central Ireland: Extent, Characteristics and Impact on the Recession of the Last Irish Ice Sheet.

Cathy Delaney, Matthew Carney, Kathryn Adamson
Manchester Metropolitan University, Manchester, United Kingdom

Ice-contact proglacial lakes are a significant component of glacial systems as they affect the behaviour of glacier margins and influence rate and dynamics of ice retreat. They also act as sediment sinks and contain important records of ice and meltwater dynamics. Some lakes contain varved sediments, which can provide high-resolution records of ice sheet dynamics, meltwater fluxes and, in some cases, climate change.

In central Ireland, a large ice-contact proglacial lake, Paleolake Riada, is known to have existed during recession of the last Irish Ice Sheet. However, little is known about the lake - while the eastern, bedrock, lake margin has been identified, the extent of the lake at maximum has not been established, nor its final drainage route. Lake water depths, and the impact of the lake on ice margin dynamics are also poorly understood. Paleolake Riada is particularly well suited for study due to the abundance of well-preserved geomorphological landforms and widespread lake sediment deposits. The combination of these two records allows for an extremely well resolved and detailed reconstruction of ice dynamics in this region.

This poster will present new geomorphological and sedimentological evidence for the extent and characteristics of Paleolake Riada, including modelling of the maximum extent and drainage route of the lake, and evidence for changing ice-marginal dynamics during its existence. Sedimentary depositional processes within the lake and the potential for constructing a chronology based on varved sediments are also considered.

P-4864

Reconstructing Retreat Dynamics of the Irish Ice Sheet Using Proglacial Lake Sediments

Matthew Carney¹, Kathryn Adamson¹, Cathy Delaney¹, Phil Hughes²

¹Manchester Metropolitan University, Manchester, United Kingdom, ²University of Manchester, Manchester, United Kingdom

Modern ice sheets have retreated rapidly during the last century in response to rising global air temperatures. Understanding the rate and pattern of current deglaciation relies on long-term records of ice sheet behaviour spanning several millennia. Such a record can be found in the Irish Midlands in the form of landforms and sediments preserved from the retreat and breakup of the Irish Ice Sheet (IIS) during the Last Glacial Termination (LGT, c.21-14 ka).

Existing reconstructions of the IIS are based on geomorphological mapping of landforms, which are inherently discontinuous in their distribution and preservation, and therefore provide only snapshots of glacial history. A more continuous archive is preserved in proglacial lake sediments. These lakes are sinks for glacially-derived meltwater and sediment, and enable continuous, spatially-integrated reconstructions of glacial and foreland environmental change, including annually or seasonally-resolved (varved) records that far exceed the temporal resolution of geomorphological techniques.

Thick sequences of laminated, potentially varved, proglacial lake sediments from Palaeolake Riada are well-preserved in the Irish Midlands and provide valuable insights into IIS behaviour and lake sedimentation. Their high temporal resolution provides a basis from which a new chronology of ice sheet behaviour can be constructed.

We present a new high-resolution analysis of laminated glacial lake sediment cores from Co. Offaly, close to IIS marginal landforms (moraines and eskers). A suite of physical and chemical analyses are used to reconstruct ice marginal processes and fluctuations of the IIS during the LGT. This preliminary analysis examines the value of multiproxy data to produce detailed reconstructions of the timing and dynamics of Irish Ice sheet retreat. This will produce insights into long term retreat patterns and behaviours of ice sheets during periods of climate amelioration, applicable to current and future dynamics of existing ice sheets.

P-4865

Chronology of proglacial lake overflows through the Arctic - Caspian watershed

Andrei Panin^{1,2}, Natalia Karpukhina¹, Redzhep Kurbanov^{1,2}, Igor Modin², Andrew Murray³

¹Institute of Geography RAS, Moscow, Russian Federation, ²Lomonosov Moscow State University, Moscow, Russian Federation, ³Nordic Laboratory for Luminescence Dating, Department of Earth Science, University of Aarhus, Roskilde, Denmark

The chronology of the overflow of ice-dammed lakes through the Main Continental Divide from the Vychegda valley to the Kama and then to the Volga River has been discussed since the middle of the 20th century. Krasnov (1948), Yakovlev (1956), Lavrov (1968, 1975), Kvasov (1975), Groswald (1998, 1999, 2009), Lavrov and Potapenko (2005, 2012), Lysa et al. (2011; 2014), Larsen et al. (2014) proposed that the last overflow through the Keltma pass, one of the ancient Early Quaternary valleys, occurred in the LGM. Sidorchuk et al. (1999, 2001), Mangerud et al. (2004), Zaretskaya et al. (2011, 2013, 2019) argued that there was no ice-dammed lake in the Vychegda valley and no inter-basin in the LGM. Mangerud et al. (2004) dated Lake Komi, the largest Late Pleistocene proglacial lake that occupied much of the Pechora and North Dvina basins, to 80-90 ka BP. Maslennikova and Mangerud (2001) proposed that the level of this lake was below the topographic threshold in the Keltma pass and therefore Lake Komi overflowed rather to the west into the Baltic Sea basin. If this was true, the overflow through the Keltma Pass would have never occurred in the Late Pleistocene.

To complete the discussion, we made a comprehensive study of the Keltma pass in the vicinity of the Kama-Vychegda watershed that included mechanical coring to a depth of up to 45 m, geophysical survey (electrical tomography, GPR sounding), OSL dating (vertical series of 17 dates), facial analysis (grain size and thin sections analysis, SEM analysis of quartz grain surface). The results allowed us to find the evidences of two ice-dammed lakes that existed in the Kewltma Pass in the last 150 ka. The lake dammed by the Moscovian (Late Saalian, MIS 6) ice sheet left a 20-m-thick varved silty-clayey sequence accumulated 145-140 ka BP. It is overlain by a 10-m-thick medium to coarse sand interpreted as deposit of the lake overflowed from the Vychegda Basin at 110-95 ka BP. Most probably it was the overflowing of Lake Komi that had occurred before its main stage dated by Mangerud et al. (2004) to 80-90 ka BP in the Pechora Basin. Next layer is the alluvia of local rivers deposited around 65-35 ka BP. The upper unit is 7-8-m-thick fine sand that makes a uniform cover over all topographic irregularities in the bottom and extends up the slopes of the of the Keltma hollow, which, along with microscopic features of the sediment and individual quartz grains, allows to interpret it as aeolian cover. The aeolian sand cover is dated to 30-10 ka BP, which excludes the occurrence of lacustrine environment during the whole MIS 2.

This study contributes to the Russian Science Foundation project No.17-17-01289.

P-4866

Characterising hydrochemical controls on lake algal communities in proglacial lake systems from the SE ice-margins of Vatnajökull, SE Iceland.

Antonia Law¹, Helen Glanville¹, Zoe Robinson¹, Erika Whiteford², Eleanor Fogwill¹, Hannah Roe¹

¹Keele University, Keele, United Kingdom, ²Nottingham Trent University, Nottingham, United Kingdom

Arctic and subarctic regions are experiencing some of the most rapid ecological and environmental changes in response to accelerated warming. As ice-margins retreat in Arctic and subarctic regions, because of accelerated warming, multiple new proglacial lakes and aquatic ecosystems are created. There is a paucity of data relating to how the source of lake water (groundwater-fed, precipitation-fed), lake hydrochemistry, lake location (ice-marginal, isolated from ice-margin) and lake age (dependent upon glacial retreat) determine the structure of proglacial lake ecosystems. Furthermore, new proglacial lakes provide a novel opportunity to investigate the very early stages of lake development (known as ontogeny) and to test hypotheses previously based on palaeolimnological datasets and to establish whether these lakes act as carbon stores or sinks in the proglacial landsystem.

Here we present preliminary data from 23 proglacial lakes created by 5 outlet glaciers (Skaftafellsjökull, Svinafellsjökull, Kviarjökull, Fjallsjökull and Breidamerkurjökull) from the SE sector of the Vatnajökull ice-sheet, SE Iceland. The lakes comprise ice-marginal lakes fed by glacial water and precipitation, isolated lakes (isolated from the ice-margin in the last ~80 years) fed by either groundwater and or precipitation and perched moraine lakes which are fed directly by precipitation. The lakes are all between 0 – 80 years in age, based on the date the lake became directly isolated from the ice-margin, identified from satellite imagery and aerial photographs. We analysed stable oxygen isotopes ratios ($^{16}\text{O}:^{18}\text{O}$) to determine lake water source; Chlorophyll *a* to measure lake biological productivity and diatom assemblages to investigate the algal ecosystems of the lakes. In addition, limnological and hydrochemical parameters were analysed in situ and at the laboratory to investigate the environmental controls on the algal lake ecosystems and to determine the type and source of organic carbon in the lakes.

Our preliminary data demonstrates that ground water may be an important driver of early lake algal ecosystems. Diatom assemblages in the majority of the lakes were characterised by high relative abundances of small benthic pioneer species (e.g., *Achnantheidium minutissimum* var. *minutissima*, *Achnantheidium minutissimum* var. *jackii*) which can tolerate turbid, low light and alkaline conditions caused by the groundwater and utilise the high concentrations of nutrients from glacial flour. *Nitzschia palea* was found in high relative abundances in some of the ground water-fed lakes possibly reflecting the high conductivity of these lakes. The precipitation-fed lakes are typically older and more distal to the ice-marginal; suggesting that the influence of groundwater on proglacial lake ecosystems may diminish over time. Early proglacial lake ecosystems are dynamic and may undergo rapid ecological changes as hydrological inputs change in proglacial areas.

P-4867

Varves, chronology and climate: progress on the re-investigation of the Swedish Timescale

Alison MacLeod¹, Stefan Wastegård², Rachel Devine³, Adrian Palmer³

¹University of Reading, Reading, United Kingdom, ²Stockholm University, Stockholm, Sweden, ³Royal Holloway University of London, Egham, United Kingdom

A central research theme in the field of Quaternary Science today relates to the question of whether high-magnitude and abrupt (millennial to decadal scale) shifts in climate occurred synchronously or asynchronously across the globe. The importance of deciphering this lies in its ability to help us understand how our climate system operates.

By investigating palaeoenvironmental archives which preserve long records of past climate fluctuations, we can more accurately assess and model how our climate system is likely to respond to future changes. Polar ice-cores provide a record of past climatic change at annual resolution. These records, however, are remote from the major populated land masses, located predominantly in the temperate latitudes. Attempts to identify whether variability exists in the expression of abrupt climate change at different latitudes are hampered by uncertainties in the timing of events, as measured through traditional chronological techniques. Thus annual records of climate recorded in palaeolake basins (akin to tree rings) provide us with an opportunity to address this challenge as they are one of very few terrestrial archives of environmental change which have the ability to provide data at a resolution comparable or better than that of the polar ice cores. Consequently, they are a key archive for assessing the spatial and temporal differences in regional environmental responses to changing climates.

The Swedish Timescale (STS), a 13,300 year-long palaeoglaciolacustrine varve record which tracks deglaciation of ice following the Last Glacial Maximum, is preserved within a network of sites from south to north Sweden (De Geer, 1912; Wohlfarth et al., 1995). However, controversy surrounds the accuracy of this chronology, with authors suggesting that there may be more than 1000 years missing during the most recent glacial-interglacial transition (Younger Dryas to Holocene; e.g. Lundqvist, 1975). This poster from our ongoing research project discusses our approach which ultimately aims to unlock the true potential of these sequences, focusing predominantly on the lateglacial period. It will present new data which has been obtained from several of the original STS sites and highlights new sites that will help test, secure and refine the chronology. In addition to this, we apply high-precision analytical techniques such as μ -XRF corescanning, x-radiography and thin section analysis allow us to test and compare our new work to the original varve counts, which were solely based on macroscale analysis of core surfaces in the field. It is anticipated that eventual refinement of this chronology will ultimately permit direct correlation and assessment of leads and lags in climate records across the North Atlantic region.
