Sediment budgeting the Last Interglacial, Last Glacial and Holocene for the Lower Rhine valleys, estuaries, deltas and coastal barriers

Kim M. Cohen^{1,2}, Jan Peeters¹, Gilles Erkens^{2,1}, Esther Stouthamer¹, Hans Middelkoop¹, Freek S. Busschers³, Marc P. Hijma², Wim Z. Hoek¹

¹Utrecht University, Utrecht, Netherlands. ²Deltares, Utrecht, Netherlands. ³TNO Geological Survey of the Netherlands, Utrecht, Netherlands

Abstract

The Late Quaternary record of the Rhine into the North Sea Basin is voluminous and fairly complete one, albeit that it is found mostly buried below youngest coastal plain deposits (the Netherlands) or shelf-sea drowned (southern North Sea and its back-barrier tidal systems). Mapping and dating of the various units has very much advanced over the last 15 years. Data collection from corings (onshore and offshore), supplemented with CPT and dedicated shallow seismic surveying, has allowed to identify architectural units and lithofacies characteristics, to sample for OSL and 14C dating, and to develop reconstructions of the geological developments. These reconstructions tie in with traditional palynology-based paleoclimatological contexts, with sea-level reconstructions and sequence stratigraphic inferences. More importantly, the mapping has complete coverage of the southern North Sea basin fill, which allows to establish time-sliced sediment budgets allowing to compare the Last Interglacial to the Holocene (natural stages, human overprinted final stages), and the first half of the Last Glacial to the second part (e.g. the Rhine valley across the North Sea floor during the cold and lowstand of 'MIS4' vs. that of 'MIS2'). Our presentation will focus on these two comparisons, based on recent papers. We will highlight what the volumetric analysis concludes, especially in terms of cross-checks of the depositional reconstructions and ideas on timing and length and reworking capacity of successive Late Pleistocene substages.

Distribution of foraminifers and ostracods in the East Frisian Wadden Sea – establishing a transfer function for relative sea-level change

Juliane Scheder^{1,2}, Anna Pint², Peter Frenzel³, Friederike Bungenstock¹, Max Engel^{4,2}, Frank Schlütz¹, Helmut Brückner²

¹Lower Saxony Institute for Historical Coastal Research, Wilhelmshaven, Germany. ²Institute of Geography, University of Cologne, Cologne, Germany. ³Institute of Earth Sciences, Friedrich Schiller University of Jena, Jena, Germany. ⁴Geological Survey of Belgium, OD Earth and History of Life, Royal Belgian Institute of Natural Science, Brussels, Belgium

Abstract

The variability of relative sea-level (RSL) change in the German Bight during the Holocene is still not entirely resolved, as it is highly influenced by different global, regional, and local driving factors. Significant vertical uncertainties are associated with peat layers (indirect relation, post-depositional compaction, lack of data for the last 2000 years etc.), the most commonly used RSL indicator. In light of rising seas and the expected future increase in frequency and magnitude of strongest storm surge events, detailed information on RSL histories and local controlling mechanisms is required to create more realistic future scenarios and to better prepare for future coastal-protection challenges. This study contributes to deciphering Holocene RSL changes at the German North Sea coast in a high vertical resolution using microfaunal and sedimentological data. It is embedded in the interdisciplinary WASA Project (*"The Wadden Sea as an archive of landscape evolution, climate change and settlement history"*, <http://nihk.de/index.php?id=483>).

Recent associations of Foraminifera and Ostracoda from low intertidal to supratidal settings of the barrier island of Spiekeroog in combination with environmental parameters (granulometry, C/N, TOC, salinity) were investigated and quantified in elevation steps of 15 cm in order to generate a transfer function (TF) of RSL change, which can be applied to the stratigraphic record. TFs model the relation between the elevation of sample points relative to mean sea level and relative abundances of foraminiferal species over time; ostracods provide additional habitat and salinity information. The combined use of foraminifers and ostracods for a TF is an entirely new approach. The application of the TF on Holocene sediment cores from nearby Norderney will enable the elaboration of a high-resolution RSL curve for the East Frisian Islands. Radiocarbon age estimates on peat layers provide the chronological framework.

Our first data of foraminifer and ostracod taxa distribution show a clear vertical zonation between the middle salt marsh and the tidal flat with very few individuals in the sand flat area suggesting removal by the tidal current or poor preservation. By means of multivariate statistics the elevation relative to mean sea level was deduced as the main driving factor. The smallest vertical error (49 cm) is associated with our new approach of combining Foraminifera and Ostracoda for a TF, which also outperforms error ranges of classical sea-level indicators, such as basal or intercalated peats. In the future, the number of samples will be increased through a second transect on the mainland side of the backbarrier area of Spiekeroog in order to further enhance the TF performance.

Long-term controls of inherited topography on glacial-postglacial stratigraphy: Late Pleistocene and Holocene landscape evolution at Dogger Bank, North Sea

Andy Emery¹, David Hodgson¹, Natasha Barlow¹, Jonathan Carrivick¹, Carol Cotterill²

¹University of Leeds, Leeds, United Kingdom. ²British Geological Survey, Edinburgh, United Kingdom

Abstract

Dogger Bank, in the southern North Sea, is a large (~17,500 km²), shallow (-15 to -25 m OD) bank surrounded by deeper (-50 m to -80 m OD) water. Site investigation data collected over Dogger Bank as part of the Forewind offshore windfarm project comprises a dense 2D grid of high-resolution, shallow seismic reflection data, boreholes and geotechnical logs, forming a comprehensive, integrated dataset. A transition from glacial to proglacial, terrestrial, coastal and marine sedimentary environments is documented, which makes Dogger Bank an ideal natural laboratory to examine the complex stratigraphic and environmental evolution in response to Quaternary climate change. As such, Dogger Bank provides an important analogue for future process response to projected climate change, allowing for planning and mitigation of effects of ice-sheet retreat, permafrost degradation and sea-level rise.

Mapping of seismic stratigraphy, calibrated to vibrocore and borehole sedimentary facies and combined with Cone Penetration Tests, has revealed the importance of inherited topography on landscape evolution. A large, buried, northeast-southwest trending ridge in the southeast of the study area has chaotic seismic facies, interpreted to represent deformation due to glaciotectonics within a large terminal thrust moraine. Retreat of the ice sheet from this position allowed a moraine-dammed proglacial lake to develop. Two phases of lake fill, an older ice-contact stage and a younger ice-distal stage, reflect a stepped ice-sheet retreat controlled by subglacial topography. Overconsolidated lake sediments imply a period of subaerial exposure leading to desiccation. A series of channels incised into the lake sediments, which are partially infilled by peats and accumulation of organic matter reflecting a warming climate. During the Early Holocene, marine transgression occurred. The rate of rise and mechanism of beach barrier overstepping was controlled by inherited moraine ridge topography, which experienced some reworking through wave ravinement. Finally, a layer of shallow marine sand was deposited, thickening towards the southwest. At the base of this sand, large, erosional forms cut into the overconsolidated proglacial lake fill. Sigmoidal reflectors within the fill of these scours suggest progradation of shallow marine systems to the southeast. The location of these scour-fills is confined to the overconsolidated lake fill.

Inherited topography of glacial origin has controlled subsequent landscape evolution at every stage of at the marine inundation of Dogger Bank. Understanding the controls of such complex stratigraphy is vital for accurate mapping subsurface units. The maps produced highlight the requirement for high-resolution data, both horizontal and vertical, in cost-effective delivery of offshore engineering projects. In the identification of topographic controls on the style and rate of deglaciation and the response of beach barrier systems to rapid sea-level rise provide vital well-preserved analogues to help inform planning and mitigate against the effects of future climate change in low-lying coastal settings.

Quaternary sediment distribution in the central and northern North Sea

Irfan Baig¹, Jan Inge Faleide¹, Johan Petter Nystuen¹, Berit Oline Hjelstuen², Hans Petter Sejrup²

¹University of Oslo, Oslo, Norway. ²University of Bergen, Bergen, Norway

Abstract

The North Sea area has been subjected to significant changes in the last ~2.7 Myr. A considerable thickness (~1000 m) of Cretaceous-early Pleistocene sediments were eroded during the Quaternary in the basin margin areas of the central and northern North Sea and deposited in deeper parts of the basin. This study focuses on the relationship between erosion and deposition, as revealed by the Quaternary succession in the North Sea Basin, and reconstruction of the latest stage of the basin evolution by the application of seismic stratigraphy. Chronostratigraphic data from a number of exploration boreholes in the Norwegian North Sea sector and shallow boreholes in the UK North Sea sector provided seismic-well ties for selected lines from regional/semi-regional 2D seismic surveys constituting the database. The work has resulted in a detailed interpretation of the Quaternary succession. A total of eight seismic sequences have been identified within the Quaternary succession. A regional downlap surface marks the base of the Quaternary succession in deep parts of the North Sea Basin. The major deposition took place during ~2.7-0.78 Ma when most of the accommodation was filled with sediments derived from the east. Depositional patterns indicate continuous subsidence of basin areas and tilting of the basin margin areas to the west in the central North Sea since Oligocene time, whereas tilting of the basin margin areas to the east started sometimes during the latest Pliocene. Open marine conditions existed in the Central Graben area at the beginning of the Quaternary, whereas coastal and/or deltaic conditions dominated to the east. The shoreline gradually migrated to the west as the accommodation was filled in by sediments. Reduced rate of sedimentation probably developed around ~0.98 Ma in the Central Graben area between 57° and 58°N. This may be linked with the filling of the accommodation and/or inception of the Norwegian Channel around ~1.1 Ma. Most of the sediments eroded in the basin margin and onshore areas since the inception of the Norwegian Channel may be transported by fast-moving ice streams to the North Sea Fan and thus restricted amounts of sediments may have entered the basin beyond the submarine margins of the channel in the central and northern North Sea. This may imply different sedimentary conditions during ~1.1-0.45 Ma within the deep basin and basin margin areas. Glacial environments were probably dominant during the last ~0.45 Ma and repeated glaciation of the central and northern North Sea caused erosion of the basin margin areas. Early Quaternary sediments are nearly completely preserved in the Central Graben area but thicknesses are reduced due to erosion towards the basin margins to the east and west.

O-0005

Buried Quaternary valleys in the Danish North Sea - Morphologies of an ice margin environment

Lasse Tésik Prins, Katrine Juul Andresen, Ole Rønø Clausen
Aarhus University, Aarhus C, Denmark

Abstract

The quaternary succession in the Danish Central Graben is dominated by buried erosional channels. We have mapped the extent of these channels using 3D seismic time slices from the Danish Central Graben area. The 3D seismic data is processed for hydrocarbon exploration, and acquisition footprints and low signal to noise ratio thus heavily distort the shallow parts. However, by combining mapping of these channels from 3D seismic time slices with high resolution 2D seismic site survey data we have been able to separate the channel systems into generations, interpret their formation based on infill geometries and plan view morphology, and thereby unravel the geological evolution of the area. We supplement the interpretations with data and age interpretations from geotechnical investigations where possible.

From this integration of different data types, we have found a river valley system that crosses the Southern Danish Central Graben. We interpret the system to have been active in the late Weichselian-Holocene, during and after deglaciation when the area was subaerially exposed. We base our interpretation on a number of observations: The system displays different fluvial styles, from straight channels to meandering, and locally braided systems, revealing large differences in energy over the area. There is a confluence point in the central part of the system, where channels from the north and from mainland Europe converge and change direction towards the east-northeast. It is a tributary system with three hierarchical degrees of tributary channels above seismic resolution. The channel infill is categorized by two seismic facies representing fluvial deposits and transgressive deposits (estuarine or marine). The area shows only little relief, and we have found a mismatch between the apparent flow direction observed from the plan view morphology, and the direction inferred from measured erosional depths of the channels. We attribute this to glacioisostatic compensation of the glacial forebulge, which, due to the low relief in the area, was sufficient to invert the apparent flow direction.

This study emphasizes the importance of differentiating river valleys and tunnel valleys in seismic geomorphology as part of understanding the Late Weichselian to Holocene development of the North Sea and particularly for areas close to the Last Glacial Maximum extent where both morphologies are expected to be present. The study can furthermore be used as input for glacioisostatic models.

Reconstruction of former landscapes and Holocene sea-level rise in the area of the island Norderney, German Wadden Sea

Frank Schlütz¹, Ben Marzeion², Dirk Enters¹, Felix Bittmann¹

¹Lower Saxony Institute for Historical Coastal Research, Wilhelmshaven, Germany. ²Institute of Geography, University of Bremen, Bremen, Germany

Abstract

The interdisciplinary joint project WASA (The Wadden Sea as an Archive of landscape evolution, climate change and settlement history: exploration – analysis – predictive modelling) focuses on the reconstruction of the late Quaternary development in the German Wadden Sea area. The aim is to identify and locate past areas suitable for human occupation before inundation by the rising sea.

More than 120 vibrocores obtained around the East Frisian island of Norderney document a wide range of different local developments explored by stratigraphical, sedimentological and palaeobiological (pollen, non-pollen palynomorphs, foraminifera, diatoms) analyses and interconnected by hydro-acoustic measurements. The AMS ¹⁴C-datings on taxonomically identified macro remains and fine bulk from organic rich layers like peat and lacustrine sediments include double and triple datings to identify outliers, to increase the reliability of age-depth models and to estimate the formation processes of organic fraction. This will provide a robust chronological framework and a detailed timeline of former palaeoecological and sea-level changes.

Close to the recent mainland a complex pattern of bogs and wet heathland characterized by cross-leaved heath (*Erica tetralix*), bog-rosemary (*Andromeda polifolia*) and the peat moss *Sphagnum papillosum* developed during the early and middle Holocene before these environments were covered by marine sediments. Near the barrier island of Norderney and further north Alder carrs existed. While the successive inundation of these landscapes reflect the Holocene eustatic sea level rise, younger peats intercalated in marine sediments clearly prove phases of a decreased (or stagnating) sea level with freshwater conditions at before marine sites. Those phases could have last only a few hundred years with gradual shoreline regression and re-transgression clearly reflected in the changing palynological signals of the marsh and swamp vegetation.

Therefore, our new data underline the existence of natural short termed sea level fluctuations with rates of several millimetres per decade as published by Behre (2007). A comparison with climatic data from the North Atlantic and the Mediterranean point to north hemispheric climate drivers behind this phenomenon, possibly related to variations of the subpolar gyre.

WASA is financed by the „Niedersächsisches Vorab“ of the VolkswagenStiftung within the funding initiative „Küsten und Meeresforschung in Niedersachsen“ of the Ministry for Science and Culture of Lower Saxony, Germany (project VW ZN3197)

Behre K.-E. (2007), A new Holocene sea-level curve for the southern North Sea. *Boreas* 36: 82–102.

O-0007

The geological evolution of the North Sea Basin during the Quaternary

Dag Ottesen¹, Christine Batchelor², Julian Dowdeswell², Helge Løseth³

¹Geological Survey of Norway, Trondheim, Norway. ²Scott Polar Reserach Institute, University of Cambridge, Cambridge, United Kingdom. ³Equinor ASA, Trondheim, Norway

Abstract

Based on an extensive 2D seismic database and data from several hydrocarbon wells, the Base Quaternary surface has been mapped over the entire North Sea Basin. The basin starts on land in the Netherlands (52°N) and ends in the transition zone to the Norwegian Sea offshore of western Norway (62°N). The basin is 1200 km long, 100-200 km wide and 1000 m deep, and is filled with up to 1000 m of sediments (140 000 km³). The basin has subsided more or less continuously along the basin axis during the Quaternary, whereas surrounding shelf and land areas have been uplifted.

The infill pattern of the basin is outlined. The southern and central basin was filled in mainly by fluvial sediments from the east and south during the Early and Middle Pleistocene.

The northern North Sea basin was filled in largely by glacial debris-flows deposited in front of an ice sheet covering southern Norway during many glacial periods during the early and middle Pleistocene. The first glaciers appear to have flowed out of the Sognefjorden palaeo-valley at the onset of Quaternary glaciations over Norway some 2.7 million years ago. The depositional regime and changing palaeo-current pattern in the North Sea Basin through the Quaternary are summarized.

Abstract

Mineral dust is both an agent and a tracer of climate change on a range of time scales. Here we briefly review the variability of the global dust cycle since the Last Glacial Maximum as reconstructed from natural archives. We then focus on Earth system model simulations including the dust cycle, and review the proposed strategy for dust experiments in PMIP4. We review the global budgets of dust emissions and atmospheric loads, and we summarize the published estimates in terms of dust feedbacks on different climate states within the last 21,000 years. Specific examples of climate impacts of dust for the mid-Holocene and Last Glacial Maximum will be also discussed.

O-0009

Atmospheric circulation changes and the simulated dust cycle in Europe during the Last Glacial Maximum

Patrick Ludwig¹, Erik Schaffernicht², Yaping Shao², Joaquim G. Pinto¹

¹Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology, Karlsruhe, Germany. ²Institute for Geophysics and Meteorology, University of Cologne, Cologne, Germany

Abstract

This study establishes a linkage between the aeolian mineral dust cycle during the Last Glacial Maximum (LGM) and the loess deposits in Europe. The glacial dust cycle in Europe is simulated at high resolution using a regional climate-dust model. The simulated dust deposition rates were compared with fieldwork-based mass accumulation rates determined from more than 70 loess sites in Europe. In contrast to the currently prevailing westerlies, we found that easterly (36%) and cyclonic (22%) weather patterns prevailed over central Europe during the LGM. Together with the cyclones, the recurring dry easterlies associated with a high-pressure system over the Eurasian Ice Sheet (EIS) dominated the dust transport from the EIS margins to eastern and central Europe. Major dust emissions occurred in the zone between the Alps/Black Sea and the southern EIS margin with the strongest emission near the German-Polish border. Based on these emissions, westwards running dust plumes resulted in high deposition rates in western Poland, the German Bight, and on the North German Plain. The agreement between our simulations and the independently reconstructed loess-based accumulation rates corroborates the proposed dust cycle hypothesis for Europe.

O-0010

Dust responses to orbital and meltwater forcing in the Community Earth System Model (CESM)

Bette L Otto-Bliesner¹, Esther C Brady¹, Clay Tabor², Natalie Mahowald³, Samuel Albani⁴, Zhengyu Liu⁵, Chengfei He⁵
¹National Center for Atmospheric Research, Boulder, USA. ²University of Connecticut, Storrs, USA. ³Cornell University, Ithaca, USA. ⁴Universita degli Studi di Milano-Biocca, Milano, Italy. ⁵Ohio State University, Columbus, USA

Abstract

Changing climate conditions over glacial-interglacial cycles affect dust emissions and transport. Predictive dust is now included in the Community Earth System Model (CESM). Atmospheric dust is mobilized from the land by wind in the CESM land model component (CLM). The most important factors determining soil erodibility and dust emission include the wind friction speed, the vegetation cover, and the soil moisture. The dust atmospheric cycle in the CESM (Albani et al., 2014) accounts for these factors and is based on the DEAD (Dust Entrainment and Deposition) model of Zender et al. (2003). Model impacts on climate and biogeochemistry include direct radiative forcing and deposition on snow, ice, and the ocean.

In this talk/poster, we will present CESM results from the iTrace transient simulations from 20ka to 14ka, forced with orbital, greenhouse gas, ice sheet and meltwater variations and from idealized forcing simulations for endmembers of these forcings. We concentrate on changes in the dust emissions, transport and deposition associated with the orbital cycles, the lower glacial greenhouse gas concentrations, and on the Heinrich 1 meltwater event during the last deglaciation.

O-0011

Minimal impact of modeled drought on natural dust emission and deposition in the Southwest United States

Stephanie Arcusa¹, Carlos Carrillo², Toby Ault², Nicholas McKay¹

¹Northern Arizona University, Flagstaff, USA. ²Cornell University, Ithaca, USA

Abstract

The assumption that the emission, burden, and deposition of fine dust particles increase during drought in the Southwest United States is common and is the basis of the expectation that future drought will exacerbate regional dustiness with impacts on snowmelt and health. This assumption is supported by observational datasets between drought and the atmospheric burden of fine particles. However, recent long-timescale dust deposition records from the region suggest that sediment availability, rather than drought, is the primary driver of dust deposition in the region, and thus also of other aspects in the dust cycle. Here we concentrate on the Last Millennium Experiment (LME) output from Community Earth System Model (CESM) to investigate further the claim that drought is the major natural driver of the dust cycle in the Southwest.

We regress dust production, atmospheric burden and dust deposition against model drought as identified by Standardized Precipitation Index (SPI) over the years 850-2005 for 10 fully forced ensemble members of the LME. We also investigate the long-term trends in ensemble mean for comparison with paleodust deposition records.

The model shows little relation between dust deposition and regional aridity from 850-2000 CE. Additionally, like the paleodust records, model output suggests relative stability in the dust cycle until the 1900's when all aspects of the dust cycle increase. However, dust deposition in the region increases much more than the increase in regional dust production. This supports the paleo record evidence that drought is not the leading driver of dust in the Southwest US. However, the lack of inclusion of dust grains coarser than 10 microns is likely biasing the model towards long-range transport and precluding any investigation into the regional dust-drought nexus. This likely has implications for other parts of the world as well, as coarse dust particles are prevalent and missing from most models. If regional dust cycles are not modeled adequately, we cannot rely on dust projections that are critical for health and water management.

O-0012

Regional contributions of ocean iron fertilization to atmospheric CO₂ changes during the last glacial termination.

Natalia Opazo, Fabrice Lambert
Pontificia Universidad Católica de Chile , Santiago, Chile

Abstract

The mineral dust aerosol generated from the wind effect on the Earth's surface, acts in the atmosphere altering the radiative balance of the Earth system, interacting with the cloud condensation nuclei and affecting the biogeochemical cycles, because it contains micro nutrients as iron, whose supplies are crucial in marine ecosystems. Effect that is amplified in areas with "High Nutrient Low Chlorophyll" (HNLC) product of its iron limitation. Through data obtained from ice cores, it has been shown that the dust has varied during glacial and interglacial periods, which coincides with the atmospheric CO₂ records, which have varied between 80-100 ppm at the same periods. What has invoked theories such as the one proposed by J. Martin, which relates the effect of iron in the soft tissue pump with the variability of atmospheric CO₂.

Through a biogeochemical model of intermediate complexity called cGENIE with an emphasis on the carbon cycle, was calculated the reduction of atmospheric CO₂ during the period from the Holocene (10 ka) until the Last Glacial Maximum (21 ka), as result of iron fertilization on the surface ocean. For which were used six dust flux fields, from a reconstruction and five simulations of coupled models. We created eight intermediate artificial levels of dust flux between both periods, and the experiment was carried out with special emphasis on the HNLC zones, in order to estimate the contribution of each of these areas in the global capture of pCO₂. We found that Southern Ocean contributed over half of the glacial-interglacial total pCO₂ change due to dust-borne iron fertilization, mostly during the older half of the termination. In contrast, the North Pacific contributed about 30% of the dust-induced pCO₂ changes, but only at the end of the termination.

Holocene dust provenance and variability in East Antarctica: new results from the SOLARICE (Dome C) ice core

Delmonte Barbara¹, Holly Winton², Mélanie Baroni³, Carlo Baroni⁴, Maria Cristina Salvatore⁴, Biancamaria Narcisi⁵, Giovanni Baccolo¹, Valter Maggi¹

¹University Milano Bicocca, Milano, Italy. ²British Antarctic Survey, Cambridge, United Kingdom. ³CEREGE Centre Européen de Recherche et d'Enseignement des Géosciences de l'Environnement, Aix en Provence, France.

⁴University of Pisa, Pisa, Italy. ⁵ENEA, C.R. Casaccia, Roma, Italy

Abstract

We provide a comprehensive overview of eolian dust flux, transport and sources for the central and marginal sectors of the East Antarctic ice sheet during Holocene. Background dust transport variability, investigated by means of dust grain size parameters, is investigated in detail for the Late Holocene through high-resolution data obtained from a new ice core drilled at Dome C in the framework of the Franco-Italian SOLARICE research project. These new results confirm the variable strength and localization of troposphere air subsidence over Antarctica, which is related to local and regional atmospheric dynamics, and highlight the importance of high-resolution ice core analyses for depicting high frequency modes of variability still hidden to discontinuous dust measurements.

We focus also on spatial differences in dust cycle between inner plateau sites and peripheral regions located close to the Transantarctic Mountains, these latter being very sensitive to regional climate changes. The importance of high-altitude rock outcrops in Victoria Land – such as relict flat structural surfaces – and remobilization of volcanic material accumulated from different volcanic sources of Victoria Land are discussed.

Paleoecology and dynamic vegetation modeling reveal past and future forest dynamics in the Olympic Mountains, USA

Christoph Schwörer^{1,2}, Daniel G. Gavin²

¹Institute of Plant Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland.

²Department of Geography, University of Oregon, Eugene, USA

Abstract

Future climate change is expected to lead to dramatic changes in species abundance and composition, especially in mountain areas with steep ecological gradients. Mountain vegetation will likely shift to higher elevations with warmer temperatures in order to remain in the present-day climatic niche. However, in the mountain ranges of Western North America, climate warming will also lead to an upward shift of the snowline and a decrease in snowpack, which could increase moisture stress during the dry summer months. It is therefore unclear if subalpine mountain forests will be contracting or expanding in the future. Dynamic vegetation models are the method of choice to make detailed projections about the future forest dynamics and associated ecosystem services. However, proper model validation in space and time is crucial for reliable model results.

Here, we use the dynamic vegetation model LandClim to simulate past and future vegetation dynamics at two study sites in the Olympic Mountains (Pacific Northwest). To accurately reflect microclimatic variation in the rugged terrain, we developed a topoclimatic model based on small temperature loggers distributed in the two study areas. We then simulated forest dynamics during the Late Holocene and compared the model output with pollen and macrofossil inferred local and regional vegetation reconstructions from Ptarmigan and Discovery Lake. The model was able to correctly simulate past vegetation composition and abundance at both study sites. We then simulated future vegetation dynamics using downscaled climate projections. Our modelling results indicate that subalpine forests are shifting to higher elevations in the wet, western side of the mountain range, with only little change in regional species composition. However, on the drier, eastern side of the Olympic Mountains, the model projects drastic changes in species composition and even a lowering of the timberline due to insufficient moisture availability.

Our results suggest a non-linear reaction of mountain forests to future climate change depending on local climatic, topographic and edaphic conditions. The projections of future vegetation changes with paleo-validated dynamic vegetation models are an invaluable source of information for ecosystem managers and show policy makers and the general public the urgency of climate change mitigation.

Holocene dynamics of the boreal forest of Eastern Canada: Untangling the drivers of vegetation change using paleoecological data and models

Emeline Chaste^{1,2}, Martin Girardin³, Jed Kaplan⁴, Yves Bergeron⁵, Christelle Hély⁶

¹AgroParisTech - Nancy center, Nancy, France. ²University of Quebec in Montreal, Montreal, Canada. ³Natural Resources Canada, Quebec, Canada. ⁴ARVE Research SARL, Pully, Switzerland. ⁵Forest Research Institute, Université du Québec en Abitibi-Témiscamingue, Rouyn-Noranda, Canada. ⁶Ecole Pratiques des Hautes Etudes, Montpellier, France

Abstract

The boreal forests of Eastern North America developed during the Holocene following the retreat of the Laurentide Ice Sheet. This region now stores a substantial amount of carbon in living biomass, soils, and peat, and has an important biogeophysical feedback to the atmosphere that influences hemispheric climate. While forests developed rapidly on bare ground following ice retreat, the boreal forest was not static over the Holocene. Paleoecological analyses indicate that major changes in species composition, soil properties, and disturbance frequency occurred over the past 6 ka. Understanding the drivers behind these ecosystem dynamics is important for projecting how this globally important forest region may respond to future climate change.

Here we present a study simulating the responses of vegetation and fire to changes in climate during the last 6000 years using a dynamic vegetation model, and evaluating the model output at multi-millennial time-scales using paleoecological archives. We used the LPJ-LMfire model, parametrized for the most abundant tree genera in eastern boreal Canada (*Picea*, *Abies*, *Pinus*, *Populus*) and driven by a Holocene scenario of climate derived from the Earth system model IPSL-CM5A-LR at 10-year resolution. LPJ-LMfire was run with a monthly time-step from 6000 to 0 BP on a 100-km² resolution grid covering the boreal forest from Manitoba to Newfoundland. LPJ-LMfire output was analyzed in terms of annual burn rates (ABR), net primary productivity, aboveground biomass and genus-specific cover percentage. We compared ABR and tree biomass simulated by LPJ-LMfire results with paleoecological reconstructions obtained from lacustrine-charcoal and pollen records, respectively.

Our results support the hypothesis that Holocene climate change had an important influence on the dynamics of the boreal forest of northeastern North America. Forest composition acted as an important “bottom-up” control on fire frequency on multi-centennial time-scales. Warm growing seasons at 6000 BP fostered the rapid establishment of vegetation in the east of our study domain, whereas cold spring temperatures limited biomass growth in the west. Low biomass and high *Populus* cover percentage contributed to low simulated ABR. Simulated changes in ABR and biomass over time were not entirely synchronous with reconstructions based on charcoal and pollen. Where LPJ-LMfire shows trends similar to the paleoecological reconstructions, these are often offset in space by several 100s of km. We suggest that the discrepancies between simulated and reconstructed vegetation time series are associated with inaccuracies in the climate model output that was used to drive LPJ-LMfire.

Examples of past and future land biosphere change: results from a dynamic global vegetation model and proxy data

Fortunat Joos¹, Sebastian Lienert¹, Jurek Müller¹, Willy Tinner², Paul D. Henne³

¹Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ²Palaeoecology, Institute of Plant Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ³U.S. Geological Survey, Geosciences and Environmental Change Science Center, Denver, USA

Abstract

The combination of models and proxy data permits the extension of short instrumental records to decadal-to-century time scales relevant under global warming. For example, palaeo-ecological data, combined with carbon-vegetation modelling, suggest that silver fir, an important European tree species, may ensure key ecosystem services including stand and slope stability, infrastructure protection, and carbon sequestration under global warming in central Europe (Ruosch et al., 2016). Ruosch et al. present results from simulations with the Land Surface Processes and Exchanges (LPX-Bern) dynamic global vegetation model to assess past and future distributions of silver fir in Europe. LPX-Bern is forced with climate anomalies from a run over the past 21 000 years with the Community Earth System Model, modern climatology, and with 21st-century multi-model ensemble results. Pollen and model results both show range expansion starting during the Bølling–Allerød warm period, interrupted by the Younger Dryas cold, and resuming during the Holocene. The distribution of silver fir expands to the north-east in all future scenarios, whereas the potential (currently unrealized) range would be substantially reduced in southern Europe under high emissions. The results suggest that silver fir could play an important role in adaptation planning in central Europe.

Measurements of the stable carbon isotope ratio on annual tree rings offer new opportunities to evaluate mechanisms of variations in photosynthesis and stomatal conductance under changing CO₂ and climate. The isotopic discrimination is indicative of the ratio between the CO₂ partial pressure in the intercellular cavities and the atmosphere and of the ratio of assimilation to stomatal conductance, termed intrinsic water use efficiency (iWUE). Keller et al. (2017) present isotope-enabled simulations over the industrial period with the land biosphere module (CLM4.5) of the Community Earth System Model and with LPX-Bern. A compilation of tree-ring records suggests on average small 20th century changes in isotopic discrimination. LPX Bern results match these century-scale reconstructions, whereas CLM4.5 simulates an increase in discrimination almost twice as large as revealed by the tree-ring data. The results point to problems associated with the formulation of photosynthesis in CLM4.5, while the proxy data and LPX-Bern results support the idea that the physiology of stomata has evolved to optimize trade-offs between carbon gain by assimilation and water loss by transpiration. In the presentation, examples of LPX-Bern results will be discussed in the context of proxy data.

Climate change and tree growth in Canada: Some forests fare better than others!

Martin Girardin

Canadian Forest Service, Quebec, Canada

Abstract

Canada's boreal zone covers 552 million hectares or 28% of the world's boreal zone, of which 223 million hectares are covered by forests. These provide a wide variety of habitats for fauna, flora, and arthropods, and many ecosystem services to humans. In this era of climate change, understanding past and predicting future forest productivity and tree growth are scientific challenges that are central to the development of sustainable forest management practices and policies. However, uncertainties are imposed by the short time period covered by existing forest and remote sensing data. Regional growth and productivity is also tremendously variable over time, such that contemporary data cannot provide information on the full range of variability a given forest experienced and adapted to. Currently available data indicate that the northernmost part of the boreal forest and tundra farther north are exposed to greater climatic warming than other world forests. This should, in theory, increase the level of growth of forest species in these areas. However, tree growth is not only limited by the length of the growing season and the cold, but also by summer drought and excess soil water in the spring and fall. In this presentation, we will synthesize the results of our recent studies on the impacts of climate change on the productivity and tree growth in Canada's boreal forest. Briefly, spatial and temporal changes in past and present forest attributes (productivity, biomass, basal area) have been reconstructed by pollen analysis, forest inventories, satellite data, and dendroecological data. This information from analyses of past amplitudes has been combined with simulations from ecophysiological and global vegetation models to predict future growth under different greenhouse gas emission scenarios. The data synthesis provides compelling evidence that effects of global warming on forest productivity and tree growth are already in progress and there is evidence that local phenotypes are showing signs of maladaptation. Results from projections suggest an increase in the importance of available soil water and heat as constraints on growth over the next century due to warming, but this response may vary to the extent that other factors such as carbon dioxide fertilization, and acclimation to high temperature, contribute to dampening these limitations. We end our presentation by showing that forest-related measures such as human-assisted movement of species' populations could help the migration of pre-adapted populations and could help stabilize the productivity in some areas.

Data-model comparisons reveal long-term vegetation dynamics in two semi-arid mountain regions

Cathy Whitlock¹, Virginia Iglesias², Steve Hostetler³

¹Montana State University, Bozeman MT, USA. ²University of Colorado, Boulder CO, USA. ³US Geological Survey, Northern Rocky Mountain Science Center, Bozeman MT, USA

Abstract

Understanding long-term ecological resilience in the face of climate change requires a network of paleoecological records with sufficient resolution to disclose past ecosystem dynamics, as well as independent information on climate variability through time. These relationships can be particularly challenging to reconstruct in mountainous settings where (1) pollen can be transported long distances; (2) taxonomic assignments of dominant pollen types are often uncertain; (3) environmental gradients are steep and change abruptly; and (4) interactions among climatic and nonclimatic factors are complex. We examine the postglacial vegetation, fire, and climate history of two semi-arid mountain regions: the mixed-conifer forests of the Greater Yellowstone Area (USA) and the forest-steppe border of the eastern Andes (Argentina). In both regions, past ecosystem dynamics are inferred from pollen and charcoal records, which are interpreted in light of modern pollen-vegetation and charcoal-fire relationships. Past variations in temperature and key moisture variables are determined from regional climate modeling (using RegCM4). The data-model comparisons provide examples of ecological stability, transient ecological instability, and abrupt nonlinear dynamics, in which the nature of the response was governed by the intensity of the climate forcing, the intrinsic properties of the ecosystem, and the legacy of past events. In Yellowstone, a striking nonlinear response to gradual warming is evident at the end of the late-glacial period when widespread no-analog assemblages, dominated by shrubs and *Juniperus*, were abruptly replaced by modern mixed-conifer parkland and forest. In contrast, ecological stability is evident in the history of mid-elevation *Pinus contorta* forest, which has exhibited little change since its formation at ca. 9,000 BP. Stability, in this case, is attributed to the ability of *P. contorta*'s to withstand a broad range of climate and fire conditions and outcompete other conifers on infertile substrates. Decreased summer temperature and increased moisture variability in the last 10,000 years is associated with decreasing fire activity and shifting forest composition at low elevations. Along the eastern Andes, late-glacial conditions supported shrubland/steppe with no modern analog. Gradual replacement, first by open *Nothofagus* forest-shrubland at 12,200 BP and then by modern mixed forest at 6,500 BP, suggests a transient unstable equilibrium, forced by changes in temperature, effective moisture, and fire. Submillennial variations between *Nothofagus* and *Austrocedrus* after 6,500 BP indicate development of multiple stable states in response to modest fluctuations in climate and fire. *Nothofagus* established after fires during wet periods, and *Austrocedrus* dominated after fires under dry conditions. Our data-model comparisons thus characterize the late-glacial as a period of unstable ecosystems, in which climate forcing induced abrupt and gradual shifts to new vegetation types and fire regimes, whereas multiple stable states are more evident in the Holocene when vegetation often maintained a dynamic equilibrium within a range of disturbance and climate conditions.

O-0020

Combining tree-ring records with a dynamic vegetation model to understand climate-driven thresholds for land-cover change in the Southern Rocky Mountains

Paul Henne, Todd Hawbaker
US Geological Survey, Denver, USA

Abstract

Dry coniferous forests in the Rocky Mountains of western North America are sensitive to drought-related disturbance, including wildfire and insect outbreaks. Such disturbances were widespread during recent drought events, prompting concern that increasing drought stress will drive extensive conversion of forests to shrublands and grasslands with corresponding losses of ecosystem carbon, in a warmer and drier future. Dynamic landscape vegetation models can simulate the interactions among climate, disturbance, and vegetation to project long-term land-cover change and therefore inform the development of management strategies that maintain ecosystem services. However, recent observations provide a short window for model evaluation relative to the lifespan of trees, and the periodicity of forest regeneration. We are addressing these challenges by combining simulations with the LandClim dynamic landscape vegetation model with long-term records of drought, fire, and stand dynamics from the Jemez Mountains of New Mexico, USA. Situated at the southern limits of the Rocky Mountains, the Jemez Mountains provide a unique setting to understand long-term climate impacts on forest dynamics. Extensive forests dominated by *Pinus ponderosa* and woodlands of *Pinus edulis* currently exist near their dry limits. Forest regeneration was very limited following recent fires, and drought-related mortality widespread, during recent droughts, which demonstrates the climatic sensitivity of forests in the region. Similar climate-related mortality and disturbance events are documented during the late Holocene by a dense network of tree-ring archives. Tree-ring records provide sub-annual climate and fire records, as well as stand demographic data. We are developing monthly climate scenarios for the period 1600 AD-present by combining tree-ring inferred records of seasonal precipitation with modern weather station data. Climate data include multiyear (i.e., 2-8 years) droughts and wet, cool seasons that affected past fire activity and regeneration. Model initialization relies upon stand demographic data, which also informs evaluation of simulated regeneration, growth, and mortality. Models evaluated with long-term data will ultimately be used to quantify climatic thresholds for mortality and regeneration and be applied to project future land cover change and post-disturbance regeneration.

¹University of Montana, Missoula, USA. ²University of Idaho, Moscow, USA. ³Kansas State University, Manhattan, USA. ⁴University of Wyoming, Laramie, USA

Abstract

Shifting disturbance regimes in forest ecosystems are predicted to lead to long-lasting directional changes in ecosystem properties and biogeochemical states, potentially influencing carbon and nitrogen balance over large spatial and temporal scales. While these ideas have a strong conceptual basis and empirical support on decadal timescales, data have been lacking to test them over longer timescales - and to consider their implications for future projections - until only recently. Here we present a framework and a set of testable hypotheses for understanding how coupled climate-fire-ecosystem dynamics scale over space and time to impact carbon and ecosystem properties. We use a combination of ecosystem modeling and palaeoecological reconstructions of fire activity and ecosystem change to test these hypotheses in Rocky Mountain subalpine forests, with a focus on the impacts of fire-regime variability on soil carbon dynamics.

At individual watershed scales, palaeoecological records and ecosystem simulations highlight distinct and significant impacts of wildfires on ecosystem properties, including vegetation, and soil carbon (C) and nitrogen (N) stocks. While ecosystem properties typically return to pre-fire levels over decades, compounding effects from variability in fire severity and the length of fire-free intervals create centennial- to millennial-scale trajectories in some ecosystem properties, including soil C. Our framework predicts that the regional importance of these dynamics depends strongly on the spatial synchrony of fire activity: under scenarios of heterogeneous fire activity across space, regional C stocks will not vary significantly over time; in contrast, during periods of regionally synchronous fire activity, C balance will largely reflect fire-regime variability over centuries or longer. Palaeo records and palaeo-informed modeling spanning millennia provide evidence of both scenarios. Our results imply that fire-regime variability can be a major driver of C trajectories in stand-replacing fire regimes, with compounding effects that may last for centuries. Predicting carbon balance, therefore, depends strongly on the ability of ecosystem models to represent a realistic range of fire-regime variability over the past several centuries to millennia.

Possible link of an exceptionally strong East Asian summer monsoon to a La Niña-like condition during the interglacial MIS-13

Hao Lu^{1,2}, Qiuzhen Yin², Jia Jia^{3,1}, Dunsheng Xia¹, Fuyuan Gao⁴

¹Key Laboratory of West China's Environmental System (Ministry of Education), College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China. ²Georges Lemaître Centre for Earth and Climate Research, Earth and Life Institute, Université Catholique de Louvain, Louvain-La-Neuve, Belgium. ³College of Geography and Environmental Science, Zhejiang Normal University, Jinhua, China. ⁴College of Geography and Environmental Engineering, Lanzhou City University, Lanzhou, China

Abstract

The S5-1 paleosol unit, which corresponds to marine isotope stage (MIS) 13, had undergone the most intense pedogenesis during the Quaternary in the central Chinese Loess Plateau (CLP). It has been suggested to represent the greatest humidity and extremely strong East Asian summer monsoon (EASM). However, the extremely strong EASM occurring in the relatively cool interglacial MIS-13 seems to be a paradox. In the meantime, evidence shows that regional diversity may exist in the relative intensity of the S5-1 soil formation. In order to understand these discrepancies, we first verify systematically the S5-1 soil development across the whole CLP by using numerous available loess records. We then examine the spatial variation of the magnetic susceptibility of different loess-paleosol sections to identify the spatial change of the EASM intensity during MIS-13. We also compare the loess records with other monsoon records in China. Our results show that there is a spatial difference in the intensity of the S5-1 paleosol formation. In the central CLP, S5-1 is indeed the strongest developed. However, in the western CLP, it is weakly developed, whereas the S4 paleosol which corresponds to MIS-11 is the most developed. As compared to MIS-11, the northern front of the EASM during MIS-13 didn't penetrate into or expanded westward, but was located more northerly and eastward. Based on the sea surface temperature records in the tropical Pacific, we suggest that the abnormal variation of the EASM during MIS-13 is related to a strong La Niña or La Niña like climate condition. Under such a condition, the Western Pacific Subtropical High (WPSH) becomes weaker and retreats more northeastward, leading to more precipitation in the mid-east region of northern China (including the east-central CLP), and the summer monsoon rain belt could not penetrate into the western inland.

The climatic fluctuation patterns of the Huaihe semi-humid region in the North and South transition zone of the Eastern China

Xiaoguang Qin¹, Lei Zhang²

¹Institute of geology and geophysics, CAS, Beijing, China. ²Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China

Abstract

The Huaihe watershed located in the North and South transition zone of the Eastern China and is the semi-humid climate region. In the region, northwest wind-transported dusts from the northern arid and semi-arid area deposited and the effect of Jianghuai-specific plum rains is also obvious. However, the climate of the region is different from both the North and the South of China. Therefore, the revealing paleo-climate change of the region is particularly important for understanding of the paleo-climatic pattern of the Eastern Asia. In the study, a Holocene loess-paleosol section in Xiangcheng and a 481m drilling core in Huainan were analyzed. The Holocene climate fluctuations are discussed according to several indices such as proxies of the dust transported distance, wind strength, spring near-surface air-temperature and effective moisture. The 481m long core was compared with paleoclimatic records from other regions by reconstructing its sequences of sedimentary facies. It was found that (1) the whole trend of the climate fluctuation pattern of the Huaihe region was the inverse of the North arid and semi-arid region in different scales since 8Ma. It was wet during cold periods such as glacial periods and dry during warm periods in the region, characterized by the interaction of lacustrine and fluvial facies deposits. During Holocene, the paleosol of the Huaihe region was 1.7-3.8kaBP that was late than 4-7kaBP of the dust source. (2) The characteristics of the climate fluctuation of the Huaihe region may result from that the northward-moving of the plum rains belt was caused by the weakening of winter monsoon and the increased plum rains was due to the westward expansion of the West Pacific subtropical high and the weakening of the India summer monsoon.

Spatial inhomogeneity of orbital-scale monsoon rainfall over Asia

Ji-Eun Kim¹, Axel Timmermann¹, Sun-Seon Lee¹, Tobias Friedrich²

¹IBS Center for Climate Physics, Busan, Korea, Republic of. ²International Pacific Research Center, Honolulu, USA

Abstract

Chinese speleothems together with loess proxies have provided invaluable information on changes in Asian monsoon variability at the orbital scale. Their close relationship with Northern Hemisphere (NH) summer insolation suggests that solar heating is an important driver of Asian monsoon dynamics. Yet, it still remains unclear how changes in solar radiation affect regional monsoon systems as well as their reflections in paleo-climate records. Furthermore, despite the close proximity of Chinese caves and loess sites, the two archives appear to be sensitive to different types of orbital-scale forcing: oxygen isotope data in speleothems are strongly correlated with NH summer insolation with a much weaker signal in the global ice volume, whereas loess proxies are strongly correlated with the ice volume and sea-level signals. To help understand, why records from nearby locations can have different orbital sensitivities and to better understand the spatial characteristics of East Asian monsoon rainfall, we perform a comprehensive analysis of precipitation and oxygen isotope over Asia using a variety of datasets ranging from interannual to orbital time scales. At the orbital scale, transient climate simulations with LOVECLIM and CESM earth system models reveal that the precipitation amount and its phase relative to the orbital forcing are spatially highly variable over Asia. Our analysis offers new insights into the mechanisms generating regional differences in the orbitally-forced East Asian monsoon system.

¹Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China. ²Dept Geosciences, National Taiwan University, Taipei, Taiwan. ³Department of Geological Sciences and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ⁴Faculty of Science, Chulalongkorn University, Bangkok, Thailand

Abstract

The characteristics and mechanisms of tropical rainfall variations on centennial- to decadal- scales are still unclear. Here, we reconstruct a replicated stalagmite-based 2700 yr long, continuous record of rainfall for the deeply convective northern central Indo-Pacific (NCIP) region. Our record reveals a decreasing rainfall trend in the NCIP over the past 2700 yr, similar with other records from the northern tropics. On centennial- to decadal-scales, notable dry climate conditions were observed both in the NCIP and southern central Indo-Pacific (SCIP) during the 20th century (Current Warm Period, CWP) and the Medieval Warm Period (MWP), corresponding to enhanced El Niño conditions. Our newly developed 2000-yr ITCZ shift index record supports an overall southward shift of the ITCZ in the central Indo-Pacific and indicates southward mean positions during the early MWP and the CWP. As a result, the drying trend since the 20th-century in the northern tropics is similar to that observed during the past warm period, suggesting that a possible anthropogenic forcing of rainfall remains indistinguishable from natural variability.

Abstract

The South American Summer Monsoon (SASM) is the most important atmospheric system in tropical South America, being the major supplier of precipitation north of 20°S. Modern climatological studies indicate that year-to-year changes of the SASM are influenced by large-scale modes of atmospheric circulation sourced in the tropics such as the Intertropical Convergence Zone (ITCZ) and El Niño Southern Oscillation (ENSO). The interplay between these modes results in pronounced precipitation anomalies in the tropical Andes and the Altiplano which impact numerous socioeconomic activities. The drivers behind SASM variations at longer timescales are, however, far less understood due to the shortness of modern instrumental timeseries and the relative low number of paleorecords. This prevents an evaluation of past feedback mechanisms, and whether or not the historical ranges of variation represent the expected boundaries for future conditions.

In this presentation we will show three new pollen-based climate reconstructions expanding the last 4000 years from the Chilean Altiplano (18-21°S), two lake sediment records and one series of 32 fossil rodent middens. The Chilean Altiplano is located at the southern margin of the SASM influence, where up to 90% of annual rainfall derives from the easterly penetration of the SASM during the austral summer. These precipitation patterns exert a tight control on the altitudinal distribution of the main vegetation communities. Hence, our pollen reconstructions allowed a fine characterization of past vegetation changes caused by shifts in the strength of the SASM during recent millennia.

The chronology of the two lake cores is based on multiple AMS ¹⁴C dating, while all rodent deposits were individually dated, providing key complementary short-term information at punctual times. Our pollen records reveal significant changes in vegetation at multi-centennial timescales, most notably a marked expansion of high-Andean vegetation along with significant increases in terrestrial plant productivity and lake levels between ~2200 and ~1400 cal yr BP. We interpret this evidence as a multi-centennial interval of increased precipitation due to a strengthening in the mean state of the SASM. Comparisons with other records from the Altiplano, the Tropical Andes and the Pacific Ocean suggest that this rainfall anomaly was largely decoupled from variations in the ITCZ and ENSO at that time. Additionally, we distinguish a marked latitudinal gradient in proxy responses where sites in the southern Altiplano display this wet anomaly more markedly than sites further north. This evidence is consistent with an extra-tropical source of moisture for the SASM. Our results suggest that the drivers of the SASM variability during recent millennia may have been more complex and variable than previously thought, and therefore caution is required in assuming that the tropical controls of this system observed in the instrumental record are stationary in time.

Abstract

Here we present stalagmite calcite $\delta^{18}\text{O}$ and inclusion water oxygen and hydrogen isotopic records over past 16.5 thousand years (ka, before 1950 AD) from Lekiraka cave in East Timor ($8^{\circ}47'10.8''\text{S}$, $126^{\circ}23'31.1''\text{E}$; 626 m above sea level), located in the Australian-Indonesian monsoon territory. The paleo-cave temperature record, calculated with coeval carbonate and inclusion water $d^{18}\text{O}$ data, shows a thermal increasing for 4-6 °C during 16 -12 ka, similar with the trend of past WPWP sea surface temperature change. One of remarkable features of the cave temperature record is 2-kyr thermal valley at 8-6 ka, which does not follow the Holocene-Maximum conditions in the northern hemisphere, instead, is concurrent with the cooling in the Antarctica. Lekiraka stalagmite calcite $d^{18}\text{O}$ record reveals relatively dry glacial and wet Holocene. Inclusion water oxygen and hydrogen isotopic data suggest that Sunda area was the more important moisture source in the Holocene than during the glacial time. Sunda Shelf landmass, associated with deglacial sea level change and global warming, may lead to the alteration of the regional atmospheric circulation and hydroclimate during deglaciation. However, the air temperature over the entire Holocene could be governed by regional insolation and southern-hemisphere high latitude forcings.

Abstract

Rainfall derived from the South American Summer Monsoon (SASM) is socially, economically, and ecologically crucial for the largest part of South America. Yet the mechanisms driving its spatio-temporal variability are poorly constrained posing a challenge for predicting its evolution under future climate change scenarios. To get insights into SASM-dynamics during the past 5 kyr we investigated a marine sediment core obtained in the vicinity of the Jequitinhonha River delta, Eastern Brazil. As the Jequitinhonha's catchment is under the influence of the SASM and particularly sensitive to changes in moisture availability, it is ideally suited to reconstruct spatio-temporal SASM variability. To assess moisture variability in the river catchment and its potential relation to changes in the marine realm, we utilized a multi-proxy approach comprising X-ray fluorescence core scanning, organic biomarker analyses (i.e., alkenones, compound-specific dD on plant waxes), and X-ray diffractometry. Our data suggests that a decline in the inter-tropical insolation gradient fostered a decrease of SASM intensity over the past ~ 2.7 kyr. This long-term trend is overprinted by centennial to millennial-scale fluctuations, probably driven by climatic forcing of high latitude North Atlantic and equatorial Pacific origin. An abrupt shift in the mean spatial configuration of the SASM occurred at ~2.0 ka, initiating a long-term establishment of drier conditions over eastern Brazil. This shift was paralleled by an abrupt increase in El Niño Southern Oscillation variability as well as by a rapid slow-down of the Atlantic Meridional Overturning Circulation, invoking a complex interplay of low and high-latitude forcing on spatio-temporal SASM dynamics.

Geological evidence for widespread deglaciation of North America during Marine Isotope Stage 3

April S. Dalton^{1,2}, Sarah A. Finkelstein¹, Steven L. Forman³, Peter J. Barnett⁴, Tamara Pico⁵, Jerry X. Mitrovica⁵
¹University of Toronto, Toronto, Canada. ²Durham University, Durham, United Kingdom. ³Baylor University, Waco, USA. ⁴Laurentian University, Sudbury, Canada. ⁵Harvard University, Cambridge, USA

Abstract

The paleorecord offers an important long-term perspective on the interactions between various components of the Earth system. Understanding the climate system during Marine Isotope Stage 3 (MIS 3; 57 to 29 kyr BP) is of particular interest because this interval consisted of a suite of abrupt climate events, notably rapid temperature fluctuations (Dansgaard-Oeschger events) and significant ice sheet instability (Heinrich events). The Laurentide Ice Sheet (LIS) was a dominant ice mass over North America during the Late Pleistocene and played a major role in sea level change, atmospheric circulation and floral/faunal migration. However, little is known with certainty about the dynamics of the LIS during MIS 3, nor the role it played in rapid climate events that characterized this interval. Here, we present evidence suggesting that the LIS was dramatically reduced during MIS 3. We synthesize >700 geochronological data points (radiocarbon determinations, cosmogenic exposure ages, optically stimulated luminescence dates) that constrain a much reduced ice margin and the presence of widespread ice-free landscapes over much of North America at ~42 ka. Key to this hypothesis are sites from the Hudson Bay Lowlands near the center of the glaciated region in east-central Canada. Chronological and paleoecological data from these stratigraphic sections suggest the development of widespread terrestrial landscapes (boreal peatlands) during this period. Interestingly, the hypothesis of a dramatically reduced LIS during MIS 3 was first raised by stratigraphic workers in the early 1980s, however the suggestion was not widely accepted because of the lack of supporting evidence. We provide such evidence using a geophysical model which shows that a reduced ice sheet is consistent with regional and global sea level markers during this interval. If this hypothesis is correct the implications are significant. Notably, dramatically reduced ice over North America during MIS 3 requires a refinement of Late Pleistocene sea level records and possibly a re-evaluation of the processes that drive Dansgaard-Oeschger and Heinrich events, which are often attributed to the dynamics of a much larger ice sheet.

Middle Wisconsinan marine shells near Repulse Bay, Nunavut, Canada: Implications for MIS 3 ice-free conditions in northwest Hudson Bay

Isabelle McMartin, Janet Campbell, Lynda Dredge
Geological Survey of Canada, Ottawa, Canada

Abstract

Evidence suggesting reduction of the Laurentide Ice Sheet (LIS) during MIS 3 is widespread but the boundaries of the ice sheet and timing of the minimum ice extent are still poorly constrained. The idea that the Middle Wisconsinan was a period of significant glacial recession in the core area of the LIS has long been debated, and is still disputed today, particularly in the Hudson Bay Lowlands (HBL). Radiocarbon dating of glacially transported marine molluscs in streamlined till south of Repulse Bay, Nunavut, Canada, provides new evidence for MIS 3 deglaciation in the northwest part of Hudson Bay. Middle Wisconsinan finite ^{14}C ages on 8 mollusc samples varying between 31.7 and 39.2 ^{14}C ka BP (~ 35.0 and 43.7 cal ka BP) indicate a marine event(s) for a minimum of ~ 8.7 cal ka. The fossiliferous calcareous till is derived from Paleozoic carbonates in proto-Roes Welcome Sound, and was deposited by a topographically controlled ice stream stemming from the eastern end of the Keewatin Ice Divide. Our findings suggest prior ice-free conditions in the ice stream source area indicating significant glacial recession of the LIS margin during the Middle Wisconsinan, much farther in the interior of the ice sheet than previously known. We propose here various possible configurations of ice limits during MIS 3 for the extended Repulse Bay region. The marine incursion possibly occurred as a result of a calving bay developed from the north in the Gulf of Boothia-Committee Bay area following the recession and collapse of an ice stream which was re-activated after the MIS 3 marine episode(s), and maintained until deglaciation. Alternatively, the development of a calving bay(s) from the east up Hudson Strait may have permitted deglaciation of Roes Welcome Sound and possibly other parts of Hudson Bay. Although these configurations of the LIS may not answer the recurring question whether MIS 3 was a time when the HBL were ice free, they significantly contrast with recent paleo-ice sheet models that suggest full ice conditions in the Repulse Bay region and can therefore contribute to the debate and configuration of the LIS during MIS 3.

The Laurentide Ice Sheet before, during and after MIS3 from a Great Lakes/St. Lawrence River Basin perspective

Michel Lamothe

Université du Québec à Montréal, Montréal, Canada

Abstract

The Great Lakes/St. Lawrence River (GL-SLR) drainage network imposes unique paleogeographical constraints for deciphering the periodical waxing and waning phases of the Laurentide Ice Sheet (LIS). In the Quebec City (QC) area, the SLR funnels the waters of the third largest drainage basin in North America. Early workers had already realized the importance of this unique geography in the interpretation of the Quaternary regional stratigraphy and hence glacial history. Indeed, the paleogeography requires that from the moment the LIS crosses the SLR in QC, a significant fraction of the surface drainage in NE North America will be diverted towards the upper reaches of the SLR drainage basin, first through the Hudson River valley and eventually overflowing the major drainage divide between the SLR and the Mississippi River.

Quaternary sediments exposing the last glacial cycle of the LIS are well exposed in the St. Lawrence Lowlands and the Appalachians of Southern Quebec as well as along the shores of Lake Ontario and Lake Erie. Physical stratigraphy is suggesting a complex history of ice margin fluctuation with consequent periodical glacial meltwater damming the upper reaches of the GL-SLR basin tributaries. Fossil organic and carbonate (mostly shells) material is found to be older or at the limit of the radiocarbon method. Fortunately, a large number of state-of-the-art Infrared Stimulated Luminescence (IRSL) dates have yielded depositional ages for waterlaid lithostratigraphic units exposed from Lake Erie to the St. Lawrence Estuary. The luminescence dating methodology has thus contributed to securing the correlation of the lithostratigraphic units across the regional depocenters and to the establishment of a robust chronostratigraphic framework at the scale of the GL-SLR basin.

Thence, an overall clearer image of the events leading from the end of the last interglacial to the Last Glacial Maximum (LGM; MIS2) is now emerging. The MIS5a (?) unglaciated but cool-climate landscape generated stratigraphically significant but thin and discontinuous non-glacial lithostratigraphic units. The transition from the geographically restrained and probably short-lived glacial paleoenvironments of MIS4 to the early MIS3 ice free landscape is poorly exposed and probably obscured by erosion. Several Mid-Wisconsinan sections expose aggrading distal sandy and silty outwash in glacio-isostatically subsiding basinal areas. These ice advance facies should have been time-transgressive over MIS3 time but at this stage of research, similar IRSL ages of ca 35 to 50 ka have been obtained for stratigraphically equivalent sediments collected in different sections of the GL-SLR. This might indicate rapid ice build-up and expansion in the mid part of MIS 3 or a lack of age resolution in the IRSL chronology. Nonetheless, it will be argued herein that the deduced paleogeography enlightens the issue of continental ice volume during MIS3.

A small Laurentide Ice Sheet until mid-MIS 3: Insights from glacial isostatic adjustment modeling, non-glacial deposits, and sea-level histories

Tamara Pico¹, Jerry X. Mitrovica¹, Leah Birch²

¹Harvard University, Cambridge, USA. ²Woods Hole Research Center, Woods Hole, USA

Abstract

While glacial geologic records track the retreat history of the Laurentide Ice Sheet, constraints on the ice-sheet build-up history are more elusive. As the Laurentide Ice Sheet expanded to its maximum extent at the Last Glacial Maximum (26 ka), it erased most evidence of previous glaciations. However, an increasing number of dated, non-glacial deposits point to a relatively confined Laurentide Ice Sheet during Marine Isotope Stage 3 (MIS 3), suggesting rapid ice growth rates leading to the Last Glacial Maximum. Previous work has demonstrated that sea-level markers along the U.S. mid-Atlantic, which record anomalously high sea-level during mid-MIS 3, are reconciled by a delayed growth of the eastern sector of the Laurentide Ice Sheet. Here we demonstrate that predictions of relative sea-level (RSL) change due to glacial isostatic adjustment involving a late and rapid growth of the Laurentide Ice Sheet are consistent with sea-level bounds associated non-glacial deposits of MIS 3 age in Canada and available RSL histories. In particular, we consider geologic records in the Hudson Bay Lowlands, the St. Lawrence Lowlands, Ontario, and Atlantic Canada. In addition, we run a simple dynamic ice model adopting the paleotopography generated from the glacial isostatic adjustment simulation and predict rapid glaciation rates starting at mid-MIS 3 (44 ka) are feasible when we adopt accumulation rates similar to those observed in the present-day Arctic.

Evidence for multiple advances of the southwestern Laurentide Ice Sheet during MIS 3

Phillip Kerr¹, Stephanie Tassier-Surine¹, Susan Kilgore², Elmer Arther Bettis III³, Kathleen Woida⁴

¹Iowa Geologic Survey, Iowa City, USA. ²Adelphi University, Garden City, USA. ³University of Iowa, Iowa City, USA.

⁴USDA-NRCS, Des Moines, USA

Abstract

The ice build-up of the Laurentide Ice Sheet (LIS) before the Last Glacial Maximum (LGM) during Marine Isotope Stage 3 (MIS 3; 57-29 kyr bp) is a growing area of interest; however, calibration of pre-MIS 2 (29- 14 kyr bp) LIS models is problematic due to the sparsity of land-based evidence. MIS 3 glacial deposits are rarely found beyond the LGM extent as MIS 2 glaciation eroded or covered most of these older sediments. Iowa, located in the midcontinent of the United States, has glacial tills from both MIS 2 and MIS 3. Extensive fieldwork in the state has collected radiocarbon ages from wood in basal tills and buried soil organics from MIS 3 deposits located below and beyond the MIS 2 boundary. The combined ages place the LIS advances in north central Iowa in two advances, ranging from 46-40 kyr bp and 34-29 kyr bp. Lithostratigraphic relationships also indicate two separate ice advances as multiple outcrops and cores display a weathering zone or weakly developed soil between the tills. The lithology of the glacial diamictons is similar to the sediment deposited by the MIS 2 Des Moines Lobe advance (17-14 kyr bp), suggesting the tills share a common Keewatin source provenance. Thus, these older tills show that Keewatin sourced ice was near or beyond the local LGM extent multiple times during MIS 3. Recent work has proposed a reduction of the LIS during MIS 3, but these radiocarbon ages and ice extents conflict with models that suggest a limited distribution of the southwestern LIS during MIS 3.

The Late Quaternary history of the Fennoscandian Ice Sheet revisited

Karin Helmens¹, Stefan Engels², Tomi Luoto³, Sakari Salonen³, Minna Väliranta³

¹Stockholm University, Stockholm, Sweden. ²Birkbeck University of London, London, United Kingdom. ³University of Helsinki, Helsinki, Finland

Abstract

Geological data in the form of long sediment records and well-dated sediments and fossil remains are increasingly available from the central areas of Fennoscandian and Laurentide glaciations. This evidence derived from terrestrial archives suggests significantly smaller global ice volumes during the Late Quaternary than classically inferred from marine foraminiferal and coral data. We here give a first compilation of data from an unusually long and fossil-rich sedimentary sequence that is preserved in a depression formed in deeply weathered rocks of a magma intrusion (Sokli Carbonatite Massif) in the Fennoscandian Shield (N Finland). The analysis of multiple proxies (pollen, NPP's, macrofossils, diatoms, chironomids, biogeochemistry), the application of diverse fossil-climate calibration models including classical and machine-learning approaches, and the dating of sediments and fossils by means of OSL and AMS ¹⁴C, have provided detailed environmental and climate reconstructions for the last 130 kyr. The results indicate highly variable environmental and climate conditions in the region. We infer that Fennoscandian glaciation during the Late Quaternary was both considerably smaller in extent as well as shorter in duration than earlier suggestions, which were previously based on the correlation of highly fragmented geological data with the deep-sea oxygen isotope stack. Regarding MIS 3, present-day summer temperatures are reconstructed and were accompanied by large-scale deglaciation. Well-dated evidence from nearby sites indicates that ice build-up to LGM extents may have started only after ca. 35 kyr BP. This newly obtained geological data from the central area of Fennoscandian glaciation calls for renewed calibration of marine data in providing estimates for global ice volumes.

O-0036

The interplay of adaptation, distribution and extinction among Quaternary large mammals

Adrian Lister

Natural History Museum, London, United Kingdom

Abstract

Mammal species of northern biomes became adapted to Quaternary conditions but were challenged by its constantly fluctuating nature. Morphometric data on the evolution of the mammoth, for example, demonstrates dental adaptation to more open landscapes and grass/herb dominated food through 2.6 myr of the Quaternary, but up to the middle Pleistocene the complex of populations included variation allowing survival in a range of habitats. Morphometric and ancient DNA studies of the woolly mammoth demonstrate a loss of both morphological and genetic variation through the Late Pleistocene, that likely contributed to the species' ultimate demise. Mapping of radiocarbon-dated mammoth remains illustrates complex range shifts in the interval from 50 kyr onwards, with net reduction of range, and this correlates with loss of DNA clades. Extinction is seen not an instantaneous event but a sequence of regional extirpations, so extinction is visualised, with sufficient data, as 'merely' the zero-point of a process of range reduction. Alternating range expansion and contraction is typical of mammalian species in response to fluctuating Quaternary climate, and extinction is most probable in the contracted refugial phase, which often represents the core area of the species. Comparison of mapped radiocarbon dates in species such as woolly mammoth, woolly rhinoceros and giant deer shows that species act individualistically, according to their individual ecology, in the timing and geographical pattern of their distributional response and ultimate extinction. Survivors may be lucky (surviving a severe bottleneck where analogous species went through the zero point of no return, e.g. musk ox vs. mammoth and woolly rhino), or benefit from adaptive flexibility at the individual and population level (e.g. red deer). Adaptability includes behavioural and ecophenotypic flexibility as well as genetically-programmed variation.

Hungry like a wolf: impacts of carnivore competition on morphology and prey choice

Lucy Flower¹, Danielle Schreve¹, Angela Lamb²

¹Royal Holloway University of London, Egham, United Kingdom. ²British Geological Survey, Keyworth, United Kingdom

Abstract

The wolf, *Canis lupus*, is a survivor of Pleistocene environmental change, making it an ideal candidate for exploring past carnivore community interactions as it persisted through multiple climatic cycles, encountered different competitors and adapted to varying prey resources. Known temporal morphological variation in the cranio-dental complex of British Pleistocene wolves provides a detailed record of relatively fast palaeodietary responses to shifts in competition and environmental change. However, in order to elucidate Pleistocene wolf prey choice and explore more fully the effects of competitive interactions with coeval large carnivores over time, a large-scale direct measurement of wolf palaeodiet through stable isotope analysis was undertaken.

Focussing on Pleistocene cave faunal assemblages from southwest England correlated to MIS 3 (60-25kya: Sandford Hill), MIS 5a (c.80kya: Banwell Bone Cave) and late MIS 7 (c.240-190kya: Hutton Cave, Bleadon Cave), bone collagen from carnivores and a range of prey species present was analysed for carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$). Well-preserved, viable bone collagen was retrieved from each site, confirming the feasibility of stable isotopic studies on material of >50kya in Britain, and notably in sites >190kya, such as Hutton Cave.

Horse *Equus ferus* was an important component of wolf diet in both MIS 7 and 3, whereas when this species was absent from Britain during MIS 5a, reindeer *Rangifer tarandus* became a significant food source. Based on common prey choices, competitive interactions between wolf and spotted hyaena *Crocuta crocuta*, when present, were more important than those with lion *Panthera leo*, whereby separation in prey choice minimised conflict. These interactions are consistent with morphological cranio-dental evidence of wolves becoming more generalist feeders in response to competitive pressure from other large carnivores in MIS 7 and 3. In contrast, elevated $\delta^{15}\text{N}$ levels in the MIS 5a faunal assemblage are indicative of high levels of meat consumption in all carnivores, combined with a strong environmental stress signal from the herbivores. Again, dietary isotope results are in agreement with the morphological evidence during this time, which suggests that wolves in MIS 5a were hyper-carnivorous in comparison to MIS 7 and MIS 3.

Stable isotope results therefore reveal that wolves shifted prey choices in response to environmental change and large carnivore competition through time, complimenting the dietary specific cranio-dental morphological data. This combined approach highlights the importance of both indirect and direct measurements of palaeodiet, as well as lending further credence to the ecological resilience of the wolf based on their morphological plasticity and behavioural flexibility.

Polar bear's range dynamics in the Late Pleistocene and the Holocene

Heikki Seppä¹, Beth Caissie², Marit-Solveig Seidenkrantz³, Marc Macias Fauria⁴

¹University of Helsinki, Helsinki, Finland. ²Iowa State University, Ames, USA. ³Aarhus University, Aarhus, Denmark.

⁴University of Oxford, Oxford, United Kingdom

Abstract

Reconstructions of species ranges during the past warming periods are important for understanding the impact of climate change on the distribution of arctic mammals. By analyzing the fossil records of key arctic species together with data on past climates and sea ice conditions, it is possible to investigate the species ranges and, eventually, make inferences about the survival strategy of arctic mammals during climatic conditions warmer than at present. Here, we use the dataset of fossil records to investigate changes in the polar bear's distribution during the Late Pleistocene and the Holocene. Over the decades, hundreds of polar bear bones and teeth have been discovered from the high latitude regions, and these findings represent a minimum number of 229 individuals from 45 sites and date from the Late Pleistocene (15 – 11.7 ka) to the Holocene (last 11.7 ka).

During the last deglaciation, the polar bear was present in the south-western and western margin of the Scandinavian Ice Sheet where it survived until the earliest Holocene about 11 ka. In the Early Holocene, fossils have been discovered from Svalbard and the Zhokhov island in the East Siberian Sea. There are no polar bear findings from 8-6 ka, which is generally the warmest period of the Holocene in the Arctic with summer temperature up to 2.5°C higher than at present, but the findings from 8-9 ka and 5-6 ka suggest that the species was able survive this Holocene thermal maximum in the cold refugias in the high arctic of the East Siberian Sea, the northernmost part of Greenland and the Canadian archipelago. Intriguingly, there are polar bear fossils findings from the Aleutian and Pribilof Islands (Unalaska and St. Paul islands) from 5.4-3.4 ka. Unalaska, the southernmost of these islands, is currently located roughly 400 km south of the modern sea-ice limit and 1000 km south from the nearest polar bear population, and our data suggest that it was outside the area of arctic sea ice in the Mid Holocene. There is firm evidence that the range of polar bear expanded over the late Holocene (last 4000 years) in tandem with the cooling climate and the expanding arctic sea ice. We conclude that an analysis of the Late Pleistocene and Holocene fossil record of the polar bear highlights the major changes in its range in response to climate changes and thus demonstrates the long-term congruence of its range with sea ice and climate.

Arctic-alpine plants survived past forest expansion: a 24,000-year ancient DNA record from the Polar Urals

Charlotte L. Clarke¹, Mary E. Edwards¹, Ludovic Gielly², Paul Hughes¹, Dorothee Ehrich³, Liudmila M. Morozova⁴, Hafliði Haflidason^{5,6}, Jan Mangerud^{5,6}, John-Inge Svendsen^{5,6}, Inger G. Alsos⁷

¹Geography and Environmental Science, University of Southampton, Southampton, United Kingdom. ²Laboratoire d'Ecologie Alpine (LECA), Université Grenoble Alpes, Grenoble, France. ³Department of Arctic and Marine Biology, UiT- The Arctic University of Norway, Tromsø, Norway. ⁴Institute of Plant and Animal Ecology, Ural Branch of Russian Academy of Sciences, Ekaterinburg, Russian Federation. ⁵Department of Earth Science, University of Bergen, Bergen, Norway. ⁶Bjerknes Centre for Climate Research, Bergen, Norway. ⁷Tromsø Museum, UiT- The Arctic University of Norway, Tromsø, Norway

Abstract

The ability of arctic and alpine plants to withstand extinction from future climate change will depend, in part, on their ecological resilience and the availability of suitable habitat in a warmer climate. Knowledge of the role of mountain landscapes as safe-havens promoting the persistence of cold-adapted arctic and alpine plants over long timescales is limited. Here, we present a 24,000-year record of plant community dynamics based on ancient DNA extracted from the sediments (*sedaDNA*) of Lake Bolshoye Schuchye, the largest and deepest lake in the Polar Ural Mountains of northern Russia. We identified 167 plant taxa based on *sedaDNA* (45 % identified to genus level, 41 % to species, 14 % to family), which included representatives from all plant functional groups.

We show that cold-adapted plants (e.g. *Arabis alpina*, *Bistorta vivipara*, *Papaver*, *Dryas octopetala*, *Saxifraga oppositifolia*) have survived and persisted in the Polar Urals in the face of changing climate and environmental conditions over the past 24,000 years, despite past northward and upward expansion of forest tree taxa (e.g. *Larix sibirica*, *Picea*, *Betula*) between 9000 - 4000 cal. years ago. The large and topographically complex catchment of Lake Bolshoye Schuchye has retained its diverse species pool over time, with a consistent long-term increase in floristic richness over the past 24,000 years.

Using our *sedaDNA* time-series, we infer that mesoclimatic heterogeneity arising from variable topography in a mountainous landscape facilitates the persistence and co-existence of both cold-adapted and forest plant taxa during warm climate episodes, thereby preserving floristic diversity. Our results highlight the importance and conservation significance of mountainous landscapes as a buffer against the extinction of arctic and alpine plants in a warmer climate.

Figure 1: Conceptual model to outline the key changes in plant community composition identified in the *sed*aDNA from Lake Bolshoye Schuchye. Note the continued persistence of arctic and alpine plant taxa through all four time periods of interest.

A study on the ecology and ethology of Pleistocene fauna (cave bear, red deer) by molecular palaeontology techniques

Aurora Grandal-d'Anglade¹, Alba Rey-Iglesia², Ana García-Vázquez¹, Gloria González-Fortes³

¹Instituto Universitario de Xeoloxía. Universidade da Coruña, A Coruña, Spain. ²Centre for Geogenetics, Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark. ³Institute for Biochemistry and Biology, University of Potsdam, Potsdam, Germany

Abstract

The palaeobiology of ancient individuals, including already extinct species, can be reconstructed using diverse types of data (i.e. isotope data, DNA, morphology). In this work, we focus on information about the behaviour of individuals and populations obtained from mitochondrial DNA, inherited through motherhood and therefore informing about the family lineage of individuals. We supplemented the study with stable isotope analyses, which are informative about the animals' diet and the environmental conditions, and Strontium isotopes indicating the geological substrate in which they lived.

Examining mitochondrial DNA sequences of Pleistocene red deer (*Cervus elaphus*) from Liñares cave (Lugo, NW of the Iberian Peninsula), we found a high genetic diversity, with individuals belonging to phylogenetically very distant lineages. This corroborates previous studies indicating that this ensemble was formed by stags that failed to form a harem. As in the current red deer, the younger (and in some cases older) male deer formed a separate group that roamed farther away and eventually died in Liñares Cave, whose accumulation in deer remains is interpreted as a catastrophic episode (by sinking or plugging the entrance).

In the case of the cave bear (*Ursus spelaeus*), we studied several caves in the North of the Iberian Peninsula (Eirós, Liñares, A Ceza, all of them in Galicia, and Amutxate, in Navarra) and observed that each site was occupied by bears sharing a single mitochondrial lineage, common to both male and females. These mitochondrial lineages were different between caves, even when we compared animals from the same time period. This is suggesting a homing behaviour (i. e., returning to the place of birth) in cave bears. This behaviour is not observed in its next of kin, the brown bear (*Ursus arctos*), neither fossil nor current, since only occasionally was the occurrence of mother and daughter pairs documented.

On the other hand, the carbon and nitrogen stable isotopes of collagen and the carbon and oxygen stable isotopes of apatite from each species and site, provide clues to the extent of the groups' habitat and how they exploited their ecological niche. We found some climate-related differences between groups of different chronology, but also in the same chronology. This may reflect a difference in the ecological niches of each species, although strontium isotopes indicate that there was no appreciable separation in the territories inhabited by both species.

American mastodon mitochondrial genomes suggest repeated colonization and extirpation in northern latitudes

Emil Karpinski¹, Dirk Hackenberger¹, Chris Widga², Daniel Fisher³, Grant Zazula⁴, Ross MacPhee⁵, Hendrik Poinar¹
¹McMaster Ancient DNA Centre, McMaster University, Hamilton, Canada. ²Center of Excellence in Paleontology, East Tennessee State University, Gray, USA. ³Museum of Paleontology and Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, USA. ⁴Yukon Palaeontology Program, Government of Yukon, Whitehorse, Canada. ⁵Mammalogy/Vertebrate Zoology & Gilder Graduate School, American Museum of Natural History, New York, USA

Abstract

Ancient DNA studies have greatly contributed to our understanding of Pleistocene megafaunal ecology, identifying demographic changes not immediately apparent in the palaeontological record. However, phylogeographic studies of North American megafauna have largely focused on grazing species (e.g. mammoths, bison) that primarily inhabited open grassland and steppe-tundra environments. This focus on animals from a single environmental context has resulted in a biased understanding of the roles that climate and human-induced factors had on the population dynamics of American megafauna, omitting key forest and mixed-environment species such as the American mastodon (*Mammuthus americanus*).

Palaeontological work has shown that mastodons and mammoths were differentially affected by climatic shifts, suggesting that forest and grassland species were asymmetrically impacted by Pleistocene glaciations. An examination of the chronology and population dynamics of proboscideans in the North American midcontinent revealed differences in regional habitation patterns of mammoths and mastodons, and extinction dynamics. Similar analyses looking at the radiocarbon record of mastodons in Alaska-Yukon have indicated that all remains are non-finite (>50 kya). Notably this supports previous palaeoecological hypotheses that suggest mastodon presence in the far north was limited to warmer interglacial periods.

To answer questions about the differential evolution and extinction of American mastodons, we extracted ancient DNA from 123 fossil remains spanning their North American range. We generated 33 complete mitochondrial genomes, which we incorporated with the only two previously sequenced mastodon mitogenomes into our phylogeographic analysis. We identified two separate mitochondrial lineages in the Alaska-Yukon region. Molecular clock dating suggests that the mean ages of the two Alaska-Yukon clades fall within at least two separate interglacial periods, with mean ages 92.2-119 kya (MIS 5e interglacial) for one clade, and 238 kya and 270 kya (MIS 7) for the two samples in the other Alaska-Yukon clade. In addition our analysis reveals comparatively low levels of genetic diversity in our largest Alaska-Yukon clade in comparison to samples from south of the ice-sheets.

Our current dataset of 33 new complete mitochondrial genomes represents an approximately 16-fold increase in available data for the American mastodon. Molecular dating analysis supports current palaeoecological theories that propose *M. americanus* occupation of northern latitudes was restricted to warmer interglacials when forests and wetlands would have been abundant. Our data also suggest that mastodon colonization and extirpation in northern latitudes was likely a recurring event that happened at least twice during the Pleistocene. These local extirpations were likely caused when forested habitats were replaced by steppe-tundra vegetation as climates returned to cold, dry conditions associated with glaciations, and will likely hold for most other larger-bodied browsers in Pleistocene

North America. A continued investigation of Pleistocene browsers is necessary to supplement our current understanding of megafauna responses to the unique climatic stressors of the Pleistocene.

O-0042

The climate of the Olympic Peninsula, northwestern USA, during the LGM based on fossil beetles, pollen and ice margin deposits

Allan Ashworth¹, Glenn Thackray², Daniel Gavin³

¹North Dakota State University, Fargo, USA. ²Idaho State University, Pocatello, USA. ³University of Oregon, Eugene, USA

Abstract

Climate during the LGM (18-25 ka) varied across North America, strongly influencing changes in plant and animal distributions and causing variations in the timing and relative magnitude of ice expansion and recession. The Olympic Peninsula is a high (2700 m) maritime terrain in northwestern Washington at the leading edge of Pacific weather systems. It is ideally situated to assess influences of the Pacific Ocean on the LGM climate when ice sheets covered most of northern North America. Stratigraphy, geomorphology, and geochronology provide evidence that mountain glaciers extended to the lowlands but were substantially less extensive during the LGM than during the mid-Wisconsin and earlier in the Pleistocene. Fossil beetle assemblages from sections at Kalaloch on the coast, and from the South Fork of the Hoh River, contain species that currently inhabit riparian and lacustrine habitats in the boreal zone of Canada and Alaska, and in higher elevations in the Cascades and Rocky Mountains. *Olophrum* species, which today are unknown from the Olympic Peninsula, are represented by fossils of *O. rotundicolle*, *O. boreale* and *O. consimile*. *O. consimile* is especially well-represented and its occurrence today at an elevation above 1000m in the Cascades of northern Washington State indicates summers during the LGM would have been about 4°C cooler. The absence of any wood-boring beetles, in contrast to assemblages from the mid-Wisconsin, indicates an open landscape. The interpretation from fossil beetles supports pollen and macrofossil evidence for an open vegetation of a Sitka spruce and mountain hemlock parkland. The closest analog at sea level for this vegetation is southwestern Alaska where temperatures are about 4°C cooler than the Olympic Peninsula today. Both the vegetation and the insects provide evidence that the climate was at least as wet as that of today and not as dry as the Puget Lowland to the east. A cool wet summer climate is consistent with glaciers advancing to the lowlands. The amount of climatic cooling on the Olympic Peninsula during the LGM is considerably less than at similar latitudes in mid-continental or eastern North America indicating a strong modulation of climate by the Pacific Ocean. *Postscript*. There are several endemic taxa in the living fauna and flora of the Olympic Peninsula which suggests that many taxa survived through multiple glaciations. Whether or not they are true endemics and evolved on the peninsula or accumulated there as a result of dispersion is debated. Among the mid-Wisconsin and LGM fossils of the Kalaloch section is a blind, flightless trechine beetle which today is unknown from North America. The closest living relatives are in the *Trechiana* lineage, known from Asia. The differences in morphology from any living species, however, indicate that isolation on the Olympic Peninsula is ancient and probably pre-Quaternary.

Mapping of mixed landform signatures of palaeo-subglacial drainage over northern Canada

Emma L.M. Lewington¹, Stephen J. Livingstone¹, Chris D. Clark¹, Andrew J. Sole¹, Felix S.L. Ng¹, Robert D. Storrar²
¹Department of Geography, University of Sheffield, Sheffield, United Kingdom. ²Department of the Natural and Built Environment, Sheffield Hallam University, Sheffield, United Kingdom

Abstract

Subglacial hydrology is a key control on ice sheet flow. To better understand the structure and evolution of the subglacial drainage network, we can use the imprint of meltwater drainage recorded on the beds of former ice sheets. This method has an advantage over contemporary observations as it facilitates the reconstruction of drainage networks over larger spatial (metres to 10's kilometres) and temporal (centennial to millennial) scales; key requirements for understanding the system and informing numerical models. Recent advances in constructing high resolution digital elevation models (DEMs e.g. ArcticDEM) have greatly improved our ability to map the geomorphology of palaeo-ice sheet beds. Nonetheless, despite a long observational history, meltwater landforms such as eskers, tunnel valleys and meltwater corridors, have typically been considered in isolation rather than as an integrated drainage system.

Here, we present the first large-scale integrated map of palaeo-subglacial meltwater pathways over northern Canada. Key to the development of this map was the inclusion of hummock corridors – elongated tracts of hummocks that often exhibit negative relief and undulating long-profiles and frequently contain eskers. These features were efficiently identified and mapped using a new automated method (Lewington *et al.*, in review) based on filtering the raw ArcticDEM data to isolate hummock corridors by wavelength and orientation (two of their defining characteristics). The automatic output was used alongside the published esker pattern to guide centreline mapping of 'complete' meltwater pathways (i.e. eskers, tunnel valleys and hummock corridors).

The output provides data on the distribution, pattern and morphometry of >2,000 meltwater pathways across northern Canada. Notably, the map reveals the commonality of hummock corridors over the area, which often 'bridge the gap' between sections of eskers and/ or tunnel valleys. In comparison to eskers alone, our integrated map reveals less fragmented subglacial drainage pathways with a greater number of tributaries and denser spacing. Along-flow transitions to/ from different meltwater landforms may suggest a meltwater landform continuum whose expression depends on the balance of controls at a particular time and place. Associations between down-flow transitions and flat spots are interpreted as the signature of subglacial lake drainage events. Overall, the consideration of large-scale integrated drainage systems is likely to reveal new associations and insights into meltwater landform formation and network organisation at an ice-sheet scale.

Glaciofluvial Corridors and Tunnel Valleys Below the South-Central Fennoscandia Ice Sheet

Gustaf Peterson^{1,2}, Mark Johnson²

¹Department of Physical Planning, Geological Survey of Sweden, Uppsala, Sweden. ²Department of Earth Sciences, Gothenburg University, Göteborg, Sweden

Abstract

Knowledge about processes active beneath ice-sheets, and in particular the process connected to glacial melt-water drainage, is crucial for a fundamental understanding of ice sheets and how they react in a warming climate. Investigating sediments and geomorphology of drainage systems below ice sheets is complicated; however, formerly glaciated regions are easily accessible. New datasets, in the form of LiDAR-derived digital elevation models (DEM), have made it possible to map formerly glaciated regions in an unprecedented detail. We have mapped an area in southern Sweden, the south Swedish uplands (SSU), that make up a fair bit of the formerly south-central part of the Fennoscandian Ice Sheet (FIS). This region was deglaciated during the Bølling-Allerød warm period, just prior to the Younger Dryas cold event. During the Bølling-Allerød, large amounts of meltwater were derived from ice-sheets.

At the SSU we have mapped elongate zones of hummocks, which we refer to as corridors. These elongate zones have distinct borders with the surrounding lineated till plain; in some places they show an anastomosing pattern. The corridors have an overall radial pattern that is sub-parallel to overall ice-flow and in places the corridors cut through glacial lineations. We analyzed the morphometry of these corridors. Many show adverse, up-to-the-margin slopes. Corridor width varies 0.2 and 4.9 km, their length are up to 11.8 km and the spacing between corridors is around 10 km, values comparable to data on tunnel valleys (TV) and glaciofluvial corridors (GFC) reported elsewhere. About 2/3 of the corridors display negative cross-profiles (they are incised in the regional till plain), others are positive forms. In the floors of some negative corridors eskers occur that are superposed on hummocks. With machine dug sections of hummocks within one of these corridors we show that at least two of these hummocks consist of subglacial traction till with deformed interbedded sorted sediments. Moreover, we show that the material in these hummocks belong to MIS 4 or 3, using OSL. Based on the morphometrics and our excavations, we interpret the negative corridors to be tunnel valleys.

The radial pattern and regular spacing of the corridors implies the positive forms also have a subglacial meltwater genesis. Using a recent reconstruction of the deglaciation of the FIS we attribute an age to the mapped corridors. Comparing the frequency of corridors per time interval with climate variations from Greenland ice-cores we suggest that the formation of corridors on SSU can be connected to delivery of abundant supraglacial meltwater to the bed during the Bølling-Allerød warm period.

Abstract

Mars is a glaciated planet with an extremely cold and hyper-arid climate. It hosts water ice within polar ice caps, ground ice, and thousands of mid-latitude debris-covered glaciers. Until recently, it was widely thought that mid-latitude glaciers on Mars' had been pervasively cold-based since their formation 10s–100s Myr ago.

However, our recent discoveries of eskers associated with ~110–150 Myr old glaciers in the Phlegra Montes [1] and Tempe Terra [2] regions of Mars' northern mid-latitudes indicate that localised wet-based glaciation has occurred during Mars' most recent geological period, possibly driven by locally-elevated geothermal heat flux and strain heating within the glacial ice [1–3]. Eskers are sinuous ridges comprising sediments deposited in glacial meltwater conduits. They are important tools for reconstructing the extent and dynamics of wet-based glaciation on Earth, and have similar potential for Mars.

We used 1–2 m/pixel digital elevation models derived from 25–50 cm/pixel High Resolution Imaging Science Experiment stereo-pair images to measure the planform and 3D morphometries of the mid-latitude Martian eskers, and compare them with the morphometries of Quaternary-aged eskers in Canada [4] and SW Finland [5]. We found that the Martian eskers have remarkably similar lengths, sinuosities and heights to terrestrial eskers, but that the Martian eskers are typically wider and have lower side slopes. Large width-height ratios of the Martian eskers are consistent with our previous measurements of ancient (~3.5 Ga) eskers close to Mars' south pole [6]. These large ratios may arise from differences in either esker degradation state or fundamental glacio-hydrological controls on esker formation between Mars and Earth.

We also used a novel morphometric approach to test evidence for spatio-temporal variations in sediment-discharge dynamics during formation of the Martian esker in Tempe Terra. Our analyses reveal that this esker has a 'stacked' morphology: the crest of a wide, round-crested underlying ridge is superposed by a narrow, sharp-crested to multi-crested ridge. The superposed ridge is aligned with a channel-like depression that incises the underlying ridge. Based on morpho-sedimentary relationships observed along terrestrial eskers [7], we interpret this stacked morphology to represent conduit adjustment as a result of waning meltwater discharge and sediment supply towards the end of the esker-forming drainage episode(s).

Modern analogues of esker formation: complexity, polygenesis and preservation potential

Robert Storrar¹, Marek Ewertowski², Aleksandra Tomczyk², Iestyn Barr³, Stephen Livingstone⁴, Alastair Ruffell⁵, Ben Stoker⁶, David Evans⁷

Abstract

Eskers are abundant on the beds of the former Eurasian and North American Ice Sheets, and form a useful record of channelised meltwater activity during deglaciation. As such, eskers have the potential to provide detailed insights into the hydrology of glaciers and ice sheets. However, our process understanding of eskers suffers from a disconnect between detailed morpho-sedimentary investigations of abundant large-scale ancient esker systems, and a relative paucity of modern analogues where esker formation has been observed and documented. Given the widespread retreat of glaciers around the world due to warming over the last ~100 years, it is perhaps surprising that few eskers have been observed forming as modern glaciers retreat. To explore why this might be, and to further our understanding of esker process-form relationships, we present the results of detailed studies into esker systems that have recently emerged from retreating glaciers in Iceland and Svalbard. We use 70 years of aerial photographs and a 2017 Unmanned Aerial Vehicle (UAV) Structure from Motion (SfM) photogrammetric survey to chart the gradual emergence of a complex esker system at Breiðamerkurjökull, Iceland, and recent high-resolution satellite imagery, a 2017 UAV-SfM survey and field observations of an esker system exhibiting similar morphological characteristics that has emerged under markedly different conditions at Hørbyebreen, Svalbard. In both of these systems, a distinctive planform morphology has developed where eskers are orientated in two dominant directions, corresponding to the direction of ice flow (which is commonly seen in ancient esker systems), and also the shape of the ice margin (which is not commonly observed in ancient eskers). These two orientations overlap to form a rectilinear pattern. The similarity in form but stark difference in context (broad, active temperate *versus* confined polythermal) suggests that complex esker morphology might be polygenetic. The eskers at Hørbyebreen contain substantial ice cores and have a high ice:sediment ratio, suggesting that they would be unlikely to survive if temperatures increase enough to melt the ice cores. The Breiðamerkurjökull eskers emerged from terrain characterised by buried ice which then melted out. Our observations lead us to conclude that eskers may reflect a wide range of processes at dynamic ice margins. Constraints on esker morphology include: topographic setting (e.g. confined valley or broad plain); sediment availability; meltwater availability; position of formation (supraglacial, englacial or subglacial); and ice-marginal dynamics such as avulsion, the formation of outwash heads or the burial and/or exhumation of dead ice.

³University of Leeds, Leeds, United Kingdom. ⁴Sheffield Hallam University, Sheffield, United Kingdom. ⁵Manchester Metropolitan University, Manchester, United Kingdom

Abstract

Kames constitute a diverse range of glaciofluvial and glaciolacustrine landform-sediment assemblages that provide information on the style and pattern of deglaciation. The Brampton Kame Belt is one of the largest (>40 km²) glaciodepositional complexes in the UK and is located at the centre of the former British-Irish Ice Sheet. A large-scale survey of the kame belt subsurface sedimentary architecture was conducted using ground-penetrating radar (GPR). A 100 MHz Mala Geosciences 'Rough Terrain Antenna' system allowed us to test the application of GPR in investigating complex glaciofluvial landform-sediment assemblages and to provide insight into the formation of the kame belt. The full range of geomorphic features were targeted, including ridges, flat-topped hills, channels and depressions. Where possible, GPR profiles were collected both along and across features in order to provide an insight into their 3D architecture. At two locations, profiles were collected above sediment exposures, which were logged in order to tie the radar data to the sedimentary facies.

The results enable a detailed understanding of individual landform evolution within the kame belt, and provide further insight into subglacial and ice-marginal meltwater drainage pathways during recession of the former British-Irish Ice Sheet. In particular, we identify two main styles of drainage: (1) major drainage axes parallel to ice flow that collapsed to form a series of aligned ice-walled lakes as glacier karst developed during deglaciation; and (2) ice-marginal drainage systems formed parallel to the ice margin as it downwasted. Variations in esker ridge internal structure indicate differences in flow conditions, styles of accretion, and degree of deformation that can be linked to observed differences in ridge morphologies.

Evidence for subglacial hydrofracturing, western Skeiðarársandur, Iceland.

Mandy Munro-Stasiuk¹, Andrew Russell², David Korte¹, Timothy Harris³, David Blauvelt⁴

¹Kent State University, Kent, USA. ²Newcastle University, Newcastle, United Kingdom. ³Staffordshire University, Stoke-on-Trent, United Kingdom. ⁴National Intelligence University, Washington, D.C., USA

Abstract

The western edge of Skeiðarársandur outwash plain has undergone a complex history of ice surging, jökulhlaups and glacial melt resulting in a landscape dominated by moraines, hummocks, glacial outwash, and a curious suite of semi-straight ridges, here referred to as the Súla Ridges. These formed between the turn of the 20th century when Skeiðarárjökull Glacier was near its maximum extent, and 1945 when expressions of the most prominent ridges can be seen on the surface of the glacier in aerial photos. This paper presents an overview of the geomorphology and the sedimentology of the Súla ridges through terrain analysis, ground penetrating radar analysis, and sedimentary analysis.

The ridges are arranged in a somewhat rectilinear pattern which would have been both parallel and at right angles to the former ice margin. They are typically 20-200 m long, 2-10 m wide and 0.5-5 m high with a handful up to 3 km long, and they are covered in pebbles, cobbles and boulders.

100 MHz ground penetrating radar (GPR) lines and grids were collected over several adjacent ridges. The GPR stratigraphy shows an average thickness of 4-8m of layered sediments. Till underlies the surface at depth preventing further significant penetration of the GPR signal. However, a well-defined network of dykes immediately below each ridge is clear in the GPR visualizations. Sedimentary analyses of sediments near the surface of the ridges in hand-dug trenches, and an analysis of the extensive Blautavísl section at the edge of the Súla River channel shows near vertical sheets of open-worked sub-rounded pebbles and cobbles, and thus the ridges are clearly the surface expression of a network of clastic dykes.

It is hypothesized that the ridges are relics of hydrofracture fills that formed during jökulhlaups. The hydrofractures formed near the ice front when rapidly increasing water-pressure during the rising stage of jökulhlaups drove water from overpressured subglacial channels and/or aquifers up through the overlying sediments and ice. These ridges represent the surface expression of where water escaped at the ice surface. As flow waned, sediment was deposited in the cracks. In-situ melting of the ice allowed gradual lowering of these sediments and preservation of the dykes. The study area is known to have been affected by several major jökulhlaups during the timeframe of probable formation, both due to the draining of ice-marginal Lake Graenalón (1935 and 1939), and ice melting during the eruption of the subglacial volcano Grimsvötn (1903, 1922, and 1938).

Late Weichselian glacial megafloods at the southern sector of the Scandinavian Ice Sheet: geomorphological record and palaeogeographical implications

Piotr Weckwerth¹, Wojciech Wysota¹, Jan A. Piotrowski², Aleksander Adamczyk¹, Arkadiusz Krawiec¹, Michał Dąbrowski¹

¹Nicolaus Copernicus University in Toruń, Toruń, Poland. ²Aarhus University, Aarhus, Denmark

Abstract

Geomorphological evidence of catastrophic glacial floods occurs in many formerly glaciated areas of North America, in the mountains of Siberia and Central Asia, and in northern Europe, but similar data have not been documented in the European Lowland thus far. Successful search for such palaeo-megafloods may help to better constrain the dynamics of glacial processes and ice/climate feedbacks during the Late Weichselian, and to inform about the impact of these events on the development of the now oversized valley systems in the European Lowland.

The main goals of our study were to (1) identify the geomorphological evidence of glacial megafloods in northern Poland, (2) determine the morphometric characteristics of landforms generated by these megafloods, and (3) constrain quantitatively the magnitude of these extreme events along the southern margin of the Scandinavian Ice Sheet (SIS).

In northern Poland, we document a Catafluvial Landform System (CLS) that consists of first-order catafluvial landforms including spillways and outwash plains, and second-order features represented by scabland-like landforms, expansion flood bars, megaripples, scour marks and clusters of kettle holes. These landforms derive from two megaflood events different in age (Frankfurt and Pomeranian phases) and in floodwater sources.

The better constrained glacial flood we identify in the eastern part of the ice-marginal spillway system had a peak discharge of about $2 \cdot 10^6 \text{ m}^3 \text{ s}^{-1}$ (flow velocities up to 17.1 ms^{-1} and mean flow depth 19 m), which is comparable with the largest glacial megafloods reconstructed elsewhere in the world. Such rapid release of large volumes of freshwater into the oceans following a transfer across the European Lowland through the meltwater spillways, may have impacted global climate by disrupting the thermohaline circulation.

Late MP site of Farah II: environmental and cultural contexts at the transition to the UP in the southern Levant.

Mae Goder-Goldberger¹, Avner Ayalon², Elisabetta Boaretto³, Valentina Caracuta⁴, Liora Kolska Horwitz⁵, Frank H. Newmann⁶, Naomi Porat², Onn Crouvi²

¹Ben-Gurion University, Beer Sheva, Israel. ²Geological Survey of Israel, Jerusalem, Israel. ³Weizmann Institute of Science, Rehovot, Israel. ⁴Université de Montpellier, Montpellier, France. ⁵The Hebrew University, Jerusalem, Israel. ⁶University of the Witwatersrand, Johannesburg, South Africa

Abstract

Two alternative perspectives have been proposed to account for the Levantine Middle to Upper Paleolithic (MP-UP) transition: The first relates the transition to a global evolutionary process closely tied to the appearance of anatomically modern humans, in which periodic climatic “windows” allowed the dispersal of hunter-gatherer groups across the Saharan-Arabian desert belt. The second approach sees the transition as a local, gradual shift in demography and culture. Within this context, it has been suggested that several environmental and/or social processes acted as driving forces for the transition.

Here we present data from new excavations held at Farah II, an open-air site situated near the Nahal (wadi) Besor at the Negev desert margins, Israel. Previous excavations at the site revealed two *in-situ* surfaces, in fluvial loess sediments, dated to 50-60 ka. The lithic assemblages were defined as non-Levallois late MP and the fauna has North African affinities. Notably, Farah II is the only late MP site in the southern region of Israel that has yielded large samples of both faunal and lithic remains, making it an ideal case study to further explore the MP-UP transition.

Initial reconstruction of the sites’ environmental setting, which has implications for understanding the context of the end of the MP was undertaken using; 1) soil and sediment analyses (grain size, carbon and oxygen stable isotopes); 2) archaeobotanical remains (identification of charcoal, pollen, phytoliths); 3) faunal taxonomy and taphonomy. In addition, we have refined the age estimation of the occupation using both Optically Stimulated Luminescence (OSL) and ¹⁴C dating.

OSL results of multi- and single-grain ages concentrate around 44-50 ka, suggesting that the site is 5-15 ka younger than previously thought. Initial results from lithic comparative studies with the MP site of Rosh Ein Mor (D15), located ~ 70 km to the south, illustrates that blade production from single platform cores were already in use within the late MP. This variability encompasses a large local pool of technological practices from which Initial Upper Paleolithic technologies could have drawn from, as demonstrated by the published assemblages from Boker Tachtit, central Negev. This observation supports a local gradual demographic shift rather than population replacement as a plausible explanation for the shift from MP-UP technological traditions.

Abstract

Chronological and geographical diversity of the IUP records in the Levant has been increasingly recognized, but our understanding of such diversity is still limited due to difficulties in identifying and dating variable IUP assemblages as well as scarce records other than lithics. This problem is more serious in inland than coastal areas because most sites in the former zone consist of shallow deposits with limited stratigraphic evidence and poor organic preservation.

To increase the IUP records of the inland Levant, this paper reports recent re-investigation at two sites (Wadi Aghar and Tor Fawaz) in the Jebel Qalkha area, southern Jordan (Kadowaki and Henry 2019), originally studied by Henry (1995), and presents analyses of lithic technology, chronology, paleoenvironment, and resource procurement behavior. The lithic assemblages from the two sites are characterized by the production of robust blades with large platforms through unidirectional flaking of cores that includes both flat-faced and prismatic forms. Retouched tools are characterized by end scrapers and burins, but they also include a few Levallois-like points. The two lithic assemblages can be grouped in the IUP through quantitative comparisons of techno-typological attributes among the Middle Paleolithic, IUP, and the Early Ahmarian in the Levant.

This observation is consistent with OSL dates (45–40 ka). This time range corresponds to a phase of increasing humidity indicated by sediment-core and shore-level records of Lake Lisan, but a question is how this correspondence was manifested near the sites. To discuss this issue, we present geochemical and sedimentological analyses of sequential sediment samples from the site sections.

The renewed excavations recovered a few marine shells, including *Strombus (Canarium) fusiformis*, *Conus* sp. or *Strombus (Conomurex)* sp., *Cypraea (Erosaria)* sp., and *Pecten* sp. cf. *jacobaeus*. Most of them are likely from the Red Sea, 55 km away, while *Pecten* sp. cf. *jacobaeus* may have been transported from the Mediterranean Sea, 185 km away. Although none of the shells show traces of modification or ochre, they are not likely food residues given their scarcity at the site and the time/distance involved for their transport. Considering the absence of shell transport in the late MP in the Levant, the transport of marine shells to Wadi Aghar and Tor Fawaz may represent one of behavioral changes from the late MP to the IUP in the Levant.

At the onset of the Initial Upper Paleolithic in Europe: reviewing the Bachokirian from the Balkan Peninsula

Tsenka Tsanova¹, Nikolay Sirakov², Shannon McPherron¹, Svoboda Sirakova², João Marreiros³, Ivaylo Krumov⁴, Nikolay Zahariev⁵, Zeljko Rezek¹, Vincent Delvigne^{6,7}, Jean-Jacques Hublin¹

¹Max Planck Institute for evolutionary anthropology, Leipzig, Germany. ²National Archaeological Institute with Museum, Sofia, Bulgaria. ³Archeological Research Centre and Museum for Human Behavior and Evolution, Monrepos, Germany. ⁴Belogradchik Historical Museum, Belogradchik, Bulgaria. ⁵New Bulgarian University, Sofia, Bulgaria. ⁶University of Liège, Liège, Belgium. ⁷PACEA- University Bordeaux 1, Bordeaux, France

Abstract

Bacho Kiro Cave is being reinvestigated since 2015 by Bulgarian-German project. The cave is located in the middle part of the Balkan Mountain range in central-north Bulgaria, near the town of Dryanovo. This work follows on the 1970s work of a Bulgarian-Polish team who conducted systematic excavations of the cave's archaeological deposits (Kozłowski 1982).

Here we present on the lithic assemblage from Layer I of the new excavation, known previously as Layer 11, which comes from the base of the Upper Palaeolithic sequence. This assemblage is difficult to place in the existing Middle-Upper Paleolithic framework. Kozłowski (1982) cautiously described it as Pre-Aurignacian, gave it the name Bachokirian, and attributed to the earliest *Homo sapiens* in the Balkans. It is generally agreed that it is not Aurignacian (Rigaud and Lucas 2006; Zilhão and d'Errico 2000; Teyssandier 2003). From a typo-technological perspective, the presence of Levallois combined with Upper Paleolithic tool types (Tsanova and Bordes 2003, Tsanova 2008, Sirakov et al. 2016), has led some to attribute the Bachokirian to the so-called Initial Upper Palaeolithic (IUP) of Eurasia (Kuhn and Zwyns 2014).

Our preliminary observations confirm and add additional details to what has been said of this assemblage. We note that we have found no evidence that its particular character comes from the mixing of separate entities and to the contrary have evidence that the layer is in a good state of preservation. The assemblage itself is characterized by 1) selection of fine-grained aptian flints which come from sources in Ludogorie region between 90 and 180 km northeast of the cave; 2) pointed blades (some of them potentially functioning as tips on projectiles based on diagnostic macro-fractures); 3) variability in the size of blades with small blades produced in continuity; 4) bladelets obtained also by reflaking tools and blanks; 5) reduction method and technique close to Levallois; 6) a high degree of retouched tools and shaping flakes, reduction by reflaking (*rédebitage*), fragmentation and retouch, according to different modalities: on anvil percussion (splintered pieces), on the ventral face of a flake (Kombewa), on the edge of a tool (burin blows); 7) micro wear traces on pointed blades and retouched blades associated with wood cutting, splintered pieces with bone and antler working, and on endscrapers associated with skin scraping; 8) absence of Aurignacian technology (lithic, osseous). Layer I also contains a large faunal assemblage accumulated anthropogenically and personal ornaments made of animal bone and teeth. The combination of these traits plus the new radiocarbon ages of ~45 ka BP (Fewlass et al., in preparation) support the interpretation that the Bachokirian is part of the spread of the IUP at this time and, therefore, very likely represents an early dispersal of *Homo sapiens* into Europe.

O-0053

The most ancient UP of the Eastern Europe: IUP stratum versus Protoaurignacian.

Andrei Sinitsyn

IHMC RAS, Saint-Petersburg, Russian Federation

Abstract

New archaeological materials obtained from the excavation at Kostenki during two last decades led to significant changes in the traditional interpretation of the structure, cultural affiliation, and chronology of the most ancient Upper Paleolithic of the Eastern Europe. The ancient chronological group has been subdivided into two groups: (1) Early Upper Paleolithic (EUP) in the temporal range of 32-36 ka (cal.~36-40 ka) with a typical European bi-modal structure comprising an Aurignacian of pan-European distribution and a local 'transitional' cultural unity – the Streletskian; and (2) a more ancient 'Initial Upper Paleolithic stratum' (IUP stratum) dating to 36-42 ka (cal.~ 41-45 ka) represented by layers both at and below the level of the Laschamp magnetic excursion (cal.~ 41 ka).

Reasons for distinguish IUP-stratum appeared to be followings:

- more ancient stratigraphic /= chronological/ position than EUP in local sequences;
- non-Aurignacian and non-"transitional" affiliation;
- lack of diagnostic mousterian features in the lithic assemblages;
- relatively short period of existence
- lack of visible predecessors and evolution
- high degree of the variability of archaeological materials included lithics, bone and artistic /decorative/ assemblages.

Two cultural unities were included in the IUP-stratum according to these criteria: Spitsyanean (cultural layer II of Kostenki 17 or Spitsyn' site) and new early unknown cultural tradition (cultural layers IVb and IVw of Kostenki 14). The most probable appears to be inclusion in IUP entity of Zaozerie site at the Middle Urals.

Three aspects of the problem are the matter of discussion

(1) Critics of using the notion of IUP for Eastern European materials (Kuhn, Zwyns, Hublin). According to technological features the most close to Middle-East IUP (where this notion come from) are Levallois-derived "transitional" industries of the Central Europe (Kozłowski

(2) Possibility for both Spitsyanean and assemblages of IVb-IVw cultural layers at Kostenki 14 to be identified as Protoaurignacian (Hoffecker, Zwyns, Demidenko, Bataille, Dinnis, Bessudnov);

(3) Increased number of the IUP assemblages in northern Asia owing to which it become to be a global phenomenon, in some measure comparable with East European materials.

The concept of UIP-stratum seems to be useful for the most ancient East European Upper Palaeolithic as a chronological context for the very variable assemblages represented for the moment by single sites.

Acknowledgments. RFBR projects 17-06-00319, 18-39-20009 and state assignment № 0184-2018-0012.

Convergence or circulation: cross-comparison between the Initial Upper Paleolithic of the Altai, the Transbaikal and the Selenga drainage system

Nicolas Zwyns

Unniversity of California-Davis, davis, USA. Department of Human Evolution, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

Abstract

With Neanderthals and Modern Humans moving into Central Asia and Siberia, at least two major human dispersals occurred across the Eurasian steppe during the Late Pleistocene. The Denisovans and visited the Siberian Altai more than once, and even met and interbred with Neanderthals, but for the most part their whereabouts remain unknown. Such evidence calls for further archaeological support to document the timing and environmental context of ancient human occupation of Central Asia with the hopes to better understand the drivers of such long-distance population movements. In this context, I present the result of a comparative analysis between three assemblages from regions with different environmental settings: Kara-Bom (Siberian Altai), Kamenka (Transbaikal) and Tolbor-16 (North Mongolia). The three assemblages are considered representative of the Initial Upper Paleolithic in the region because they share clear similarities in terms of typology, blade technology and chronology. Here I focus on the details of the reduction patterns and compare them between the regions. The main questions I would like to address in this presentation are: how similar are these reduction systems? What are the environmental and economic pressure driving the technological choices? Are differences and similarities better explained in terms of adaptation or population history? For analytical purposes, I hypothesize that the stronger the adaptation is, the more support there would be for a scenario of convergent evolution. The lack of apparent change in different environmental settings, however, would suggest that the pattern observed is better explained by alternative hypotheses (e.g. considering degrees of social intimacy, or populations phylogeny links between the contiguous regions). Features potentially sensitive to the local environment such as raw material management, intensity of core reduction, or the alternate use of unidirectional vs. bidirectional flaking, are used as proxy to evaluate the adaptive pressure relevant to the composition of the assemblage. Ultimately, the goal is to discuss the technological consistency of the regional Initial Upper Paleolithic whose sudden appearance coincides with the first occurrence of Modern Humans in Central and Northeast Asia.

Initial Upper Paleolithic/Early Upper Paleolithic interactions in the mountain belt of southern Siberia and eastern Central Asia

Evgeny Rybin, Arina Khatsenovich

Institute of Archaeology and Ethnography, Russian Academy of Sciences, Siberian Branch, Novosibirsk, Russian Federation

Abstract

The habitat of hominins, the bearers of Middle Paleolithic (MP) and Upper Paleolithic (UP) traditions in southern Siberia and Mongolia, is associated with the Altai and Sayan ranges of Transbaikalia and Mongolia. The first UP complexes appearing there constitute a distinctive Initial Upper Paleolithic (IUP). Setting aside possible variations related to settlement systems and the specifics of raw material exploitation, this cultural expression was characterized by bidirectional reduction technology targeting the production of large pointed blades, as well as burin-core technology and small subprismatic core reduction for the manufacture of bladelets, as well as an artifact assemblage that included specific tool types and personal ornaments. Paleoanthropological assessment what which hominin species created this technocomplex is speculative and open to discussion. It has been assumed that the IUP was replaced by the Early UP in most areas around 40,000-35,000 kya. New data challenge this simple scenario. The EUP co-existed with the IUP in the Altai region, where they are very similar excluding one unique technology. The presumed EUP in northern Mongolia stands out from the IUP in quantitative, though not qualitative ways. The IUP in southern Mongolia probably persisted until the end of MIS3. There are IUP complexes in Transbaikalia, chronologically younger than fully flake-based EUP industries, which appeared there no later than 40,000 kya. Seen in this way, interactions between the IUP and EUP were far more complex than a simple progression of sequential changes in different cultural traditions. Here, we focus on questions of chronostratigraphy and interaction among presumably different technocomplexes, and possible implications for the peopling of the southern Siberian and Central Asian mountain belt during the second half of MIS3.

Abstract

About 45,000 kya, large-blade based Initial Upper Paleolithic industries appeared almost synchronically in the Altai Mountains, eastern Kazakhstan, Xinjiang, Mongolia, and Transbaikalia. These Karabomian-type industries, originated in the Altai Mountains and spread to the east and south, eventually encompassing all of eastern Central Asia. The Altai Mountain system in Russia and eastern Kazakhstan, along with ranges in Xinjiang and, partially, the Mongolian Altai collectively comprise the so-called Inner Asian Mountain Corridor, primarily associated with the development and dispersal of agriculture (Spengler et al., 2014) and, later, with the Silk Road, going back as far as the hypothetical dispersal of Middle Paleolithic human populations (Glantz et al., 2017). Well-known recently discovered large-blade Initial Upper Paleolithic sites also occur in and near the Inner Asian Mountain Corridor and delineate its new branches, penetrating both mountain ranges and highlands. The main research question driving our work is why did these IUP populations settle in those areas? Our primary project has been focused on the IUP of northern Mongolia. All of the stratified sites in the Orkhon-Selenga belt share a common feature: sources of lithic raw material suitable for manufacturing artifacts, including both primary outcrops and alluvial pebbles, occur at distances of no more than several hundred meters from the archaeological sites in which they are found. Ancient humans preferentially exploited chert clasts; other stone varieties are rare in these archaeological assemblages. The study of human migration routes is associated with the occurrence of sedimentary rocks, widespread throughout the Orkhon-Selenga belt and occurring throughout Central Asia, including Uzbekistan, eastern Kazakhstan, northwest China (Xinjiang), Mongolia and, probably, the Tibetan Plateau. Human migrations through the Selenga Corridor have been the subject of recent study. Preliminary analyses of lithic raw materials indicate that IUP industries here were based on the same sedimentary rocks present in the middle Selenga River region. More than 150 samples from various parts of the IUP zone of dispersal (including the Russian Altai, eastern Kazakhstan, Mongolia and China) were analyzed, providing the opportunity to model the relationship between this technocomplex and primary raw material outcrops on a large geographical scale, including possible migration corridors.

The history and future of strontium isotopes in ecological and paleoecological applications

Brooke Crowley

University of Cincinnati, Cincinnati, USA

Abstract

The ability for strontium isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$) to answer questions about the mobility of both living and extinct organisms has been recognized for almost 30 years. Yet only a handful of researchers have utilized this geochemical tool to date. This likely reflects prohibitively expensive analytical costs combined with the need for researchers to build empirical reference datasets. However, in recent years, analytical advances have lowered costs. Additionally, spatially-explicit predictive models (called isoscapes), which can provide reference data without the need to conduct laborious field and laboratory studies, are now available for a number of regions on the planet. Accordingly, we may be entering a golden age for strontium isotope research. Nevertheless, there are still a number of gaps in our fundamental understanding of how strontium works. In this talk, I will review our current understanding of the factors that drive spatial variability in strontium isotopes, provide several examples of innovative ways that this geochemical tool has been used to infer the mobility of animals in the past, present additional promising applications of $^{87}\text{Sr}/^{86}\text{Sr}$ in both modern and paleo-contexts, and discuss important “next steps” for moving the field forward.

Advances in Terrestrial Bioavailable Strontium Isoscaping

Clement P. Bataille¹, Brooke E. Crowley², Alejandro Serna³, Juliette Funck⁴, Matthew J. Wooller⁴

¹University of Ottawa, Ottawa, Canada. ²University of Cincinnati, Cincinnati, USA. ³National University of La Plata, Buenos Aires, Argentina. ⁴University of Alaska Fairbanks, Fairbanks, USA

Abstract

Applying strontium isotope in provenance studies requires a baseline (or isoscape) of how strontium isotope ratios vary spatially in the main sources of food and water consumed by an organism of interest. This “bioavailable” strontium isotopic pool is difficult to predict because it is primarily shaped by the underlying geology but also vary with other geoenvironmental variables including soil properties, aerosol deposition or climate. We first review the advantages and limitations of existing methods to map the bioavailable strontium isotope variations on the landscape. We then propose a globally applicable, scalable, and editable framework for creating bioavailable terrestrial strontium isoscapes for provenance studies. This framework relies on: 1) a global georeferenced compilation of terrestrial bioavailable strontium isotope data, 2) global maps of strontium isotope variations in rocks derived from a process-based model, 3) global climate, soils, aerosols, and geoenvironmental map products, and 4) a random forest regression method (R script). The random forest regression integrates the bioavailable data with selected auxiliary variables (e.g., bedrock model products, and geoenvironmental data) to predict bioavailable strontium isotope variations and a conservative estimate of spatial uncertainty. Here, we test the benefits of using this framework to predict strontium isotope variations in Madagascar, Alaska, and Argentina using new bioavailable strontium isotope datasets generated for these areas. We show that, for each dataset, the calibrated strontium isoscapes explain more than 60% of the variance after independent cross-validation. More importantly, the model efficiently predicts the multi-scale patterning of strontium isotope variations on the landscape by accounting for geological, geomorphological and atmospheric controls. This novel mapping framework will be entirely accessible online and will help scientists interested in using strontium isotopes for provenance applications to generate more systematic and accurate bioavailable strontium isoscapes. This framework can also be integrated with other isotopic systems (e.g., oxygen and hydrogen) to provide more precise geolocation assessment in Quaternary and modern ecosystem studies. We demonstrate the increased precision allowed by dual isotope geolocation through a case study in Alaska. We measure oxygen and strontium isotopes in a 9,000-year-old child’s tooth from the Ancient Beringians Trail Creek site. The combined oxygen and strontium isotopic signature of this infant strongly indicates an origin in the interior upland areas of the Seward Peninsula close to the location where the tooth was recovered. This precise isotope geolocation coupled with analysis of archeological artifacts recovered at the site provided a strong basis to interpret genetic analyses performed on the tooth.

This work was partially funded by NSF BCS-1749676 and NSF 1137336 Inter-university Training in Continental-scale Ecology.

Strontium isotopes confirm giant extinct lemurs had small home ranges

Brooke Crowley¹, Laurie Godfrey²

¹University of Cincinnati, Cincinnati, USA. ²University of Massachusetts, Amherst, Amherst, USA

Abstract

The island of Madagascar is currently home to over 100 species of lemurs, and at least 17 additional species were present until the late Holocene. The living taxa are relatively small-bodied and weigh <10 kg. Conversely, all of the now-extinct species were relatively large, ranging in body mass from ca. 12 kg to >100 kg. Among mammals, smaller-bodied species tend to have smaller home ranges than larger-bodied species. This is true for ungulates, carnivores, and anthropoid primates. We might therefore expect that now-extinct large-bodied lemurs had larger home ranges than still extant smaller-bodied taxa. Yet multiple lines of evidence suggest that the extinct lemurs were relatively inactive. These include postcranial (vertebral, sacral, pelvic, limb, hand and foot) anatomy, small semicircular canals (which are balance organs within the inner ear), low periodicity of incremental growth bands in their tooth enamel, and dental morphology (which is related to diet, and in turn activity level in living primates). Thus, on the basis of this evidence, we might expect that now-extinct lemurs had relatively small home-ranges, perhaps as small as those of much smaller-bodied extant lemurs. We use strontium isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) to compare mobility of co-occurring extinct and extant lemurs at three subfossil localities with relatively robust sample sizes and varying bedrock geology: (1) Ankilitelo/Mikoboka, a series of sinkholes in a limestone plateau in southwestern Madagascar; (2) Taolambiby, a seepage deposit underlain by Quaternary alluvium and upper Paleozoic through Triassic sediments in southwestern Madagascar; and (3) Ampasambazimba, a wetland underlain by a variety of Neoproterozoic through Tertiary igneous and metamorphic rocks in central Madagascar. We include eight genera in our analysis: *Eulemur*, *Lemur*, *Lepilemur*, and *Propithecus* (extant), and *Archaeolemur*, *Megaladapis*, *Pachylemur*, and *Palaeopropithecus* (extinct). There are no differences in variance or median $^{87}\text{Sr}/^{86}\text{Sr}$ between extinct and extant taxa at any of the sites. A single *Palaeopropithecus* at Ankilitelo and a single *Eulemur* at Ampasambazimba have unusually elevated ratios compared to other individuals at the same sites. Extant lemurs have apparently more variable $^{87}\text{Sr}/^{86}\text{Sr}$ at Taolambiby. This is driven by *Propithecus*, which has significantly more variable $^{87}\text{Sr}/^{86}\text{Sr}$ than *Pachylemur* (Bartlett $p=0.0224$). These results demonstrate the value of strontium isotopes for testing hypotheses related to the behavior of now-extinct species. Overall, the data support small home ranges for extinct lemurs and instead suggest that, if anything, extinct taxa may have been less active than extant species. This is true for all four extinct genera, including *Palaeopropithecus*, which is thought to have been a suspensory folivore, and *Archaeolemur*, which was likely more terrestrial and more of a generalist. Small apparent isotopic differences among co-occurring taxa may reflect consumption of different foods or spatial partitioning.

This research was supported by NSF BCS-1749676 and NSF BCS-1750598.

Trail of the mastodon: Reconstructing landscape use with stable oxygen and strontium isotope ratios from a serially sampled tusk

Joshua H. Miller¹, Brooke E. Crowley¹, Daniel C. Fisher², Ross Secord³

¹University of Cincinnati, Cincinnati, OH, USA. ²University of Michigan, Ann Arbor, MI, USA. ³University of Nebraska-Lincoln, Lincoln, NE, USA

Abstract

The mobility of a species affects home range size, landscape use, dispersal patterns, and ability to migrate, making it a fundamental driver of species interactions and community ecology. Improved understanding of the mobility of extinct taxa would fill fundamental voids in our knowledge of past faunas and the evolution of many ecological traits. Strontium isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) show promise for evaluating paleo-mobility because they vary across landscapes largely as a function of bedrock composition and age. Further, organismal tissues incorporate biologically available $^{87}\text{Sr}/^{86}\text{Sr}$ with minimal fractionation, thereby recording this geographical fingerprint. A limitation of the $^{87}\text{Sr}/^{86}\text{Sr}$ system is that it requires a reference map of bioavailable $^{87}\text{Sr}/^{86}\text{Sr}$ to which biological specimens can be compared. These maps are typically developed by sampling $^{87}\text{Sr}/^{86}\text{Sr}$ in the field, which is time-intensive, costly, and limits the spatial resolution and extent of subsequent analyses. Regional-scale models of $^{87}\text{Sr}/^{86}\text{Sr}$ have relieved some of these limitations and offer opportunities to reconstruct paleo-mobility and movement patterns at previously impractical scales. Here, we use a published isoscape for North America and a serially sampled male mastodon tusk (*Mammuth americanum*, terminal Pleistocene, Indiana, USA; ISM 71.3.261) to reconstruct intra-annual changes in landscape use for this individual. Using modern elephant ecology as a reference, we also test for changes in landscape use and geographic range between when the male was young (part of a matriarchal herd) and mature (when he likely lived in greater isolation). Further, this individual has perimortem cranial damage evidently induced by another proboscidean's tusk. In modern elephants, such damage is generally inflicted when males battle for access to receptive females. By evaluating paleo-landscape use, we test whether this damage was inflicted in a region used throughout the year, or one with seasonal use. We sampled five years from the mastodon's early life and the three years before death. Powders were milled in ~0.5-mm increments (averaging eight samples per year, with each year visible as a structural unit in tusk dentin) and analyzed for $\delta^{18}\text{O}$ and $^{87}\text{Sr}/^{86}\text{Sr}$. Resulting $\delta^{18}\text{O}$ data are strongly cyclic, reflecting seasonal variability. Strontium isotope ratios differ significantly between earlier- and later-formed samples, indicating shifts in geography. Early in life, $^{87}\text{Sr}/^{86}\text{Sr}$ displays less annual cyclicality compared to $\delta^{18}\text{O}$ values. With maturity, $^{87}\text{Sr}/^{86}\text{Sr}$ becomes more cyclic. Spatial modeling indicates the mastodon traveled less during earlier years, changing to larger-scale movements as an adult. The mastodon spent substantial time in Indiana and the Minnesota/Iowa/Illinois area early in life. As an adult, he repeatedly visited the Indiana/Ohio/Kentucky area during late-spring and summer; the inferred mastodon mating season. Seasonal timing of these visits paired with inferred cause of death suggests that parts of Indiana/Ohio/Kentucky were this individual's preferred mating area, to which he made extensive (10^3 -km round-trip) annual journeys.

Quaternary Sr isotopic record for the Black Sea and Caspian Sea: Implications for palaeoenvironmental change and endemic fauna

Diksha Bista^{1,2}, Dirk Simon^{3,4}, Thomas M. Hoyle³, David A. Richards^{1,2}, Rachel Flecker¹

¹School of Geographical Sciences, University of Bristol, Bristol, United Kingdom. ²Bristol Isotope Group, Bristol, United Kingdom. ³Utrecht University, Utrecht, Netherlands. ⁴University of Bristol, Bristol, United Kingdom

Abstract

Constraining the timing and nature of the connections between hydrographic systems is critical to understanding the rates of biological adaptation and faunal migration. Quaternary sediments of both the Caspian Sea and Black Sea contain endemic faunas and their temporal and spatial occurrence has been the principle means of reconstructing the connectivity history of the two basins. However, faunal-turnover is a response to changing environmental conditions (e.g. nutrient and oxygen content, salinity), which can result from aspects of a basin's hydrography (e.g. precipitation – evaporation balance, fluvial discharge, circulation) that are not exclusively controlled by water exchange between the two basins. Consequently, fossil-based reconstructions of the Quaternary connectivity history between Caspian and Black seas are contradictory.

Strontium isotopic ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) in well-preserved fossil carbonates provide an excellent alternative approach because the $^{87}\text{Sr}/^{86}\text{Sr}$ value of non-marine systems is sensitive to the relative flux of different water sources. We have combined the $^{87}\text{Sr}/^{86}\text{Sr}$ of fossil ostracods from the Black and Caspian seas with salinity estimates provided by ostracod and dinoflagellate cyst assemblages in a numerical box model to constrain the input sources, and consequently the timing and nature of the connection between the two.

The early-mid Quaternary $^{87}\text{Sr}/^{86}\text{Sr}$ records from both the Black and Caspian seas overlap and are lower than today's Black Sea ratio suggesting an enduring connection between the two basins either via one-way flow or two-way exchange and isolation of the Black Sea from the Mediterranean up until ~ 1 Ma. Subsequent rise in the $^{87}\text{Sr}/^{86}\text{Sr}$ of the Black Sea and divergence from the persistently low Caspian Sea ratios indicate episodic Mediterranean input however, with influxes consistently lower than the present day levels until the Holocene. Quantitative analysis of the Caspian Sr isotope data suggests two water sources that do not contribute to Caspian today: the Amu Darya and, prior to ~ 2 Ma, a minor component of ocean water from the Arctic.

The geochemical records are broadly consistent with coeval evidence of faunal exchange. However, the paired Sr-salinity data provide a more detailed and robust connectivity history with respect to both the timing and nature of past connections. As such we now have a connectivity framework against which complex faunal patterns of expansion and extinction can be interpreted.

The energetic cost of travel: Linking strontium and nitrogen isotope analyses from bison as indices of mobility and nutritional stress

Juliette Funck¹, Cade Kellam¹, Tom Seaton², Clement Bataille³, Matthew Wooller¹

¹University of Alaska Fairbanks, Fairbanks, USA. ²Alaska Department of Fish and Game, Fairbanks, USA. ³University of Ottawa, Ottawa, Canada

Abstract

Bison were a dominant feature on northern landscapes during the Late Quaternary. We employ a novel approach coupling and comparing strontium and nitrogen isotopes present in ancient and modern bison to provide proxies of bison mobility and nutritional status. As a modern analogue, we conducted stable nitrogen isotope analyses of sequentially sampled tail hairs (keratin) from modern bison from Alaska. These modern bison composed a recently established (Spring 2015) herd of wood bison (*Bison bison athabasca*) released into the wilds of Alaska. In addition to analyses of many typical members of the main herd, we also analyzed tail hairs from a suite of individuals that had either undergone starvation and subsequent death, or had traveled large distances, corroborated by satellite tracking. Nutritional stresses caused by starvation and the caloric tolls of long distance travel both produced a notable increase in the stable nitrogen isotope values. This pattern resulted from these individuals essentially consuming their own proteins, which imparts a sequential isotopic record in nitrogen rich tissues that grow incrementally, such as tail hairs or horn sheaths. Although tail hairs from bison are not typically found in the fossil record, similar nitrogen isotope analyses aimed at examining the physiological status of ancient bison can be conducted on cores taken from the keratin composing bison horn sheaths. These horn sheaths are abundant in the Beringian fossil record and maintain a continuous record of physiological changes and stresses throughout a bison's lifetime. Stable nitrogen isotope analyses of horn sheaths can then be coupled with analyses of strontium isotope ratios (Sr87/86 values) of tooth enamel serial sampled from bison molars (molars 1,2 and 3) used as proxies for paleo-mobility. Strontium isotope ratios have previously been used as a geological tracker of (paleo) mobility, as Sr87/86 ratios vary according to a landscape's underlying geology and location. By coupling these two isotopic paleoecological proxies it is possible to examine whether bison travelled large distances and whether they experienced physiological costs associated with travel. To enhance our use of strontium isotopes to geolocate bison, we conducted and present results from strontium isotope analyses of modern, georeferenced rodents, used to create a spatial model of bioavailable strontium isotope signatures across Beringia ('RodeMap'). We also present a case study coupling nitrogen and strontium isotope analyses of a single well-preserved, articulated steppe bison specimen (>50,000 years old), demonstrating the advantages of a multi-isotope approach to examine this particular bison's life history. The early life of this individual showed evidence of both significant markers of paleo-mobility and physiological stress. Our multi-isotope method allows us to examine possible causes of death (i.e. starvation) periods of resource-limitation through life, migrations, and illustrates the potential costs of paleo-mobility in ancient bison.

Tracking ~30 years of movement and feeding ecology of a 17,000-year-old woolly mammoth (*Mammuthus primigenius*) from Arctic Alaska

Matthew Wooller¹, Clement Bataille², Patrick Druckenmiller¹, Gregory Erickson³, Pam Groves¹, Norma Haubenstock¹, Tim Howe¹, Johanna Irrgeher⁴, Daniel Mann¹, Thomas Prohaska⁴, Karen Spaleta¹

¹University of Alaska Fairbanks, Fairbanks, USA. ²University of Ottawa, Ottawa, Canada. ³Florida State University, Tallahassee, USA. ⁴University of Natural Resources and Life Sciences, Vienna, Austria

Abstract

Arctic Alaska is experiencing rapid environmental changes in response to recent warming. Radical environmental changes also occurred during and after the last glacial maximum (LGM, ~21,000 years ago). During the LGM, this region was inhabited by a variety of now extinct megafauna, including the iconic woolly mammoth (*Mammuthus primigenius*). What caused the extinctions of these ice-age megafauna is still hotly debated. Although the life of mammoths has sometimes been portrayed as including large seasonal migrations, this inference remains untested and is based on the behavior of extant proboscideans rather than on paleo-data. To gain insight into the life history of a mammoth from the Arctic, we longitudinally split the curved, 1.5-meter-long tusk of a bull mammoth using a band saw. The specimen is one of two tusks associated with a skull from a single individual found north of the Brooks Range above the Arctic Circle. Calibrated radiocarbon dates from both the skull and one of the tusks indicate this bull mammoth died 17,000 calendar years ago during the closing millennium of the LGM in this part of the Arctic. After sectioning the tusk to reveal annual growth bands, we used sequential samples taken from along the entire length of the exposed inner surface of the tusk for stable isotope analyses (N and C on the organic fraction and C and O on the inorganic fraction) as well as strontium isotope ratio ($\text{Sr}^{87}/\text{Sr}^{86}$) analysis in order to reconstruct the animal's feeding ecology, environment, as well as its movements through the course of its life. This temporally precise, multi-isotope reconstruction allows insight into the life history of a woolly mammoth between birth and death, including its diet, changing nutritional state, and geographic movement. Based on histological and seasonal isotopic oscillations, we estimate this mammoth was ca. 30 years old when it died and that he wandered extensively during several, multi-year periods of his life. Death seems to have followed an extended period of starvation.

O-0064

Cultural heritage sites in coastal areas. Use, monitor, manage and preserve sites & landscapes under climate change and development pressure (CULTCOAST)

Vibeke Vandrup Martens

NIKU - Norwegian Institute for Cultural Heritage Research, Oslo, Norway

Abstract

Cultural heritage (CH) and cultural environments are highly valued environmental goods, but these values are under serious threat from multiple sources. Climate is changing now at an even higher rate than expected in some of the worst-case climate scenarios, with increasing temperatures, changes in precipitation, decreasing permafrost, more frequent and severe storms, sea level rise, reduction of sea ice, floods, avalanches and changing vegetation (Climate Research Unit, 2018). These changes increase the risks of geo-hazards, e.g. erosion caused by wind, waves and rivers that threaten particularly coastal CH sites, environments and landscapes. The northern areas are particularly sensitive because they suffer more from combined threats and have previously been well protected by the aid of permafrost and sea ice. The Arctic areas act as a sensor and an early warning-system for the rest of the world. Impacts there are likely to be felt further south in the future. This emphasizes the need for further research on climate change impacts in the northern areas. As impacts and effects of climate change are global and the bequest value of heritage, preserving it for future generations, is of relevance everywhere, our studies will be transferable to CH management plans and mitigation actions at national and global scales, to meet the UN Sustainable Development Goals on resilient and sustainable settlements and taking urgent action to combat climate change and its impacts.

Our project focuses on the individual and combined impacts of climate change induced geo-hazards and pressure from tourism and development in northern Norway, using the Arctic and sub-Arctic sites as basis for future modelling that will have global use. Based on existing methodologies for mapping and documentation, strategies for mitigation and conservation will be developed to protect these sites in the decades towards the year 2100. We intend to map, monitor and gather input from selected case sites below and above ground on Svalbard and Andøya to develop improved knowledge-based methods for evaluating and prioritizing sites. We'll further develop mitigation measures and management strategies related particularly to coastal CH sites, environments and landscapes threatened by geo-hazards, in close cooperation with national and international expertise. Our interdisciplinary approach of combining archaeology, architecture, geography, quaternary geology and climate science has not previously been considered or implemented.

This research will produce impacts in the form of compilations and analyses of existing data, definitions of change indicators, standardised methods for defining baseline conditions and methods for deciding on monitoring programmes. We also aim to provide a positive environmental impact by producing management and mitigation strategies for individual sites as well as for national and international strategies on CH preservation and adaptation. We also aim to raise awareness about CH and Climate Change among the general public.

O-0065

Fragile heritage from high-elevation ice: understanding and protecting the archaeo-ecology of ice patches in the Greater Yellowstone Area, USA

Craig Lee

University of Colorado - Institute of Arctic and Alpine Research (INSTAAR), Boulder, USA

Abstract

Changing climate is causing perennial ice patches at high latitudes and high elevations to melt, resulting in the release of ancient paleobiological and archaeological materials that, until recently, were in cryogenic-like stasis. Ancient organic artifacts emerging from the ice include baskets, leather and hair cordage, and millennia-old wooden shafts once used for hunting. Ice patches are also releasing stone tools, plants, and the remains of animals. In North America, the field of “ice patch archaeology” refers to the study of anthropogenic materials recovered in association with these retreating features. Researchers in Europe frequently refer to this field as “glacial archaeology,” in part because of archaeological finds in glaciated passes. The stable ice in these ice patch features exhibits little internal deformation or movement and can preserve otherwise perishable materials for millennia.

The exposure of ancient archaeological and paleobiological materials in the Greater Yellowstone Area (GYA) of Wyoming, Montana and Idaho, USA, is a tangible indication of climate change in the Rocky Mountain West (Lee and Puseman 2017). The well-preserved materials that are emerging—and the historical and environmental contexts we find them in—hold clues about past and present climate change, and in the U.S. and Canada they also speak to how indigenous populations interacted with high-elevation landscapes. Areas that today are often characterized as “empty” wilderness were home to groups of Native Americans for millennia. The mountains remain sacred to many peoples, and the heritage of many Native American tribes is inexorably tied to the Rocky Mountains through story, song, traditional ecological knowledge, and ceremony (Lee et al. 2004).

Ice patch materials are charismatic and useful for engaging and educating the public about the long tenure of Native American people in the alpine and about the Earth’s changing climate (Lee et al. 2018). While enormous loss has likely occurred, increased snow loads at some ice patches suggest there is still time to engage with these features in a thoughtful manner (Reckin 2017). Yellowstone National Park has been a strong supporter of this research, and the talk will highlight ongoing efforts there.

Severe Weather and the Reliability of Desk-Based Vulnerability Assessments. The impact of Hurricane Maria to Puerto Rico's Coastal Archaeology

Isabel Rivera-Collazo

University of California San Diego, La Jolla, USA. Scripps Institution of Oceanography, La Jolla, USA. Center for Applied Tropical Ecology and Conservation, University of Puerto Rico, Rio Piedras, Puerto Rico

Abstract

Within the context of climate change, sea level rise is threatening not only coastal communities globally, but also the archaeological record of their history, knowledge and culture. As a response, inter-institutional databases of heritage are increasingly being coupled with other widely-available cyberinfrastructure to assess the magnitude of the threat and the vulnerability of cultural heritage, in order to begin the design of actionable steps or mitigation of impact. This presentation focuses on the coastal archaeology of Puerto Rico to assess the reliability of desk-based vulnerability assessments in the context of disasters against the backdrop of the damage caused by Hurricane Maria. The study conducted a walkover survey of 11 km of coast on the north-central portion of Puerto Rico and documented context, visible impact, and level of threat from coastal erosion, among other factors. The analysis demonstrated that a desk-based assessment conducted in 2017 severely underestimated the vulnerability of coastal resources. While two sites were predicted to be vulnerable, the survey identified eight damaged sites. In addition to damaged sites, which in our study location was 400% above expected, the process of climate change is occurring as traumatic catastrophic events, after which hundreds of volunteers pour in to provide support. Notwithstanding their often well-intentioned response, the sense of urgency of relief efforts ends up ignoring local processes, knowledge, traditions and social dynamics. The period of recovery after a catastrophe is a highly sensitive time for affected communities, and the process of recovery jeopardizes the preservation of intangible cultural heritage. These results call for heightened attention to the actual process of climate change and post-catastrophe recovery, not just for cultural heritage, but also for coastal and marine ecosystem management and for the resilience of human communities.

O-0067

Impact of Sea level Rise on Heritage Resources of the Delaware Estuary

Daria Nikitina¹, Heather Wholey², Kyle Knox²

¹West Chester University, West Chester, USA. ²West Chester University, West Chester, USA

Abstract

The Delaware Bay is the second largest estuary along the U.S. Atlantic coast that has been occupied by humans throughout Holocene. Using geoarchaeological approach we conducted paleo-landscape reconstructions at selected sites with documented coastal archeological resources in order to reveal connections between human settlement and coastal environments. We documented more than 10,000 archeological sites within the Delaware Bay coastal zone. Sea level rise (SLR) poses a major threat to natural and historical resources present in the low-lying coastal areas. Most of the estuarine shoreline is fringed by salt marshes that have been developing for the past 2,000 years but are now being lost at various rates. We applied the knowledge of wetland evolution driven by RSL from site specific to estuarine scale in order to assess the vulnerability of existing cultural resources along the coast of the Delaware Bay. Predictive models of future SLR suggest that 10% of the archeological and historical resources will be inundated or surrounded by salt marsh by 2050.

Our multi-disciplinary approach contributes to the development of a multi-scalar “Landscape Archaeology of Wetlands” methodology for contextualizing the archaeological record of wetland landscapes and the results will help to prioritize protection of Delaware Bay heritage resources and promote the development of stakeholder partnerships for future resources conservation and/or management.

Using Ground-penetrating Radar and Citizen Science to Document and Monitor Erosion of Coast Shell Middens, Maine, USA

Alice Kelley

University of Maine, Orono Maine, USA. Climate Change Institute, Orono, ME, USA

Abstract

Archaeological sites are threatened by climate change as increasing rates of sea level rise intensifies damage from storm-driven waves. In Maine, USA, over 2,000 indigenous shell middens containing mollusk shells, artifacts, and faunal remains are disappearing as a result of sea-level rise, storm intensification, and increased freeze-thaw action. Composed primarily of shells, these middens also contain artifacts and faunal remains that document up to 4,000 years of indigenous coastal occupation. These sites range in size from the impressive, 5-6 meter thick oyster shell middens of the midcoast region to the many smaller clam shell middens dotting mainland and island coasts. Most of the known sites are documented on the basis of the presence of eroding material or cursory testing, with few being revisited within decades of original description. Only one to two middens per year can be professionally excavated due to funding constraints. As a result, the current condition of most of these sites is unknown and knowledge of erosion is anecdotal.

This presentation details a two-pronged approach to developing a database of shell midden information for use by culture heritage managers to understand patterns of loss and prioritize scarce resources. 1) Typically, shell midden areal extent and thickness is determined using widely spaced test units. This approach provides limited and discontinuous information. However, a ground-penetrating radar (GPR) survey, in combination with stratigraphic information from previous documentation or limited excavation, provides a continuous record of profiles across the site. Additionally the technique is nondestructive, requires minimal staff, and allows for efficient data collection. While individual artifacts cannot be resolved in GPR records, accumulations of rocks, soil layers, and potential occupation horizons may be identified. Although GPR cannot entirely replace a detailed excavation, an initial GPR survey of a shell midden site can provide information regarding site extent and vertical shell distribution. 2) Site characterization is important, but without ongoing monitoring provides no information on site condition or erosion rates. To address this challenge, a citizen science group, the Maine Midden Minders, is being developed to train interested volunteers from conservation organizations, tribal communities, and individual citizens to document seasonal to annual changes at middens. Measurements are made using simple tools, and site conditions documented using digital photography. This information is collected into database that will archive site location, size, condition, and photographs. This data will be available only to state cultural heritage agencies and researchers as a way of protecting site integrity and landowner privacy. The resulting database can then be used to identify vulnerable sites and allocate resources. The result of these two approaches in to combine proven archaeological and geoarchaeological techniques with citizen science observations to develop an integrated approach to management and rescue of important coastal heritage.

Weekly oxygen isotope measurements in teeth reveal environmental variation

Tanya M. Smith¹, Daniel R. Green^{2,3}, Ian S. Williams⁴

¹Griffith University, Brisbane, Australia. ²Forsyth Institute, Cambridge, USA. ³Harvard University, Cambridge, USA.

⁴Australian National University, Canberra, Australia

Abstract

Oxygen isotopes in tooth enamel vary with temperature, precipitation and evaporation cycles during an organism's development, aiding reconstructions of past environments. Enamel is typically sampled by drilling to recover oxygen inputs from food and water consumed during tooth formation. This method has limited spatial resolution, yielding samples that integrate long formation times of unknown chronological age and therefore limit the recovery of seasonal environmental patterns from teeth.

To address this dilemma we employ a Sensitive High Resolution Ion Microprobe (SHRIMP SI) to measure oxygen isotope compositions ($\delta^{18}\text{O}$) from tooth enamel on a spatial scale of 15-30 μm , which can be related to daily increments and birth lines to determine formation times and calendar ages. $\delta^{18}\text{O}$ values of sheep enamel measured by SHRIMP SI are nearly identical to those from silver phosphate microprecipitation, confirming the fidelity of this approach for enamel bioapatite oxygen recovery (Smith et al. 2018). Here we analyze teeth from wild orangutans collected more than a century ago, along with two fossil orangutan teeth from Lida Ajer, Sumatra –the site that yielded the oldest insular Southeast Asian human remains 63-73,000 years ago (Westaway et al. 2017). Molars were sectioned following standard procedures, and sequentially sampled on a spatial scale corresponding to a near-weekly timeframe along the enamel-dentine junction using secondary-ion mass spectrometry. Standardized $\delta^{18}\text{O}$ values were related to temporal records of formation over 3-4 years per tooth (Smith 2016).

Oxygen isotope values in wild-shot Bornean and Sumatran orangutan first molars ranged from 11.3-19.9 ‰ and 13.4-20.4 ‰, respectively. Concurrently forming left and right molars from the same fossil orangutan ranged from 15.4-20.1 ‰ and 15.1-19.9 ‰, supporting the biogenic fidelity of this palaeoclimate record. All teeth showed isotopic variation on a circannual basis, particularly after the initial period of exclusive mother's milk intake.

Enamel is the most impermeable tissue in the human body, and the recovery of similar $\delta^{18}\text{O}$ values from these unburied and fossilized orangutan molars strengthens the usefulness of teeth for probing ancient climates. We have demonstrated here and in other studies that isotope variation in mammalian tooth enamel formed over multiple years is substantial, even in equatorial regions. Future research on slow-growing primate teeth may help to conclusively establish whether environmental variation was a significant force in the evolution and dispersal of the human genus (*Homo*) and our own species 300,000 years ago.

Abstract

Environmental seasonality is often invoked as a driver of the evolution of novel hominin and nonhuman primate adaptations, but it is difficult to reconstruct, particularly in association with relevant fossil remains. Here we employ a Sensitive High Resolution Ion Microprobe (SHRIMP SI) to measure enamel oxygen isotope compositions ($\delta^{18}\text{O}$) on a spatial scale of 15 μm in two *Afropithecus turkanensis* specimens from the early Miocene site of Kalodirr (Western Lake Turkana, Kenya) (Leakey and Leakey, 1986). Thin sections of the teeth were sampled sequentially along the enamel-dentine junction using secondary-ion mass spectrometry, and standardized $\delta^{18}\text{O}$ values were related to daily and near-weekly temporal records of enamel formation (Smith *et al.*, 2003).

Sequential near-weekly measurements reveal several years of seasonal fluctuations in $\delta^{18}\text{O}$ values associated with temporal variation in regional hydrology, animal physiology, and behavior. Measurements from both molars reveal mean $\delta^{18}\text{O}$ values (24.1 and 20.5 ‰, VSMOW) that are distinct, with greater seasonal variation in the molar with higher $\delta^{18}\text{O}$ values (ranges 5.5 and 3.3 ‰). Evaluation of molar formation times suggests that the temporal oscillations that account for most variation in $\delta^{18}\text{O}$ values are yearly, with shorter cycles accounting for approximately one third of the observed $\delta^{18}\text{O}$ variation.

$\delta^{18}\text{O}$ values in these apes are similar to bulk enamel measures from nearby Plio-Pleistocene fossil monkey (*Theropithecus*) specimens (average 21.2 ‰: Cerling *et al.*, 2013), despite the fact that Miocene sites are generally thought to have wetter, more forested environments. Our data demonstrate substantial seasonal variability at a single locality. Intra-tooth $\delta^{18}\text{O}$ variation in both *A. turkanensis* molars is comparable to inter-tooth variation in *Theropithecus* specimens at individual sites in eastern and western Turkana that span millions of years. Furthermore, seasonal patterns measured here in both molars barely overlap, altogether showing variation of ~8 ‰ across both specimens, suggesting that the species inhabited hydrologically diverse landscapes over a relatively narrow temporal and geographic window. In particular the larger range of values seen in one individual may suggest a strongly seasonal environment, supporting anatomically-based reconstructions of *A. turkanensis* as a hard-object (sclerocarp) feeder (Rossie and MacLatchy, 2013). Spatially precise and developmentally informed microsampling strategies have the potential to recover seasonal climatic and behavior patterns as long ago as the early Miocene, and will contribute to elucidating the complex relationship between seasonality, primate behavior, and evolution.

Abstract

Exploration of the relationship between paleoclimate and hominin behaviour is central to Palaeolithic Archaeology and the study of past human lifeways. At middle and high latitudes the consideration of seasonal climatic conditions and temperatures is particularly important as a means of better understanding human-environment interactions and hominin adaptations. However, much of the existing palaeoclimate record is derived from broad regional or global scale proxies, and it remains a challenge to explore the implications of such climate reconstructions on temporal and spatial scales that are relevant to hominin activity at individual sites. Palaeotemperature information gleaned from oxygen isotopic analyses of faunal remains provides an opportunity to gain insights into sub-annual resolution seasonal temperature cycles on a smaller, more local level that, significantly, can be linked directly to archaeological contexts.

Here we present high resolution seasonal temperature data to contextualize Neanderthal activity during the early and middle Weichselian glaciation (MIS 4 and 3) at the site of La Ferrassie, southwest France. Palaeotemperatures are obtained from oxygen isotope analyses of sequential enamel samples from herbivore teeth from Layers 2, 5A and 5B. Carbon and nitrogen isotope ratios of bone collagen from Levels 2 through 5 are used to corroborate diachronic trends seen in the $\delta^{18}\text{O}$ data. Exploiting the direct relationship between faunal remains and hominin activity at the site, we explore changes in palaeotemperature and palaeoseasonality during MIS3 and MIS4 across multiple levels of occupation. The isotope data document change in environmental conditions from MIS 4 to MIS 3, not only in more well known average conditions but also showing substantial differences in summer and winter temperature extremes. Using the high resolution isotope data, we reconstruct a more rounded picture of climatic conditions faced by Neanderthals during warm and cold phases of the Weichselian glaciation. Combining new isotopic results with existing studies of the site, we investigate the relationship between environmental change, site use, and faunal resource exploitation at La Ferrassie. In this framework, we also explore the challenges and opportunities of integrating high-resolution isotope data with lower resolution isotope data as well as additional environmental indicators, such as faunal spectrum and micromorphological data, along with broader climatic models.

Sub-seasonal palaeoenvironmental records from mollusc shells and implications for Upper Palaeolithic modern human occupation in the Levant

Amy Prendergast¹, Marjolein Bosch², Marcello Mannino³, Bernd Schöne⁴

¹University of Melbourne, Melbourne, Australia. ²University of Cambridge, Cambridge, United Kingdom. ³Aarhus University, Højbjerg, Denmark. ⁴University of Mainz, Mainz, Germany

Abstract

Humans respond to changes in their local environment on daily to seasonal timescales. Therefore, a robust assessment of the impact of environmental change on human behaviour requires an understanding of local environmental change at seasonal to sub-seasonal resolution. Stable isotope records from mollusc shells provide one of the few sub-seasonal resolution palaeoenvironmental proxies in the mid to high latitudes. Obtaining these records from food-refuse archaeological specimens enables the reconstruction of a more detailed picture of how humans responded to environmental changes in the past.

Here we present sub-seasonally resolved environmental reconstructions from stable isotope analyses of marine and terrestrial mollusc shells from the Upper Palaeolithic archaeological assemblage of Ksar Akil in Lebanon. Oxygen isotope analyses of marine mollusc shells provide sub-monthly resolved snapshots of sea surface temperature, whilst oxygen and carbon isotope analyses of terrestrial gastropod shells provide sub-seasonally-resolved records of rainfall variability and vegetation change. These highly resolved environmental records, coupled with well-dated archaeological sequences provide a framework for assessing the complex interplay between early modern humans and their local environments. We found evidence for fluctuating temperature, rainfall and seasonality regimes throughout marine isotope stage (MIS) 3, some of which appear to be linked to northern hemisphere millennial-scale climate oscillations. The archaeological records show human occupation occurred during both warmer and cooler phases and during both high and low seasonality regimes, indicating that modern human populations were somewhat resilient to the resource uncertainty that would have accompanied these changing temperature and seasonality regimes. These paired cultural-environmental records have enabled an examination of human-environment interactions during critical periods of the late Pleistocene in a region with comparatively few high-resolution climate records.

Carbonates in human water systems as a high-resolution rainfall proxy

Duncan Keenan-Jones¹, Russell Drysdale²

¹University of Queensland, Brisbane, Australia. ²University of Melbourne, Melbourne, Australia

Abstract

Ancient Rome represents a rare opportunity to compare a longitudinal study of rainfall records with an unusually extensive historical record covering more than a millennium. The few existing climate records covering this period and region suffer from dating uncertainty, discontinuity and human impact, however. This paper investigates the potential of dark layering in calcium carbonate deposits formed in past water systems as a well-dated and high-resolution proxy for rainfall distributions, through a case study in ancient Rome's Anio Novus aqueduct. Such a proxy would have broad applicability, since carbonate deposits are found in water systems from Australia's Great Artesian Basin to pre-Columbian North America.

The historical and archaeological evidence relating to the water system provides precise chronological boundaries for the formation of these deposits. Dark, mm-scale aqueduct travertine layers have often been thought to represent annual growth bands, which would improve dating of the deposits within the historical boundaries. In each case, however, the layering needs to be tested for annual cycles of oxygen isotopes (Passchier et al., 2016).

Dark-coloured layers within deposits from ancient Rome's Anio Novus aqueduct are present on multiple scales down to the micron-scale (Keenan-Jones et al., 2014). The dark layers' multi-scalar distribution and elevated organic concentrations are consistent with formation during the organic-rich flows of the Anio Novus' source water (the Aniene River) during storm events, well-characterized by ancient and modern sources. Growth rate estimation suggests that the mm-scale dark-layer clusters represent extended rainy periods, of which there are now 1 or 2 each year. The practically instantaneous response of the upper Aniene River to rainfall events makes it possible that micron-scale dark layers in the Anio Novus travertine represent a period of hours, and thus likely record individual storm cells.

This paper will present stable isotope ratio measurements from the Anio Novus deposits to investigate the time period over which these mm-scale dark layers formed. The oxygen isotope ratio of the Aniene River is now largely constant throughout the year due to the dampening effect of the limestone aquifers, which are currently the subject of a monitoring program. Hence, seasonal temperature changes should lead to seasonal cycles in the oxygen isotope ratio of the Anio Novus' carbonates. These measurements will also be a record of temperature variation.

Apart from its palaeoclimatic value, this rainfall record will illuminate the influence of climate on flooding, disease and fire, all concerns in densely-populated ancient Rome.

The WAIS Divide ice core water-isotope record: new constraints for multi-year Pacific Basin climate variability over the last 31,000 years

Tyler R. Jones¹, William H. G. Roberts², Bradley R. Markle³, Eric J. Steig⁴, Kurt M. Cuffey⁵, James W. C. White⁶
¹Institute of Arctic and Alpine Research, University of Colorado, Boulder, USA. ²Geography and Environmental Sciences, Northumbria University, Newcastle, United Kingdom. ³Division of Geologic and Planetary Sciences, California Institute of Technology, Pasadena, USA. ⁴Quaternary Research Center and Department of Earth and Space Sciences, University of Washington, Seattle, USA. ⁵Department of Geography, University of California, Berkeley, Berkeley, USA. ⁶Institute of Arctic and Alpine Research and Department of Geological Sciences, University of Colorado, Boulder, USA

Abstract

Ultra-high resolution water isotope measurements (δD and $\delta^{18}O$) from the WAIS Divide Ice Core (WDC) have been analyzed using a continuous flow analysis system. The water isotopes are a proxy for local and regional temperature, as dictated by the hydrologic cycle and broad-scale atmospheric circulation patterns. An annual signal is preserved across the entire Holocene. Multi-annual signals persist for at least the last 31,000 years, which is the extent of the annually-resolved depth-age scale. When a diffusion correction is applied to the data, we observe a decline in the multi-year signal strength at ~ 16 ka bp. General Circulation Modeling using HadCM3 shows this change point arises from an inter-hemispheric cascade of events: the decay of the Laurentide/Cordilleran ice sheets altered the tropical Pacific mean state and affected the strength of interactions between the tropical Pacific and high southern latitudes. Ultimately, this change was responsible for a shift in Indonesian ecosystems from grassland to rainforest, and reduced inter-annual and decadal variability in West Antarctica by nearly half. During the Holocene, the multi-annual signal strength is rather constant, but additional variability is revealed in the annual signal amplitude, maximum summer, and minimum winter values. The warmest winters occur at ~ 9.3 ka bp, concurrent with the largest collapse of the east Asian monsoon and possibly linked-reductions in the extent of West Antarctic sea ice. The summer signal dominates the amplitude of the summer-winter signal, and appears to trace with max solar insolation curves centered on the Southern Ocean. There is also millennial-scale variability apparent in the annual amplitude that bears similarity to other millennial oscillations in the North Atlantic, tropical Pacific, the Asian-Australian monsoon system, and possibly elsewhere. Overall, the high-resolution nature of the WDC water isotope record has transformed our understanding of sub-decadal climate signals within the most recent glacial-interglacial cycle, and provides an unprecedented opportunity to improve model skill for paleoclimate environments linked to the Pacific Basin.

Abstract

A high-resolution (near annual) paleoecological record from “Alberta Lake East”, a boreal upland lake in Northeastern Alberta, Canada archives the ecological history of the lake ca. AD 1875-2010. We use this record to quantify the response of the lake to regional warming during recovery from the colder climate conditions that prevailed there during the Little Ice Age (LIA). Arcellinida (testate lobose amoebae), which are an important intermediary food web component in lakes and preserve well in the sedimentary record, were utilized as a proxy of temporal ecological change in the lake. In the late 19th century the arcellinidan fauna was dominated by opportunistic centropxyxids, which were well suited to the lower productivity LIA conditions. By the early 20th century, as the polar front had retreated northward at the close of the LIA, the arcellinidan populations became initially dominated by difflugiids and subsequently by *Centropxyxis tricuspis*, indicative of progressively higher productivity conditions associated with longer ice free seasons and warmer summer water temperatures. Time series analysis of temporal changes in the abundance of individual arcellinidan taxa and functional groups obtained from a chronologically well constrained freeze core were used to identify overprinting cyclic climatic influences on lake hydroecology, particularly that of El Niño Southern Oscillation (ENSO) and Pacific Decadal Oscillation (PDO). The ENSO phenomenon is known to have a significant influence on interannual climate variability in western Canada, and has been associated with fluctuations in winter precipitation and temperature in the study region. Positive PDO conditions are associated principally with variation in winter temperatures across the region. Wavelet analysis identified a strong ca. 2-9 year cyclicity that correlates well with ENSO frequency in all arcellinidan proxies, and a weaker ca. 60 year cyclicity that correlates well with PDO frequency within the difflugiid and *C. tricuspis* populations. Correlation analysis between arcellinidan populations and the Nino 3.4 and PDO instrumental data revealed that taxa associated with higher productivity (e.g. difflugiids) were negatively correlated with +ENSO and +PDO conditions, which are associated with decreased precipitation and reduced nutrient runoff from lake catchments. The close relationship between arcellinidan ecology and subdecadal changes in climate at Alberta Lake East demonstrates the high sensitivity of northern lake ecosystems to climate variability.

Organic geochemical markers of sea-level changes

Martina Conti¹, Kirsty Penkman¹, Brendan Keely¹, Natasha Barlow², Martin Bates³

¹University of York, York, United Kingdom. ²University of Leeds, Leeds, United Kingdom. ³University of Wales, Trinity Saint David, Lampeter, United Kingdom

Abstract

Targeted analysis of organic materials in soils is useful for evaluating past environmental conditions, as specific fauna / flora are related to sea-level changes. However, this depends on the preservation of macro and microfossils in the sediment. Specific molecular fossil compounds (termed biological markers or biomarkers), preserved in the soil matrix, may also be directly linked to organisms and hence to the conditions in which they thrived. Variations in biomarker distributions have therefore become a powerful tool for understanding changes in palaeoclimate conditions. Understanding the main drivers for local past climate changes can inform predictions of future sea-level rise.

This work determines the utility of molecular fossil marker evidence for Quaternary sea-level changes in sediment deposits from the UK, alongside establishing detailed chronologies for the sediments by amino acid racemisation (AAR) dating of carbonate shells and foraminifera. The cores consisted of unconsolidated immature sediments from the mid-late Pleistocene (< 500,000 years) that represented sea-level transgressions. The production of organic geochemistry biomarkers (such as chlorophyll pigments and lipids) change as a response to palaeoenvironmental conditions, providing a useful marker for sea-level changes. Fluctuations in the pigment and *n*-alkane distribution reflect changes in primary producer activity, while the GDGT-based index of branched and isoprenoid tetraether lipids (BIT) differentiates between terrigenous and marine organic matter inputs. Lipids were analysed by GC-FID and HPLC-MS while analysis of chlorophyll pigments was carried out using a new UHPLC-DAD method. The AAR chronology provides temporal constraints to the transgressions, enabling the reconstruction of Pleistocene sea-level changes beyond the capabilities of ¹⁴C dating.

The results from biomarker analyses show excellent time-resolved agreement with the lithological and ecological interpretation, but enabled a more sensitive response of different primary producers to changing conditions to be observed. Linking the pigment, lipid and chronological records, the impact of climate change on the primary producer communities and preservation of molecular signatures can therefore be assessed over transgressive phases of sea-level change. This coupled approach - using biogeochemical markers within temporally constrained deposits - enables exploration of a far wider set of sediments for understanding the past.

O-0079

Are relative sea-level databases always reproducible?

Udita Mukherjee, Torbjorn Tornqvist

Department of Earth and Environmental Sciences, Tulane University, New Orleans, Louisiana, USA

Abstract

Collating and presenting relative sea-level (RSL) data from around the world in a well-defined sea-level protocol, considering all the possible errors involved, has become an essential part of sea-level studies. Interpretation and analysis of various sea-level indicators form the most important part of such an exercise, and different approaches during this endeavor can cause major differences between databases which are essentially sourced from the same data. Here we present an RSL database from southern Africa, a tectonically stable far-field region, prepared using data from the published literature to encompass the post-Last Glacial Maximum (LGM) sea-level history spanning 21 to 5 ka. This database currently contains 39 sea-level indicators, including four sea level index points (SLIPs), one upper limiting data point and 34 lower limiting data points. The database presented by Cooper et al. (2018) describes RSL change in southern Africa since the LGM using beachrock, *in situ* biological indicators, and geomorphological and sedimentological indicators, consisting of ~15 SLIPs. We use the same set of indicators and a similar protocol (Hijma et al., 2015), yet there are some fundamental differences between the two databases. The number of SLIPs is limited to four beachrock samples in the database presented here, as the indicative meaning of the *in situ* biological indicators described from this area only makes them suitable as limiting data points. The indicators described from paleovalley fills and storm beaches are likely to have been subject to sediment compaction or reworking, making them unsuitable for our purpose. The ΔR used for reservoir age correction for samples dated using radiocarbon can also create a difference for a database. The ΔR used in the databases is the same for the western coast but differs for the eastern coast, with an uncertainty of 175 years for our database. Although the broad RSL history is similar for both databases, with RSL rise between the LGM and ~8 ka followed by a highstand between ~7 ka and ~5 ka, the precise timing and elevation varies depending on the way sea-level indicators and their ages are interpreted. Specifically, replacing SLIPs by limiting data leads to much higher levels of uncertainty about the RSL history for a given region. Such differences in interpreting RSL change could have a significant effect on glacial isostatic adjustment (GIA) modeling because of its potential implications for quantitative data-model comparisons.

Rapid sea-level rise and climate change: lessons from the early Holocene.

Graham Rush¹, Roland Gehrels¹, Mark Bateman², Grant Bigg²

¹University of York, York, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom

Abstract

The '8.2 ka cold event' is recognised as the largest magnitude Holocene cooling event in the North Atlantic region. Freshwater input from the retreating Laurentide Ice Sheet drove a slowdown of the Atlantic Meridional Overturning Circulation (AMOC) which subsequently caused the observed climatic shift. A 160 year period of temperature cooling of 3.3 ± 1.1 °C and reduced precipitation are observed in Greenland, with contemporaneous climate shifts recognised in many other records around the North Atlantic region and further afield. In this presentation two new high-resolution sea-level reconstructions from both hemispheres will be presented with the aim of resolving the history of North Atlantic melt-water input prior to the 8.2 ka event.

Litho- and bio-stratigraphic data alongside high-precision radiocarbon dates have been collected from the Ythan Estuary (NE Scotland) and Swan Inlet (Falkland Islands) for the centuries prior to the 8.2 ka event. In the Ythan Estuary, two complimentary single core analyses utilise a foraminifera based transfer function and multiple high-precision radiocarbon dates to produce a robust high-resolution reconstruction. Swan Inlet is the first southern hemisphere location where a rapid flooding event preceding the 8.2 ka event has been discovered. Optically Stimulated Luminescence analysis shows that the observed sea-level rise, in the order of 2-4 m, occurred in Swan Inlet within a few centuries. This is further constrained by radiocarbon dating and a diatom-based transfer function to resolve the phase(s) and magnitude of this rise.

The combination of sea-level reconstructions from both hemispheres allows confirmation of a Laurentide melt-water source as the trigger of the 8.2 ka event by comparing the magnitudes in conjunction with sea-level fingerprint models. Identifying the freshwater source(s) and quantifying melt-water input allow climate models to be tested in order to apply them more confidently to future AMOC responses to scenarios of warming and ice melt. Thus, this work ultimately will help to improve understanding of the impacts of Arctic ice melt on oceanic changes and future climate, especially in the North Atlantic region.

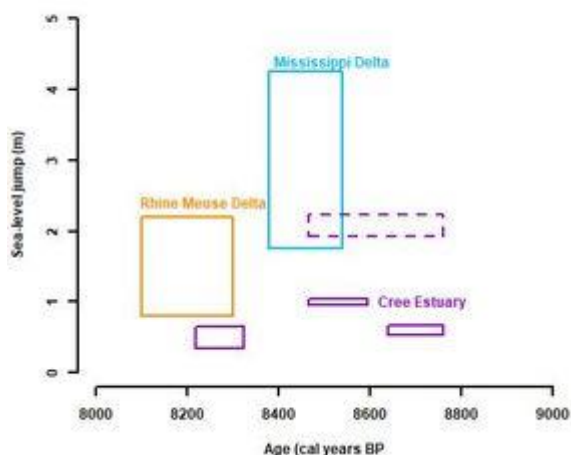

Figure 1. The timing and magnitude of previously observed sea level jumps from sites shown in figure 2, highlighting the current disagreement.

Figure 2. Numerically predicted sea-level fingerprint due to the melt-water input from the retreating Laurentide Ice Sheet at 8.4 ka, normalized by a eustatic rise (0.4 m). The coloured squares represent sites of previous sea-level measurements shown in figure 1 and the white squares are sites from this study. (Adapted from: (Kendall *et al.* 2008)

Holocene relative sea-level changes along the Atlantic coast of South America

Timothy Shaw¹, Nicole Khan¹, Erica Ashe², Keven Roy¹, Richard Peltier³, Benjamin Horton¹

¹Nanyang Technological University, Singapore, Singapore. ²Rutgers University, New Jersey, USA. ³University of Toronto, Toronto, Canada

Abstract

The spatial and temporal variability of Holocene relative sea level (RSL) changes along the Atlantic coastline of South America are assessed using a newly compiled Holocene sea-level database. The database covers a large spatial area from Suriname to southern Argentina. The southernmost region of the Atlantic South American continent is especially important because the Patagonian Shelf was fully exposed at Last Glacial Maximum and the reported very high mid-Holocene sea levels that could have been strongly influenced by the eventual inundation of the shelf during deglaciation and the expected sharp change in tidal range.

The database comprises sea-level index points and terrestrial and marine limiting data derived from a variety of geological and biological indicators including mangrove and salt marsh peat, beach rock, vermetids, and storm beach deposits. The data was compiled following newly outlined protocols in assembling published sea-level data allowing comparison of regional RSL trends after consideration of vertical and temporal uncertainties in the sea level data and local scale processes (e.g. sediment compaction). We estimated magnitudes and rates of RSL change and the amplitude and timing of the mid-Holocene highstand along a latitudinal gradient by applying a spatio-temporal empirical hierarchical model. Furthermore, we compare regional RSL trends with glacial isostatic adjustment predictions using the latest iteration of the Toronto model ICE-7G_NA (VM7) of Roy and Peltier (2017).

The RSL records are characterized by higher rates of RSL rise during the early Holocene. The transition to the mid-Holocene period is characterized by spatially variable RSL rising to values higher than present level. For example, RSL records from Suriname and Guyana show RSL at 2.0 (\pm 1.1) m at 3.7 ka. In central South America, RSL records from Brazil show RSL at 4.8 (\pm 1.4) m at 5.3 ka while RSL records from the Beagle Channel show RSL at 6.6 (\pm 2.1) m at 5.9 ka. Following the mid-Holocene highstand, the potential oscillatory nature of RSL changes towards the present is assessed after full consideration of the data uncertainty.

O-0082

Investigating hydro-isostasy as a driver of Holocene sea-level variability in Northland, New Zealand

Alastair Clement¹, Pippa Whitehouse²

¹Massey University, Palmerston North, New Zealand. ²Durham University, Durham, United Kingdom

Abstract

Meltwater-driven ocean loading on the continental shelf is hypothesised to be a significant driver of spatial and temporal variability in Holocene sea-level (SL) changes around the New Zealand coast. The Northland peninsula, at the northern end of the North Island, is a key laboratory for examining the impact of meltwater loading on land deformation and SL variability in New Zealand: the coastline is convoluted with a variable-width continental shelf; the region is tectonically stable during the Holocene; was ice-free during the last glaciation; and contains a major sub-set of the population of SL index points assembled for the New Zealand palaeo sea-level database.

Glacial isostatic adjustment (GIA) modelling for sites along the length of the peninsula predicts significant variability in Holocene SL changes over relatively short distances. This variability is the product of spatial variations in solid Earth deformation driven by postglacial meltwater loading on the continental shelf and is controlled by the width of the shelf. At the southern end of the peninsula modelling predicts ~1 m of subsidence during the Holocene. The amount of subsidence increases to the north, with the northern end of the peninsula predicted to subside ~12 metres during the Holocene. The effect of this spatially variable subsidence on predicted RSL change is dramatic. Modelling predicts the southern end of the peninsula experienced a pronounced RSL highstand of +2.5 m above present beginning c. 8,000 years BP. With increasing distance to the north the magnitude of the predicted highstand decreases to ~1 m above present, with the onset of highstand conditions postponed until c. 4,000 years BP at the northern tip of the peninsula.

SL index points recovered from coastal environments around the peninsula show an overall moderate agreement with the GIA-model predicted spatial patterns in the timing and magnitude of SL changes. Ongoing work seeks to validate GIA model predictions with observational data, and new results obtained over the Southern Hemisphere summer 2018-2019 field season will be presented. New SL index points are being collected from localities around Northland where few or no index points currently exist, including Mangawhai, Pakiri, and Whangarei Harbour. Results from a study of the geomorphic evolution of the Hokianga Harbour will be presented: the Hokianga is hypothesised to have experienced SL rise until c. 4,000 years BP due to hydro-isostatic subsidence. This contrasts with other New Zealand estuaries that have been shown to experience a SL highstand beginning c. 7,000 years BP.

O-0083

Holocene sea-levels and isostatic adjustment along the Mediterranean coasts. Where are we now?

Matteo Vacchi

Dipartimento di Scienze della Terra, Università di Pisa, Pisa, Italy. Geography, University of Exeter, Exeter, United Kingdom

Abstract

Glacial and hydro-isostatic adjustment (GIA) constitutes an important driver of past, present and future sea-level variability. For this reason, a major focus of current sea-level research is the continuous improvement of GIA geophysical models in an attempt to provide more accurate constraints for future sea-level scenarios.

GIA-related deformation in the Mediterranean Sea is mainly controlled by water loading, which has resulted in widespread subsidence throughout much of the basin at an average rate of RSL rise of ~ 1 mm/y over the last 6000 years. However, available GIA models show discrepancy in the estimates of both variability and magnitude of the isostatic signal along the Mediterranean basin.

To solve these issues, comprehensive and quality controlled Relative Sea Level (RSL) databases were recently compiled for a large portion of Mediterranean coastlines. This included the re-evaluation of sea-level indicators from geological and archaeological investigations to produce a new suite of sea-level index points and marine/terrestrial limiting points. These are derived mainly from salt and freshwater marshes or adjacent estuarine sediment, fixed biological indicators, beachrocks and coastal archaeological structures.

I will outline some of the common difficulties and provide potential solutions to analyse sea-level data in such different depositional environments. In particular, I emphasize problems related to the definition of standardized indicative meaning (i.e., the relationship between the indicator and paleo mean sea level) and to the re-evaluation of old radiocarbon samples.

I will further discuss the results of the databases which allowed providing new insights into the anatomy of Holocene RSL changes of the Mediterranean basin. These data are particularly useful in the western portion of the basin that is relatively less affected by tectonic activity and where GIA was the major driver of the sea-level evolution in the mid to late Holocene period.

The isostatic pattern defined from newly assembled databases shows significant disparity with respect to those predicted by present GIA models, notably in the bulk of the basin where sea-level data suggests a general overestimation of the magnitude of the GIA contribution. This has implication in the definition of future scenarios of coastal inundation in the Mediterranean region being the GIA-related vertical motions a key parameter to quantify any possible post-industrial sea-level rise acceleration.

Abstract

One of the best sea-level indicators on rocky coasts in the microtidal environment are bio-constructions formed by the alga *Lithophyllum byssoides*, called *Lithophyllum* rims. Their vertical precision (± 10 cm) comes from the restricted environmental conditions of the alga as their living range is constrained around sea level. The alga thus creates the highest biogenic build-up in the Mediterranean. Consequently, the latest research on relative sea-level change along the eastern Adriatic has been centred on algal rims. Here we present new precise relative sea-level (RSL) reconstruction for the past 1500 yr based on the study of four algal rims on the Istrian peninsula. The chronology is based on 47 radiocarbon dates which were accurately calibrated in order to provide precise relative sea-level curve, to relate sea level changes to periods of climate changes and to try to distinguish land-level changes in the studied area. The RSL reconstruction was quantitatively analysed using an error in-variables integrated Gaussian process (EIV-IGP) model to identify sea-level trends with full consideration of the available uncertainty.

The data from the algal rims enabled the distinction of four phases of relative sea-level (RSL) changes. The rims from the southern Istrian coast show that RSL was almost stable during the Early Middle Ages. After AD 1000, during the Medieval Climate Anomaly (MCA) the RSL rise at a rate of ~ 0.8 mm/y. The following Little Ice Age period, LIA I interval, is again characterised by the relative sea level stability which allows the rims at the southern coast to reach the width of ~ 40 to ~ 80 cm at its highest parts. After AD 1600 on the southern coast the major rim building phase is stopped. On the other side, along the eastern coast of Istria the rim building favourable conditions are achieved only after AD 1400 but the growth is very limited as favourable periods are obviously very short. Between AD ~ 1600 and 1750, during the colder LIA II interval, algal rims do not form. From the second part of the 19th century the RSL rise again.

Following the correction for estimated land-level changes during the MCA the sea level rise at a rate of 0.5 mm/y assumed to be a consequence of the Medieval warmth. This increased RSL rise during the MCA was already previously observed in the Central Adriatic. Furthermore, *L. byssoides* $\delta^{18}\text{O}$ records show that those periods of different sea-level changes are generally consistent with changes in temperature and with periods of rapid climate changes.

Droughts in the Czech Lands based on documentary and instrumental data in the 1501–2017 period

Rudolf Brázdil^{1,2}, Ladislava Řezníčková^{1,2}, Lukáš Dolák^{1,2}, Petr Dobrovolný^{1,2}, Miroslav Trnka^{2,3}, Jiří Mikšovský^{2,4}, Oldřich Kotyza⁵

Abstract

Rich documentary and instrumental sources allow an analysis of droughts and their impacts in the Czech Lands during the 1501–2017 period. Reconstructions of mean monthly temperatures and precipitation totals created for the Czech Lands with use of documentary evidence (narrative sources, daily weather records, financial-economic reports etc.) and long-term instrumental measurements were used to calculate three different seasonal, summer half-year and annual drought indices (SPI, SPEI and Z-index). The resulting time-series reflect interannual-to-multi-decadal drought variability. Regression analysis of external forcings and large-scale climate drivers in drought series indicates the importance of the North Atlantic Oscillation phase and the aggregate effect of anthropogenic forcing (driven largely by increases in CO₂ concentration). Other factors, such as solar irradiation and the Southern Oscillation phase make only minor contributions to drought variability. Based on the calculation of return period for series of drought indices, extreme droughts were determined for seasons and summer half-year as cases when all three indices indicated a return period of ≥ 20 years. The years 1536, 1540, 1590, 1616, 1631, 1727–1728 were indicated as those with the most severe summer half-year droughts in the 16th–18th centuries (pre-instrumental period). Higher temperatures and lower precipitation totals during the extreme droughts resulted in impacts on agriculture (e.g. failure of harvest of grain, vegetables and fruits, dried pastures and meadows), water resources (e.g. lack of water, low water levels or drying of rivers, water-mills out of operation, decline of groundwater levels) or socio-economic patterns (increase in prices of goods, reduction of cattle, lack of flour and bread, forest fires, poverty etc.). (This work was supported by Czech Science Foundation, project no. 15-11805S “Windstorms in the Czech Lands during the past 500 years” and by the Ministry of Education, Youth and Sports of the Czech Republic, project no. Historical and dendrochronological analysis of extreme climate years in Nunatsiavut between 1750-1950

Marie-Michèle Ouellet-Bernier, Anne de Vernal, Daniel Chartier, Étienne Boucher
Université du Québec à Montréal, Montréal, Canada

Abstract

There are several Nunatsiavut historical sources of information, which provide valuable data in an area where instrumental records and proxy record reconstructions are sparse. In the present study, the Moravian archives were used as the main documentary sources. In addition, discursive information gathering textual products such as novels or traveler's journals were taken into consideration as they have the propensity to show extreme weather events that are unpredictable and most often variable in strength, time and place.

Moravian missionaries established several missions along the coast of Nunatsiavut. From 1771 to 1926, their main contact with the outside world was by the Mission ship – usually named the *Harmony* – departing from London in early June, every year. Periodical accounts relating major achievement of the missions, exceptional events and navigation conditions were sent back to London and Herrnhut, the Moravian headquarters in Germany. The mission ship arrival dates, along with descriptive climatic conditions, are used here as indicators of climate variations. For example, in the beginning of the record, 1824 was a joyful year as the ship had never arrived so early and exceptional cold conditions were experimented in 1826-1830 and 1836-1841, during which Moravians mentioned unusual quantities of ice and exceptional summer frosts.

Statistical analyses were performed on the mission ship arrival dates and the tree-ring data, which consisted in maximal wood density, as extracted from a Quebec-Labrador network of tree-ring analysis. Extreme values of both mission ship arrival dates (> 90th percentile) and maximal wood density (< 10th percentile) were identified in the time series. Among others, 1816 – known as the Year Without a Summer – related with the Tambora eruption in Indonesia in 1815 shows a strong correlation in historical and dendrochronological records. 1816 and 1853 were the only years during which the mission ship did not stop in Hopedale due to the dramatic quantity of ice. Dendrochronological analysis also demonstrated that such cold years had longer-term persistent effects on the ecosystem.

Hydroclimatic Variations over the eastern China during the past 1000 years

Zhixin Hao, Jingyun Zheng

Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China

Abstract

Global warming has caused obvious changes in precipitation, especially altered the drought and extreme precipitation spatial patterns. The existing hydroclimate dataset is difficult to analyze the interannual-interdecadal variations of the hydroclimate and related East Asia monsoon activities before 1470. And several important teleconnected patterns at interdecadal time scale and the stability of internal variability in the climate system cannot be detected. Here, we reconstructed a hydroclimatic dataset derived from Chinese historical documents including 9 regions over the eastern China during the past millennium, and then analyze the spatial-temporal hydroclimate variations, extreme events, the teleconnection modes and their differences between the MCA, LIA and PWP. The results showed that Eastern China has significant 2-7a, 15-35a and 60-80a oscillation signals. On 60-80a time scale, the first EOF showed the same pattern in MCA and PWP, both have south-north opposite patterns divided by the Huaihe River; while in LIA, the first and second EOF showed the patterns with south-north pattern but divided by the Yangtze River, and longitude pattern divided by the 112°E. And on 15-35a time scale, more complex patterns are showed in the three periods. We found these patterns could have possible link with ENSO, PDO and PMO.

Combining historical documentary evidence and instrumental data to assess the severity of the 2015-16 drought in northern South Africa

David Nash^{1,2}, Clare Kelso³

¹University of Brighton, Brighton, United Kingdom. ²University of the Witwatersrand, Johannesburg, South Africa.

³University of Johannesburg, Johannesburg, South Africa

Abstract

The rainy season of 2015-16 was a particularly dry one over large areas of the summer rainfall zone of southern Africa, with drought conditions related to El Niño prevailing from October 2015 into early 2016. Rainfall levels were, in places, less than 65% of the 1982-2011 average, with many areas experiencing their driest rainy season of the last 35 years. The densely-populated Gauteng province and adjacent areas of Mpumalanga were severely drought affected, with a number of municipalities requesting disaster management assistance from national government. This drought, and the more recent one impacting the Cape Town area, have raised questions of how unusual such dry periods are in the historical record. In this study, we combine instrumental rainfall data for the area encompassing Gauteng and southern Mpumalanga with documentary evidence from the late-19th century to address this question. With the exception of Joubert Park meteorological station in central Johannesburg, which has precipitation data back to 1889, rainfall series for the study area are restricted to the 20th and 21st centuries. We use statistical techniques to quality control and analyse the available data, and demonstrate that 2015-16 was one of the top 15 driest rainy seasons of the instrumental period, but certainly not the driest. Historical newspapers are used to provide insights into periods of drought prior to the instrumental period. We analyse titles including *The Transvaal Argus and Commercial Gazette*, *Transvaal Advertiser*, *The Standard and Transvaal Mining Chronicle*, *Transvaal Observer*, *Diggers' News and Witwatersrand Advertiser*, *Eastern Star* and *The Star* using standard historical climatology approaches, to reconstruct regional rainfall variability back to the 1876-77 rainy season. Only one severe drought season (1881-82) stands out during this period. We conclude by comparing our results against other rainfall series for the southern African subcontinent, to place our drought series in regional context.

A *ca.* 120 year-long record of variations in transboundary atmospheric pollution in tropical Asia

Qinqin Chen, Chris Gouramanis, David Taylor
National University of Singapore, Singapore, Singapore

Abstract

Atmospheric pollution is a global problem, imposing serious adverse health and economic effects. This is particularly the case in parts of Asia, due to weak pollution controls. Atmospheric pollution in a defined geographical area comprises two components: locally produced, and non-local or transboundary pollution. Many atmospheric pollutants, such as heavy metals, have considerable atmospheric residence time, enabling their long-distance dispersal. Pollutants transported over jurisdictional boundaries can become sources of geo-political tensions, exerting potentially uncompensated, negative externalities on recipient jurisdictions. However, the same pollutants may be locally produced. Distinguishing, quantifying and determining the local and transboundary components over time is essential in linking pollution sources and sinks. A better understanding of source to sink pathways, and of pollution effects in receiving areas, can lead to the development and implementation of an effective regulatory response.

This paper describes a novel approach through which a *ca.* 120 year long (AD 1900-2016) record of transboundary atmospheric pollution is reconstructed for a site in tropical Asia, one of the world's most rapidly changing regions. In particular, the paper applies a combination of National Emission Inventory (NEI) and palaeolimnological data to reconstruct past local and transboundary chromium (Cr) contributions to the densely populated main island of Singapore. Concentrations and fluxes of Cr, a relatively poorly studied pollutant with potentially serious adverse health effects, were established from five radiometrically-dated sediment cores from a reservoir in the central catchment, Singapore. The sediment core data (total received Cr) were compared with NEI-derived Cr emission data (local Cr emission) for Singapore. The transboundary Cr pollution component was then established through mass balance: subtracting local Cr emission from total received Cr.

Results show that from *ca.* 1900 to 1960 CE, levels of Cr pollution increased slowly, but the quantities remained small. From *ca.* 1960 to 1970 CE, levels of Cr pollution accelerated, with local anthropogenic sources predominant due to rapid industrialization after Singapore's independence in 1965 CE. From *ca.* 1970 to 2000 CE, levels of pollution from local sources were gradually reduced, owing to a tightening of local environmental regulations. From *ca.* 2000 CE onwards, transboundary anthropogenic sources appear to have been dominant. This is demonstrated by a peak of total received Cr pollution in the palaeolimnological records, and the insignificant local emissions over the same period according to the NEI analysis.

This is the first research that differentiates and quantifies local and transboundary pollution over such a long time period in tropical Asia. The approach could be applied to other atmospheric pollutants or regions and has the potential to provide a basis for improved environmental governance and regional cooperation.

Abstract

We use historical pressure and wind data from land stations, and ships' logbooks, to reconstruct past variability in the Southern Annular Mode (SAM) with a focus on the inter-war period. The Southern Annular Mode is the major mode of circulation variability in the extratropical Southern Hemisphere, representing changes in the strength and location of the Southern Hemisphere storm tracks. In recent decades the SAM has moved to its positive phase (stronger and more poleward storm tracks) due to stratospheric ozone depletion. Extending the record back in time is important to put these human-induced changes into a longer-term context. Existing instrumental-based SAM reconstructions are based on teleconnections between mid and high latitudes, and contain very little high latitude data prior to the mid-20th century when regular meteorological measurements started at Antarctic stations.

Our reconstructions use newly-rescued pressure data from the project ACRE Antarctica (from both ships' logbooks and land stations), combined with pressure and wind data from ships' logbooks from the ICOADS (International Comprehensive Ocean-Atmosphere Data Set) dataset, to reconstruct past variability in the SAM. These reconstructions, and the rescued observations, will be used to evaluate the Twentieth Century Reanalysis at high southern latitudes, and to evaluate the influence on the quality of the Reanalysis of assimilation of new observations.

Abstract

Long-term, quality assured records underpin our understanding of climate variability and change. Globally, few such records extend to the 18th Century, particularly for precipitation. The England Wales Precipitation (EWP) series is a notable exception that provides a continuous monthly record from 1766. EWP has found widespread use across diverse fields of research including; trend detection, evaluation of climate model simulations, as a proxy for mid-latitude atmospheric circulation, a predictor in long-term European gridded precipitation datasets, the assessment of drought and extremes, tree-ring reconstructions and as a benchmark for other regional series. A key finding from EWP has been the trends towards wetter winters and drier summers. We statistically reconstruct winter and summer EWP using independent, quality-assured temperature, pressure and circulation indices. Using a sleet and snow series for the UK derived by Prof. Gordon Manley and Prof. Elizabeth Shaw to examine reconstructions, we show that precipitation totals for pre-1870 winters are biased low due to gauge under-catch of snowfall and a higher incidence of snowfall during this period. When these factors are accounted for the trend to wetter winters in EWP is no longer evident. For summer, we find that pre-1820 precipitation totals are too high due to decreasing network density and uncertain data at key stations. A significant trend to drier summers is not robustly present in our reconstructions of the EWP series, with significance depending on start/end year and predictors used in model reconstructions. Our findings challenge current assumptions about historic climate variability and change in north-western Europe. It is also likely that the identified biases in EWP have distorted many other long-term European precipitation series.

Abstract

Mineral dust plays an important role in the ocean's carbon cycle through the input of nutrients and metals which potentially fertilise phytoplankton, and by ballasting organic matter from the surface ocean to the sea floor. However, time series and records of open-ocean dust deposition fluxes are sparse. Here, we present a two-year time series of the spatial and temporal evolution of dust-deposition fluxes from a trans-Atlantic array of dust-collecting instruments (surface dust collectors and moored submarine traps) directly below the core of the Saharan dust plume along 12°N. By combining observational data of actually deposited dust with model simulations and satellite observations, we argue that dust deposition in the Atlantic is strongly influenced by summer rains. Using *in-situ* incubation experiments we demonstrate that such wet deposition increases the release of nutrients up to an order-of-magnitude relative to dry deposition. As a result, we hypothesise that rain-amplified bioavailability of these nutrients may well be the key to increased surface-ocean productivity in remote and oligotrophic parts of the oceans and, potentially, continental ecosystems.

Abstract

For the last three decades, more and more attention has been drawn on mineral dust and anthropogenic airborne particles. The long-range atmospheric transport and deposition have become important processes that control and modify the biogeochemical cycles of many elements in the Earth system. In particular, dust plays a key role on the primary productivity in the “High Nutrient Low Chlorophyll” zones, like the Southern Ocean, providing essential elements (e.g., Fe) for the phytoplankton growth and therefore contributing to the global carbon cycle. Aerosol deposition can be found far away from their sources and hence, they are considered to be excellent paleoclimate proxies. In Antarctica, most of the studies dedicated to the dust tracing have mainly been carried out on ice cores extracted from Central East Antarctica and, based on elemental or Sr, Nd and Pb isotopic compositions, X-ray, magnetic properties, or single element analyses. The results of these studies have presented unequivocal evidence demonstrating that during glacial/interglacial periods, the dust trapped in Antarctic ice mainly originates from Southern South America (SSA). However, the aerosol fluxes and sources in Antarctica as a whole and specifically at the coast in the East Antarctica such the case of Dronning Maud Land, are still poorly constrained. Additionally, coastal wind conditions may provide different dust origins as what is observed on the high plateau. Addressing this, we collected atmospheric particles using Sigma 2 passive samplers and active collectors together with sub-surface snow samples. The sampling was performed following a ~250 km transect from the high plateau to the coast at six different sampling sites. Here, we present the preliminary results of the two first field campaigns accomplished during the austral summer of 2017-18 and 2018-19. Samples were analyzed for their physicochemical properties (SEM-EDS, Rare Earth and other trace elements by HR-ICP-MS) in order to define the geochemical signature that characterizes the present-day airborne particles in Dronning Maud Land, East Antarctica. Overall, this study will enhance our knowledge about the geochemical signature variations from the coast to inland plateau of this area and, improve the understanding of dust transport and deposition, atmospheric composition evolution and its close relationship with the southern Ocean and the lower latitude wind circulations.

Abstract

Atmospheric dust production, long-distance transport and subsequent deposition are intricately linked to source conditions, climate and human activities [1]. Holocene dust origins and deposition processes are poorly understood in the Southern Indian Ocean, which limits our understanding of Southern Hemisphere (SH) climate change. An important feature of SH climate is the Southern Westerly Wind Belt (SWW), which influences Southern African, Australian and Southern American aeolian dust trajectories [2].

Here we use elemental and Nd isotope (denoted as ϵNd) proxies in a peat core from Amsterdam Island (AMS) to reconstruct past mineral dust flux, dust provenance, climate change and anthropogenic influence. The peat core covers 6600 years and provides a high-resolution record (0.76 mm yr^{-1}) of dust deposition from the mid to late Holocene. Two mineral dust flux minima occur during 6.2 - 4.9 cal. kyr BP and 3.9 - 2.7 cal. kyr BP, and may correspond to a strengthening/expansion of the SWW at its northern edge [3, 4]. Lower dust deposition on the peatland under higher wind speed can be explained by wetter local conditions (decreasing dust mobility), and removal of distal airborne particles by enhanced turbulent wind and enhanced wet deposition [5]. The ϵNd and REE ratios show that mineral dust deposited at AMS is a mixture of local and distal sources. This highlights the influence of SWW transporting the dust particles. Using a multi-proxy mixing model, ϵNd and REE ratios indicate that the peat received approximately 45% local, 15% Southern African and 50% Southern South American dust. Proportional dust contribution from these three sources were relatively constant for 6600 years, except during the last 120 years. Since 1890 AD, there is a distinct decrease in the local dust input (15%), while the contribution of Southern Africa doubled (32%). The contribution of Southern South America input is relatively constant (53%). Moreover, ϵNd values shift from 0.5 to -9.6 over the last 120 years in parallel with a southward-shifted SWW. This suggests an enhanced dust mobilization in the distal sources due to land use, over-grazing and agriculture, especially in Southern Africa. Recent dust compositions therefore suggest that anthropogenic activities play more and more a key role in the SH dust cycle during the last 120 years.

Abstract

We performed X-ray absorption near edge structure (XANES) measurements at the Fe K-edge on aeolian dust samples extracted from the TALDICE ice core (Talos Dome, peripheral East Antarctica) and sediment samples from the major potential dust sources of the Southern Hemisphere.

We obtained the highest Fe oxidation levels from Australian sources, while South American sources interestingly show a progressive increase in Fe oxidation with decreasing latitude. Antarctic sources from Victoria Land show Fe oxidation levels higher than expected in such a cold polar environment, a feature which has been related to their very high exposure ages.

The Fe oxidation state of insoluble mineral dust particles from TALDICE are investigated for the last climatic cycle, from MIS 2 to the late Holocene (30-2 ka BP). A general trend from more oxidized to less oxidized values can be observed from the Early to the Late Holocene. This can be tentatively interpreted as a progressive change in the relative importance of different dust sources, with Antarctic local sources becoming progressively more important from past to present, but further studies are needed in this respect, in particular about *in situ* processes. During the Last Glacial Maximum, conversely, this trend seems interrupted by the input of dust from Patagonia and Tierra del Fuego.

Although these results and interpretations will be refined in future with additional studies on the TALDICE ice core, this research highlights the great potential of X-ray absorption spectroscopy applied to ice core samples for paloclimate and paleoenvironmental reconstructions.

33 kyr records of continental dust fluxes in Hawaii: paleoclimatic implications

Soo Hyun Kim, Joseph Mason, Stephen Meyers, Oliver Chadwick, Sara Hotchkiss
University of Wisconsin, Madison, USA

Abstract

Quartz in Hawaiian soils is significant evidence for continental dust flux into Hawaii because Hawaiian bedrock is quartz-absent mafic rock. Modern meteorological studies have demonstrated that climate changes linked to Asian dust processes affect dust deposition rates in Hawaii. Paleorecords from marine cores have contributed to detecting Asian dust-climate interactions, amplitudes and timescales beyond those available in modern observations. However, existing paleorecords are concentrated near the equator and mid-latitudes remote from Hawaii. In this study, we present the first paleorecord of continental dust flux (proxy: quartz accumulation rates) from Hawaiian peat sediments over the last 33,000 years. We investigate temporal correlations of the quartz flux data with potential climatic drivers most likely related to emission, transport and deposition pathways from East Asia and Hawaii.

O-0097

Post-Glacial Lacustrine Records of Mineral Dust Deposition in the Uinta Mountains, Utah, USA

Jeffrey Munroe

Middlebury College, Middlebury, USA

Abstract

The Uinta Mountains are a major component of the Rocky Mountain system in northeastern Utah, USA. Previous work has shown that eolian delivery of mineral dust to these mountains has influenced pedogenesis, soil nutrient status, and surface water chemistry. Lacustrine sediments are being used to develop a record of dust deposition in these mountains over the post-glacial period. Radiocarbon-dated sediment cores collected from three subalpine lakes extend from local deglaciation (ca. 13 ka BP) to the late Holocene. Passive dust collectors near each lake constrain the geochemical properties of modern dust. Samples of regolith, retrieved from below surficial soil horizons in hand-dug pits and tree-tip mounds, and bedrock constrain properties of the local material within the watershed. Geochemical analysis of the sediment cores allows the relative contribution of allochthonous dust and autochthonous regolith to the lake to be considered as a time series. XRF and ICP-MS analysis reveal that the abundance of Ca in dust is greater than in local material. Conversely, the abundance of Al is greater in regolith and bedrock than in dust. As a result, the ratio Ca/Al is a useful index for the dust content of the lake sediments. ICP-MS analysis of sediments from one lake was used to develop a preliminary record of Ca/Al over time. The 2-cm spacing of the samples corresponds to an interval of ~100 yrs per sample. In cores from two other lakes, XRF scanning was employed to develop a high resolution (2 mm, ~10 to 15 yrs per sample) Ca/Al record. All three lakes exhibit synchronous high values of Ca/Al between 6 and 5 ka BP, and values in 2 lakes were high again ca. 4 ka BP. A core from near the center of the range was truncated at 2 ka BP during collection, but in two other cores from the extreme west and east ends, values of Ca/Al rose between 2 and 1 ka BP. Synchronous high values of Ca/Al in multiple lakes in different parts of the Uinta Mountains are considered evidence of enhanced dust deposition over this region at these times. On the other hand, an interval of sustained low Ca/Al values between 8.6 and 6.5 ka BP in the easternmost lake is not seen in the others. Values of Ca/Al were also high in this lake ca. 9 ka BP. The significance of these inter-lake variations is not yet clear, however spatial patterns and other geochemical and sedimentological proxies may prove useful in interpreting these differences.

Provenance of Lower Volga loess: Using detrital zircon U-Pb ages to trace source material

Chiara Költringer¹, Thomas Stevens¹, Redzhep Kurbanov^{2,3}

¹Dept. of Earth Science, Uppsala University, Uppsala, Sweden. ²Faculty of Geography, M.V. Lomonosov Moscow State University, Leninskie Gori, MSU, 1, Moscow 119992, Russian Federation. ³Laboratory of Evolutionary Geography, Institute of Geography RAS, Staromonetny, 29, Moscow 119017, Russian Federation

Abstract

Loess contains an excellent terrestrial record of near-source aeolian mineral dust. Understanding past atmospheric circulation and dust dynamics can only be addressed through constraining the sources of this wind-blown dust yet in many regions the precise sources of loess and dust deposits are poorly constrained. Along the Lower Volga River in the Caspian Sea region in Russia, sequences of relatively under studied loess deposits crop out in sections along with Caspian Sea and Volga River sediments. Very little is known about the nature, source, transport and accumulation of these Late Quaternary dust deposits as well as their implications for understanding Caspian Sea and Volga River history. In comparison to the well-studied loess regions in Europe and East Asia the Lower Volga loess, located in the middle of the vast Eurasian loess belt, represents a missing link for developing full understanding of aeolian dust and Eurasian continental atmospheric circulation history. Hence, resolving the source and transport of this Volga loess is crucial for understanding climate and dust evolution in Eurasia.

U-Pb dating of detrital zircons from loess and potential source sediments represents a powerful tool to determine loess provenance and overcomes ambiguities in deciphering multiple sources from bulk sample geochemical data. Here we present high n zircon U-Pb age datasets from Lower Volga loess as well as from samples of possible source regions, obtained via multi collector laser ablation ICPMS.

Considering likely paleoclimate conditions, the possibility of multi-step fluvial transport and not least the amount of material an area would need to be able to supply when acting as source region, the following areas are considered as potential sources of Lower Volga loess: The floodplains of the Volga River and Don River, sands of the Caspian Sea, desert sediments from Central Asia, eroded bedrock material from the Caucasian and Crimea and moraine/loessic material from the East European/Russian plain.

The first results show that the zircon U-Pb age spectra of Volga loess are very similar at different stratigraphic levels, and show close similarities to Volga River sediments, strongly suggesting a close relationship between river and aeolian sediment material origin. The possibility of the Caucasus being a major source area to Volga loess is excluded based on this data. We will discuss these and further results from other potential source regions, as well as the implications for aeolian dust transport in the region.

Abstract

Paleoecological data have revealed that Mediterranean island landscapes are the result of complex long-term climatic and socio-environmental interactions (Beffa et al. 2015, Burjachs et al. 2017, Servera-Vives et al. 2018, Tinner et al. 2009, 2016). The Mediterranean islands have all their characteristic early Holocene ecological footprints. So does Sardinia, where treelike *Erica* species (*E. scoparia* and *E. arborea*) played a key role before 5000 cal. BP, whereas on other Mediterranean Island e.g. in Sicily or on Minorca, *Pistacia* or *Buxus* together with *Juniperus* were dominant (Beffa et al. 2015, Burjachs et al. 2017, Tinner et al. 2016). Here, using a multiproxy approach, three coastal lake sites on Sardinia (Sta Cucurica, Lago di Baratz, Chia) covering the past 8000 years are used to study the vegetation dynamics considering climate, land use, erosion, salinity and fire. A dynamic modelling approach helps to answer the question about the dominance of *Erica* species before 5000 cal. BP and to test the hypothesis that the today's dominance of evergreen oaks (*Quercus ilex*-type) is a consequence of intensive landuse and/or moisture seasonality changes.

Ecological legacies of the Amazonian rubber boom

Crystal McMichael¹, Kenneth Feeley², Rick de Regt¹, William Gosling¹, Mark Bush³

¹University of Amsterdam, Amsterdam, Netherlands. ²University of Miami, Miami, USA. ³Florida Institute of Technology, Melbourne, USA

Abstract

Recent evidence suggests that pre-Columbian people living in Amazonia left a legacy on the vegetation that persists in today's forests. The post-Columbian era, including the time of European colonization and the Amazonian rubber boom (c. A.D. 1850-1920), has largely been omitted from the discussion of legacy effects from past human disturbances. Historical documents illustrating the locations of the early Amazonian settlers have yet to be digitized or quantified. Here, we examine the spatial distribution of early European colonists and the subsequent rubber boom period in Amazonian forests using a novel method that combines early collection records with species distribution modeling techniques.

We find that the distribution of people living in Amazonia after European colonization is similar to the pre-Columbian era. The locations of forest inventory and recensus plots, which are used to measure Amazonian biodiversity and carbon dynamics, are disproportionately located in areas that were likely disturbed during the post-Columbian era compared with random site selection. The probabilities of past disturbances at forest inventory plots increased by 29% between the pre-Columbian and post-Columbian era. By the population collapse at the end of the rubber boom, 20% of the forest inventory plots had likely been through at least two major disturbance and recovery periods due to past human activities, and 13% had likely experienced three major disturbance and recovery periods. The recurrent occupation or use of forest locations through time is positively related to accessibility via rivers. Our results suggest that Amazonian ecology is seen through the lens of a shifted baseline. Uncritical acceptance of forests as being mature, when they are actually early- to mid-successional, exaggerates the potential for the overestimation of the Amazonian carbon sink and has ramifications for global carbon budgets.

¹University of California - Merced, Merced, USA. ²University of Maryland Center for Environmental Science, Frostburg, USA. ³University of Wisconsin - Madison, Madison, USA. ⁴Orma J. Smith Museum of Natural History, College of Idaho, Caldwell, USA. ⁵University of Cordoba, Cordoba, Spain

Abstract

Climate influences the structure of both mammal and plant assemblages across space and time, seen most clearly in the emergence of no-analog mammal and plant assemblages coincident with no-analog climates at the end of the Pleistocene. Prior work has examined separately the influence of climate on mammals and plants, with little consideration of how these two taxonomic groups are integrated with and co-dependent on one another -- for habitat, dispersal, resources, and other important interactions. Including both assemblages within ecological models may be necessary to capture a fuller set of processes influencing spatiotemporal changes in species distributions and community structure. In this study, focused on assemblages occurring in eastern North America over the last 21,000 years, we used datasets of fossil faunal and pollen data from the Neotoma Paleoecology Database and generalized dissimilarity modeling to examine whether including cross-trophic associations, in addition to climate, as predictors in community-level models improved the explained amount of assemblage variation across space and time. We found that including mammal richness in models of spatial pollen assemblages influenced the amount of variation explained to only a small extent, and that mammalian assemblage turnover was not well explained by climate, with or without the addition of fossil pollen data. We further explore the magnitude of cross-trophic associations and determine which components of the mammal or plant assemblages most strongly influenced variation in community structure, as well as explore how modifications of the fossil mammal data may improve the ecological models.

Late Quaternary Megafaunal Extinctions in South America: assessing the role of environmental drivers using Species Distribution Models

Natalia Villavicencio^{1,2}, Derek Corcoran^{1,2}, Pablo Marquet^{1,2}

¹Ecology Department, Pontificia Universidad Católica de Chile, Santiago, Chile. ²Institute of Ecology and Biodiversity, Santiago, Chile

Abstract

At the end of the Pleistocene the world lost most of the mammals weighing over 44 kg in what is known as the Late Quaternary Extinction event. In this context South America was one of the most affected places losing an 83% of all megafaunal genera that inhabited the continent during the Pleistocene. As for other regions of the planet, the discussion about the causes behind these extinctions revolves around the role of modern humans arriving into the continent and the one of climate changes proper of the last glacial-interglacial transition.

Analyses of the radiocarbon chronology of megafaunal extinction in South America show extinctions happening earlier in areas more sensitive to climate change (i.e. high latitude and high-altitude areas) and later in the lowlands near the Atlantic coast. In some regions, such as southern Patagonia and the Pampas, the timing of last appearance of some taxa coincides with the timing of major environmental changes, especially changes in vegetation. These observations open the question about how environmental changes could have contributed to drive some of these extinctions in the continent.

To address the role of environmental changes in driving megafaunal extinctions we use Species Distribution Models (SDM) to understand the dynamics of suitable environments for different taxa of megafauna between 21- 8 Ka. The selected taxa are 10 genera of extinct megafauna for which we have a robust record of presences consisting of radiocarbon and stratigraphically dated specimens. For some of these genera it was possible to explore the distribution of individual species as well. Climate conditions for the different time periods analyzed were extracted using the software Paleoview and the SDM generated using MaxEnt.

For those taxa with a distribution in the lowlands of the Atlantic coast (e.g. *Equus neogeus*) our results show broad areas of suitable conditions during most of the glacial maximum between 21-17 Ka. Suitable environments start to contract between 16-8 Ka. A similar situation is observed for taxa distributed in the high Andes. A very different result was obtained for megafauna with a distribution in southern Patagonia (e.g. *Hippidion saldiasi*). For taxa located there, suitable environments between 21-17 Ka were very reduced, becoming broader between 16-10 Ka and reducing again during the early Holocene. Areas of suitable habitat for the different taxa never completely disappear during the time interval analyzed.

The models presented here helps us to tackle the role of environmental changes in the process of megafaunal extinctions, showing how suitable environments probably became reduced during the Pleistocene-Holocene transition increasing the risk of extinction for these taxa at the time.

Abstract

How the first people who entered Sahul (New Guinea, mainland Australia and Tasmania connected during periods of low sea level) and subsequently colonised the entire continent is still poorly understood owing to incomplete sampling and the antiquity of the event (50-60 ka). But quantifying the plausible demographic conditions of this rapidly expanding population is essential to determine how colonisation of Sahul occurred. We developed a stochastic, cellular-lattice model incorporating generationally scaled human population dynamics based on plausible rates of intrinsic growth with compensatory density feedback. We built cell-specific dynamic carrying capacities hindcasted with LOVECLIM global circulation model's net primary productivity for Sahul at 1000-year intervals from 60 ka to the present. The cellular-lattice model includes both nearest-neighbour immigration and emigration conditioned on relative carrying capacity and landscape rugosity, and finite-probability long-distance dispersal. Results show a peopling of the entire continent of Sahul within approximately 400 generations (~ 11,200 years) from initial colonisation, with dominant colonisation pathways southwards initially following the east and west coasts, and then easterly along the southern coast of Australia. Validated using reliably dated archaeological material, our model demonstrates for the first time the most likely pathways the first people of Australia took to colonise Sahul based on the ecological properties of their ancient environment.

Effects of climate and humans on lakes of continental interiors: Applications of the Energy-mass flux framework from seasons to millennia.

Peter Leavitt

Queen's University Belfast, Belfast, United Kingdom. University of Regina, Regina, Canada

Abstract

The Energy-mass (Em) flux framework predicts that climate transmits environmental variability to lakes via influx of energy (E ; irradiance, heat, kinetic energy) and mass (m ; water, solutes, suspended matter) through 11 direct and indirect pathways. This presentation applies the Em flux paradigm to lakes of central North America on time scales ranging from seasonal (spring plankton phenology), through decadal (ecosystem synchrony), to centennial (climate-agricultural interactions) and millennial (continental water sources) using an explicit combination of limnology and paleoecology. At seasonal scales, influx of E as irradiance and atmospheric heat regulated time series development within the lakes, except where unusual mass influxes as (cold) water intervened to reset the sequence. At annual scales, changes in nutrient influx and air temperature regulated overall ecosystem primary production. At longer time scales, the relative effect of climate and humans depended on the relative magnitude of forcing functions. Considered together, the findings confirm that the hierarchical relationships among climatic and human pathways depend mainly on the ratio of influx : ecosystem content of either E or m , rather than intrinsic susceptibility of lakes to specific E or m fluxes. Importantly, anthropogenic activities which mainly increase m fluxes usually overwhelm the unique effects of climate in basins where both human activity and climate change occur. Given that the rate of economic growth (~3% per annum) greatly exceeds that of global warming, the Em flux framework forecasts that anthropogenic factors may regulate lake ecosystem change in proximate future decades, whereas climatic controls may be paramount on longer time scales primarily when there are large state changes in climate systems.

Simulating the Eurasian Mammoth Steppe using a coupled vegetation–megafauna model

Wolfgang Traylor¹, Matthew Forrest¹, Theresa Stratmann^{1,2}, Thomas Hickler^{1,3}

¹Senckenberg Biodiversity and Climate Research Institute, Frankfurt, Germany. ²Department of Biological Sciences at the Goethe University, Frankfurt, Germany. ³Department of Physical Geography at Goethe University, Frankfurt, Germany

Abstract

Between the Last Glacial Maximum (LGM) and the beginning of the Holocene, ecosystems in northern high latitudes changed from graminoid-dominated steppe to taiga and tundra. Concurrently, populations of megafauna species collapsed, among them the three most important large grazers: woolly mammoth, steppe bison, and Pleistocene horse.

Our study focuses on two questions: In what numbers did these large herbivores populate the Pleistocene steppe biome? How did they influence their habitat and shape the ecosystem?

We approach these questions with mechanistic simulations using a new physiological model for the three big grazers. Our herbivore model is directly coupled with a dynamic global vegetation model, and for paleoclimatic driving data we used output of a global circulation model.

We present simulation results from Beringia and northern Eurasia after the LGM.

Multidecadal summer drought variability in Northwest Africa during the last 700 years: evidence for a circum-global oscillation in subtropical precipitation

William Fletcher¹, Kelsey Copes-Gerbitz², Sandy Harrison³

¹University of Manchester, Manchester, United Kingdom. ²University of British Columbia, Vancouver, Canada.

³University of Reading, Reading, United Kingdom

Abstract

Northwest Africa is a key region for exploring the interaction of temperate (Atlantic) and tropical (Saharan) climate systems. The Atlas cedar (*Cedrus atlantica*, CEAT) is a long-lived and climate sensitive tree species facing extinction across its NW African range. A large body of work has explored the climate signal in CEAT tree rings, yielding long drought reconstructions and providing insight into the occurrence of past extreme drought years. These reconstructions have been integrated into multi-proxy reconstructions of the North Atlantic Oscillation (NAO), the dominant mode of Atlantic winter climate variability. To date, however, periodic dynamics in the CEAT records have been little studied and the drivers of low frequency change remain poorly understood. Here we show that the growth signal from the old growth forests of the Middle and High Atlas throughout the last 700 years is characterised by significant multidecadal fluctuations with periodic components of around 95, 60 and 21 yr. For the interval of historical climate data (1900 CE onwards), we do not find climatological support for significant influence of winter precipitation variability, but instead show that this signal reflects summer precipitation variability, associated with either enhanced convective activity at the Atlas-Sahara margin and/or enhanced moisture transport via tropical plumes (tropical-extratropical interactions). Weak explanatory power of NAO forcing at decadal timescales suggests that CEAT drought reconstructions should not be included in multi-proxy reconstruction of the NAO at the risk of confounding summer (tropical) and winter (temperate) climate signals. Multidecadal increases in the CEAT growth signal correspond to increases in proxies for monsoon precipitation over the Indian subcontinent and weakening of the El Niño Southern Oscillation (ENSO) and Interdecadal Pacific Oscillation (IPO). As such, the signal from NW Africa points to a circum-global teleconnected pattern of precipitation variability at subtropical and low temperate latitudes. The wide spatial expression of the multidecadal pattern makes it difficult to distinguish driver and response regions from the climate proxies. Strong coherence, however, with multidecadal variability in ice core ^{10}Be flux points to an external driver of the 60 yr climate oscillation.

When the dam breaks

Shawn Lu¹, Ludvig Löwemark¹, Kweku Yamoah², Yuan-Pin Chang³

¹National Taiwan University, Taipei, Taiwan. ²University of Birmingham, Birmingham, United Kingdom. ³National Sun Yat-sen University, Kaoshiung, Taiwan

Abstract

In many of the cores recovered from the Arctic Ocean during the YMER-80, ARCTIC OCEAN-96, and LOMROG expeditions, a gray layer of unknown origins is observed (eg. Jakobsson et al 2000, Löwemark et al 2008). This gray layer has heterogeneous thickness across the Eurasian Arctic areas spanned by the sediment cores, and is noticeably absent in the Canadian Basin side of the Arctic Ocean. In addition, previous studies on this gray layer show a sharp lower contact, indicating rapid onset of deposition. XRF scanning shows distinct Ti, Fe, Ca, and Mn signatures, which suggests unique provenance compared to adjacent sediments (Mellquist 2009). The Mn minima in particular suggests a redox front formed when the rapidly deposited gray layer created an anoxic environment (Mellquist 2009). Based on this it was hypothesized that the gray layer could be recording the sudden drainage of an ice-dammed lake along West Siberia (eg. Mellquist 2009, Eriksson et al 2012). These lakes form when the ice sheets expand over northern Siberia during the ice ages, blocking and rerouting the river drainages (Mangerud et al 2004), and can catastrophically release their waters when the blockage is compromised (Spielhagen et al 2004). A key test to this hypothesis is whether biomarker signatures also record a sudden change across the gray layer. An abruptly elevated brGDGT in the layer is expected, which could indicate a strong lacustrine input (Zell et al 2014). The catastrophic drainage of ice-dammed lakes can have severe consequences far beyond the Arctic realm. The most familiar example likely is the drainage of Lake Agassiz, which is believed to have triggered the Younger Dryas cold event (eg. Broecker et al 1989, Clark et al 2001). If the gray layer of the Eurasian Basin can be tied to a drainage event, then huge amounts of fresh water must have been injected into the Arctic and North Atlantic oceans, which could alter the thermohaline circulation (THC) significantly (Broecker et al 1989). The exact consequences of this fresh water input on mid- and low latitude climate remains elusive.

Abrupt, global, synchronous megadrought at 4.2 ka BP

Harvey Weiss

Yale University, New Haven, USA

Abstract

More than two hundred glacial, marine, lake, and speleothem cores provide high-resolution proxy data for the ca. 4.2 - 3.9 ka BP megadrought. The proxy data, displayed here with ERA-I Interim moisture vectors, are distributed across seven continents and the Atlantic, Pacific and Indian Oceans, and indicate regionally coherent and synchronous disruption of the westerlies, the Indian Monsoon, the East Asian Monsoon and the diverse monsoon systems of North America, South America and Africa. Decadal global synchronicity is observable with multi-proxy stacks of Greenland, European, west Asian, African, Indus, Chinese and Andean time series.

The megadrought appears in several regions as a cold, windy, three-stage event, two lengthy droughts separated by a brief wet interlude. Megadrought exceptions at 4.2 ka BP, however, are rare: at Mt Logan, Yukon ice core there is an abrupt wet event, while at Agassiz ice core and NoGRIP an abrupt warm spike is observed. Hypothesized proximate causes for the 4.2 ka BP event prominently include southward deflection of the ITCZ, but the subequatorial distribution of proxy records does not support this hypothesis. Despite the global proxy distribution and the robust atmospheric and marine linkages, ultimate explanations for the 4.2 ka BP event have not been identified.

The imprint of Heinrich Stadials and Dansgaard-Oeschger cycles on the latitudinal distribution of methane sources inferred from ice-core gas records

Jon Edwards¹, Edward Brook¹, James Lee^{1,2}, Christo Buizert¹, Benjamin Young¹, Jenna Epifanio¹

¹College of Earth Ocean and Atmospheric Sciences, Oregon State University, Corvallis, USA. ²Los Alamos National Laboratory, Los Alamos, USA

Abstract

Ice core records of atmospheric methane show that on orbital and millennial timescales methane closely follows changes in Greenland temperature, presumably driven by variations in tropical precipitation/hydrology. Over the last glacial period, warm events referred to as Dansgaard-Oeschger events or Greenland Interstadials (GI), noted in Greenland ice core $\delta^{18}\text{O}$ records and other global climate archives, are characterized by a coeval rise in atmospheric methane. At the onset of these events, methane rises by 50-300ppb from cold Greenland Stadial (GS) concentrations. In addition to the GI/GS methane variations, there are distinct, though smaller, increases in methane during Heinrich Stadials (HS) 1, 2, 4 and 5. These Heinrich Stadial features in the methane record are unique as there is no coeval change in Greenland water isotopes.

Using the Inter-Polar Difference (IPD) of atmospheric methane, we investigate these periods and determine how latitudinal source distributions change between GS/IS cycles, to test a hypothesis that the Inter-Tropical Convergence Zone, normally positioned north of the equator, shifted southward during Heinrich Stadials, causing an intensification of monsoons and tropical wetland methanogenesis in the southern hemisphere and drying in the northern hemisphere.

We measured high-resolution records of CH_4 from the GISP2 and WAIS Divide ice cores and calculated the IPD for the periods, GS 10 through GI 8 and GI 13 through GI 11. We also reanalyzed previous IPD measurements covering the LGM and Bølling/Allerød. For the first time, our records incorporate a correction for excess methane production associated with dust in Greenland cores. This correction implies an overall reduction in the IPD relative to previous studies. We furthermore resolve centennial-scale CH_4 variability in both records for the first time, greatly reducing chronological uncertainties.

We show that the tropical to boreal source ratio between GS and GI periods remains relatively constant, indicating a coeval response in both regions during a GS warming event. Heinrich Stadials, by contrast, are characterized by a significant increase in the tropical to boreal source ratio, suggesting a likely shut down the boreal sources and a potential increase in Southern Hemisphere or tropical sources.

Glacial history of the Coats Land region, East Antarctica

Mike Bentley¹, Dom Hodgson^{2,1}, Andy Hein³, Pippa Whitehouse¹, Peter Clarke⁴

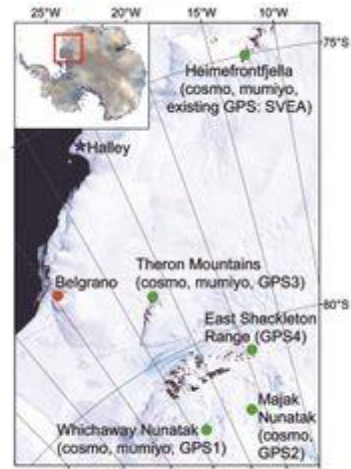

¹Durham University, Durham, United Kingdom. ²British Antarctic Survey, Cambridge, United Kingdom. ³Edinburgh University, Edinburgh, United Kingdom. ⁴Newcastle University, Newcastle, United Kingdom

Abstract

Satellite gravimetry is a widely-used technique of assessing ice sheet mass change. For its application it requires a correction for glacio-isostatic adjustment, which can be of an order of magnitude comparable to that of the 'raw' gravimetric signal. In order to improve these GIA corrections one powerful approach is to reduce uncertainties in the two main inputs: (i) the ice load history and (ii) the understanding of solid Earth structure in the loaded region. For the Antarctic ice sheet the largest differences between modelled GIA corrections occurs in Coats Land, that part of the East Antarctic Ice Sheet that drains into the north-eastern Weddell Sea Embayment (Fig 1). Here we report a multi-disciplinary study to improve our understanding of ice load and Earth structure in this region. We report here on a programme of glacial geology, GPS and seismometer deployment, and modelling; all aimed at improving GIA corrections and thus reducing the uncertainties in ice sheet mass balance in a key region.

We have mapped and sampled the glacial geological record of ice sheet fluctuations on a transect of nunatak sites stretching ~900 km from the Heimefrontfjella (74° 30'S) to the Whichaway nunataks (81° 30'). The glacial geomorphology is a consistent pattern of landforms and glacial deposits, which record a glacial (ice loading) history of the region that we have dated using two independent approaches of cosmogenic Be-10 surface exposure dating and by radiocarbon dating of mumiyo (preserved stratigraphic deposits of proventricular stomach oil from snow petrels, *Pagodroma nivea*). We have deployed GPS receivers in a network to record contemporary surface motion, and at some sites have installed co-located seismometers to provide data for tomographic reconstructions of Earth structure. The glacial history provides constraints for our ice sheet modelling. Once we have preferred data-constrained simulations of ice sheet (load) history then we aim to run GIA models to provide updated GIA corrections for improved satellite gravimetry measurements of this region.

Figure 1: The four left and centre panels show the different predicted uplift rates from four GIA models for the Coats Land region. The differences between models are larger than for any other region of Antarctica. The right hand panel shows the sites we have undertaken glacial geology work and GPS/seismometer deployments.

Constraining Cordilleran Ice Sheet retreat in western Canada using cosmogenic ^{10}Be nuclide exposure dating

Christopher Darvill¹, Brian Menounos², Brent Goehring³, Marc Caffee⁴

¹The University of Manchester, Manchester, United Kingdom. ²University of Northern British Columbia, Prince George, Canada. ³Tulane University, New Orleans, USA. ⁴Purdue University, West Lafayette, USA

Abstract

Reconstructions of Cordilleran Ice Sheet retreat add to our understanding of ice sheet demise, sea level change and the peopling of the Americas. Recent work shows deglaciation along the west coast of North America was complex, with diachronous retreat of different ice margins, and there remain important chronological gaps along this coastline. Our own work reveals that ice retreat occurred by 18.1 ka, exposing low-lying islands by 17.7 ka, with significant implications for a coastal human migration route. However, the extent to which this pattern of ice retreat was indicative of the whole western margin remains unclear. Here, we present new data from Pitt Island (53.7°N, 130.1°W), Porcher Island (54.0°N, 130.6°W), Banks Island (53.3°N, 129.9°W) and Aristazabal Island (52.7°N, 129.2°W) on the west coast of British Columbia, Canada. Fifteen new terrestrial cosmogenic ^{10}Be nuclide exposure ages from erratic boulders constrain lateral retreat and ice sheet thinning during deglaciation within this region. Importantly, our new data fill the gap between recent chronological campaigns around Calvert Island to the south (Darvill *et al.*, 2018) and Suemez Island to the north (Lesnek *et al.*, 2018). Radiocarbon dating of sediments from the island of Haida Gwaii to the west (Mathews & Clague, 2017) demonstrates ice advanced at 30.0 ka and retreated by 19.4 ka; our new ages complete the history of this sector of the Cordilleran Ice Sheet margin. With chronologies published in the last two years and our new exposure data, we present the most detailed reconstruction of western Cordilleran Ice Sheet retreat to date.

Abstract

Changes in late Holocene ice-cap dimensions around the North Atlantic Arctic are dominantly set by changes in summer temperature allowing us to compare time of ice expansion with modeled summer temperatures. We reconstruct times of ice cap expansion for the Eastern Canadian Arctic, Svalbard, and a portion of West Greenland using the radiocarbon ages of entombed tundra plants exposed as the cryosphere recedes under warming summers. Plant ages define when the cryosphere expanded, killing plants and preserving them for centuries to millennia. In most cases ice remained continuously over each site until the modern warming. Compositing the individual probability density functions of the calibrated ages defines periods of sustained summertime cooling in each region. Our summaries are based on 232 ¹⁴C dates from the Eastern Canadian Arctic, 20 ¹⁴C dates from West Greenland, and 37 ¹⁴C dates from Svalbard, all <2 ka. We use changes in varve thickness from a high-resolution lake sediment core to track changes in the dimensions of Langjökull, second largest ice cap in Iceland. Almost all regions show an expanding cryosphere between 100 and 500 CE, a lack of expansion between 500 and 700 CE, followed by all regions recording cryosphere expansion between 700 and 950 CE. During Medieval times (1000-1250 CE) there is little or no evidence of an expanding cryosphere except for a few sites on Svalbard, but summer temperatures were not warm enough in any region to cause ice recession behind first millennium expansions. All four regions record renewed cryosphere expansion late in the 13th Century CE through the mid 15th Century CE, with the greatest ice extent occurring between 1450 and 1900 CE. We compare these results with a new 2 ka fully coupled climate transient using CESM1, with forcing data from PMIP4, including insolation, volcanic aerosols, land-cover, and GHG. The CESM results show a ~0.5°C reduction in summer temperature between 100 and 500 CE, consistent with widespread cryosphere expansion then. A second phase of persistent summer cooling in the model occurs between 800 and 950 CE, followed by slightly warmer summers between 950 and 1150 CE, although not as warm as early in the first millennium CE. Summers cool again in the model after 1150 CE, with stronger cooling after 1450 CE, reaching a minimum shortly after 1850 CE, ~1°C lower than at the start of the experiment. Orbital driven declines in summer insolation appears to be the dominant forcing early in the first millennium CE, with volcanism and solar irradiance reductions increasingly important in the second millennium CE, but positive feedbacks from sea ice and the overturning circulation are necessary to explain the magnitude of peak LIA cooling.

Saltmarsh records of post Little Ice Age mass balance changes in Greenland

Sarah Woodroffe¹, Leanne Wake², Natasha Barlow³, Kristian Kjeldsen⁴, Louise Best⁵, Juliet Sefton¹

³University of Leeds, Leeds, United Kingdom. ⁴GEUS, Copenhagen, Denmark. ⁵University of Gloucestershire, Cheltenham, United Kingdom

Abstract

Saltmarshes provide excellent archives of relative sea-level (RSL) changes over a range of different timescales. In Greenland they yield precise RSL data over the past few decades to hundreds of years that can help constrain Greenland Ice Sheet mass changes during and after the Little Ice Age (LIA). They are particularly valuable as they provide a longer term context upon which to evaluate recent tide gauge and GPS records which span only the past decade or so. In Southeast Greenland the current rate of crustal uplift recorded by GPS is approximately +7 mm/yr at the open coast and up to +18 mm/yr close to the ice sheet margin. At Ilulissat Isfjord on the west coast uplift rates are similarly 7.9 mm/yr at the open coast and 18.8 mm/yr at the head of the isfjord. These rapid crustal uplift rates reflect high rates of recent mass loss in west and southeast Greenland.

This study investigates fossil saltmarshes located within 5 km of the ice sheet margin at the head of Skjoldungen fjord in southeast Greenland, and just south of Ilulissat isfjord in west Greenland. The aim in both locations is to use RSL data to establish the timing and magnitude of mass loss since the end of the LIA. This is the first time that saltmarshes so close to the ice sheet margin, and close to the globally important Jakobshavn Isbrae ice stream have been utilised to create high precision proxy-GPS data for the last few hundred years.

Microfossil (diatom) evidence from saltmarsh sediments at the southeast site record a recent change from RSL rise to stable RSL, then RSL fall during the past 200 years. We interpret the change from RSL rise to stable RSL as evidence for the initial onset of mass loss locally from the Greenland Ice Sheet at the end of the Little Ice Age. Later RSL fall occurs as mass loss accelerates during the 20th Century. A similar pattern is seen in the west but with RSL rise interrupted by RSL fall caused by post-LIA mass loss, and changes in the rate of RSL change coincide with fluctuations in the frontal position of Jakobshavn Isbrae over the last few hundred years.

This study provides the first direct evidence that saltmarsh sediments from near-field sites can be used to reconstruct the timing of recent mass loss change from ice streams and other marginal areas of the Greenland Ice Sheet, extending direct GPS observations back to the end of the Little Ice Age and beyond using geological data.

Formal subdivision of the Quaternary System: a review and ongoing initiatives

Martin Head

Brock University, St. Catharines, Canada

Abstract

The Quaternary System was officially defined in 2009 following a struggle spanning two executive committees of the International Commission on Stratigraphy (ICS). The global boundary stratotype section and point (GSSP) for the Gelasian Stage, dated at 2.58 Ma, serves as its base. The Vrica GSSP, 1.80 Ma, which had earlier defined the base of the Pleistocene Series, was repurposed in 2011 to define the Calabrian Stage, effectively completing the Lower Pleistocene Subseries. A 10-year moratorium, stabilizing a now firmly rooted definition, lifts in 2019. The candidate for the Middle Pleistocene GSSP, dated at ~773 ka, is the Chiba section in Japan, having been selected by the Early–Middle Pleistocene boundary working group in 2017, and approved by the Subcommittee on Quaternary Stratigraphy (SQS) in 2018. The Chiba proposal (Chibanian Stage, Middle Pleistocene Subseries) will be submitted to ICS for approval in 2019. The Upper Pleistocene Subseries, with a base traditionally aligned with the onset of the last interglacial, is not yet defined by GSSP and a priority for the SQS. The Holocene Series was formally defined in 2008 using, for the first time, an ice core for the GSSP. In 2018, the Holocene was subdivided into the Greenlandian, Northgrippian and Meghalayan stages/ages and their corresponding Lower/Early, Middle, Upper/Late subseries/subepochs. The GSSP for the Greenlandian is that of the Holocene as previously defined in the NGRIP2 Greenland ice core, and dated at 11,700 yr b2k (before 2000 CE). The Northgrippian GSSP is located in the NGRIP1 Greenland ice core, and dated at 8236 yr b2k; that for the Meghalayan is in a speleothem from Mawmluh Cave, Meghalaya, northeast India with a date of 4250 yr b2k. This subdivision formally introduces the rank of subseries to the geological time scale, and incorporates by far the briefest of all stages. Defining a GSSP in a speleothem is another innovation, and this GSSP is appropriately displayed at the Birbal Sahni Institute of Palaeosciences, Lucknow, India. The Anthropocene is presently undefined, but the SQS Anthropocene Working Group is actively supporting research on prospective candidate sections. The rationale for formalization is compelling. The term is already used extensively in the scientific literature and, like Holocene subdivisional terms, its functionality will be enhanced by formal definition. To correct a misconception, the Anthropocene is not strictly anthropogenic: it reflects the Earth-system response to progressive human impacts, not the impacts themselves. As a concept, the Anthropocene is Earth-centric, not human-centric. The formal Anthropocene, as currently envisioned, would start in the early 1950s. It would hold the rank of series, terminating the Holocene but not interfering with its subdivision other than to terminate the Meghalayan Stage at a time when the Holocene is already evenly subdivided.

Abstract

The Chiba composite section is a continuous and expanded marine sedimentary succession situated near the Pacific coast of the central Japanese archipelago. It contains well-preserved pollen, marine micro- and macrofossils, a tightly-defined Matuyama–Brunhes (M–B) paleomagnetic polarity boundary, and numerous tephra beds, allowing the establishment of a robust and precise chronostratigraphic framework across the Lower–Middle Pleistocene boundary. Its shallow-marine, open-ocean continental slope setting, coupled with sedimentation rates of 89 cm/kyr at the boundary with no evidence of abrupt deposition, has resulted in the capture of both terrestrial and marine environmental changes in and around Marine Isotope Stage 19 (MIS 19). We have performed ultra-high-resolution oxygen isotope analysis, as well as detailed sedimentological, geochemical, and biostratigraphic studies of the Chiba composite section, confirming the completeness of the stratigraphic interval spanning the Lower–Middle Pleistocene boundary. The M–B reversal serves as the agreed primary guide for the Lower–Middle Pleistocene boundary, and the Chiba composite section represents one of the most detailed marine sedimentary records yet obtained for this reversal, yielding an astronomical age of 772.9 ka with a duration of ca. 1.9 kyr. This section therefore offers an exceptional opportunity to calibrate the geological time scale as well as understand the dynamics of the geodynamo. The widespread Byk-E tephra bed lies close to the reversal, allowing precise regional lithostratigraphic correlation. The Chiba composite section is easy to access by public transport or car from international airports nearby. The section will be permanently preserved and maintained by the local government as a natural monument. Therefore, we propose the extensively studied Chiba section of the Chiba composite section as the Global Boundary Stratotype Section and Point (GSSP) to define the base of the Middle Pleistocene Subseries and Chibanian Stage.

Basal age for the Salawusuan Stage of the Upper Pleistocene Subseries in Chinese Quaternary chronostratigraphy

Liping Zhou¹, Fengyue Qiu^{1,2}, Yuetian Li¹, Jintang Qin^{1,3}

¹Key Laboratory for Earth Surface Processes, Department of Geography, Peking University, Beijing, China. ²State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, China. ³State Key Laboratory of Earthquake Dynamics, Institute of Geology, China Earthquake Administration, Beijing, China

Abstract

The precise basal age of the Upper Pleistocene for the global Quaternary stratigraphy is important but has not yet been agreed. Here we report a dating study in the region where the stratotype section for the Salawusuan Stage which represents the Upper Pleistocene of the terrestrial Chinese Quaternary is located. We focus on the basal age of the lithostratigraphic unit of the Salawusu Formation. The stratigraphy in the region has been intensively studied since the seminal work by Pierre Teilhard de Chardin and Emile Licent nearly 100 years ago. The Salawusu (Sjara-Osso-Gol) Formation was proposed to describe a stratigraphic unit characterised by alternating fluvial/lacustrine sediments which are interbedded with aeolian sand. The age of this Formation has been determined by various methods. In this study, we date selected sand units using luminescence method. Both coarse-grained quartz and K-feldspar extracts were used and the single aliquot regenerative dose (SAR) optically stimulated luminescence (OSL) and the elevated temperature post-infrared infrared stimulated luminescence (post-IR IRSL) protocols were applied. Three sets of luminescence age estimates, based on quartz SAR, K-feldspar IRSL at 200°C and post-IR IRSL at 290°C protocols respectively, are markedly different from previously obtained age estimates. The base of the Salawusu Formation previously dated to ~130 -150 ka is shown to vary from ~80 ka to > 450 ka. Such great disparity for the base of the Salawusu Formation, hence the basal age for the Salawusuan Stage points to the complication in the regional stratigraphy apparently affected by the landscape evolution in the valley of the Salawusan River. Both require systematic investigation.

Prevalent known and cryptic extinctions in the Pleistocene have conservation lessons for the next century

Jacquelyn Gill¹, Dov Sax²

¹University of Maine, Orono, USA. ²Brown University, Providence, USA

Abstract

The growing field of conservation paleobiology provides a perspective on the range of species responses to global change beyond the limited scale of human observation. Given the challenges posed by future warming, ecologists are increasingly turning to natural experiments of the recent fossil record to characterize the risks to modern biodiversity. The Quaternary fossil record documents widespread shifts in species' ranges and abundances in response to glacial-interglacial cycles, but aside from the late Quaternary extinctions of large mammals, it is typically thought that climate-driven extinction was rare. This has resulted in the emerging paradigm that species may be more resilient than expected in the face of climate change. In contrast, our re-examination of the Quaternary fossil record indicates that the synergistic effects of climate change (both direct and indirect) and other landscape drivers put many species at greater risk than is currently appreciated. This is true both with respect to known, documented extinctions, but also to unidentified, or 'cryptic,' extinctions. Documented extinctions are more prevalent than commonly thought due to previous temporal, regional and taxonomic biases in the literature. Further, predominate attention paid to the species losses during the last glacial cycle misses pulses of extinction during the Plio-Pleistocene boundary, and during in the mid-Pleistocene, during which glacial cycles lengthened and intensified. Clade-based approaches tend to integrate taxa from different regions or habitat types, down-playing the mechanisms that drive extinction risk. Cases of rapid speciation within habitats that are ephemeral relative to glacial-interglacial cycles provide a model for "cryptic" extinctions, which were likely common during the Pleistocene but also provide context for processes that could also drive extinction risk today. By linking the mechanisms behind both known and cryptic extinctions, we identify processes by which climate change contributes to past and future extinction risk, providing a new framework for identifying climate-driven threats to biodiversity going forward. We argue that the fossil record has yet to be fully marshaled to document extinction risk associated with climate change or to draw lessons from these extinctions for conservation challenges going forward. Our Quaternary casualty list is likely incomplete, representing an opportunity for conservation paleobiology.

Reconstructing two million years of *Gigantopithecus blacki* fossil teeth geochemical record

Renaud Joannes-Boyau¹, Yingqi Zhang², Wang Wei³, Russell Ciochon⁴, Ian Moffat⁵, Kira Westaway⁶

¹Southern Cross University, Lismore, Australia. ²IVPP, Beijing, China. ³Nanning Anthropological Museum, Nanning, China. ⁴University of Iowa, Iowa city, USA. ⁵Flinders University, Adelaide, Australia. ⁶Macquarie University, Sydney, Australia

Abstract

Gigantopithecus blacki (Giganto) was the largest ape ever recovered from the fossil record. So far only known by a few hundred teeth and three mandibles. Giganto was an important species part of the Asian megafauna, along with other large mammals that appear about two million years ago to disappear (for most species) in the late Pleistocene. While the timing and circumstances of the disappearance of Giganto remain abstruse, it has been hypothesised that modification of the environment around 350ka might have led to a deterioration of the species ecological niche. The large body mass animal would have been particularly prone to depleted food source and shrinking habitat. Our current effort to establish a comprehensive chronology of the extinction window for *Gigantopithecus blacki* is providing also key understanding on the palaeoenvironment changes at the time. Yet, in order to comprehend better what may have happen to the only apes that went extinct in the Quaternary, our project is combining an accurate timing for the species with a meticulous study of the early life history of several specimen. By studying Giganto's fossil teeth from 2 million years ago all the way to the extinction window, we are able to investigate the evolution of key adaptive strategies of the animal.

In this talk, we will show the evolution of important adaptive traits of the species, such as a potential change of diet, change of habitat, migration pattern, seasonal dietary adaptation, stress related markers and potential breastfeeding change of pattern of the Quaternary period. By combining the chronology, palaeoenvironmental record and the geochemical mapping of the teeth, our research will shed light on the potential reason for the demise of *Gigantopithecus blacki* in southern China.

Abstract

Absolute dating of formerly analysed mammal faunas from two cave localities in Hungary (Jankovich Cave, Rejteck Rock Shelter) combined with AMS ¹⁴C dating of the Hungarian Natural History Museum's Late Quaternary mammoth bone collection allowed us to determine the approximate extinction time of several rodent and large mammal species in the Carpathian Basin. These extinctions occurred in the Late Pleniglacial and Late Glacial period (c. 26 500 - 11 600 cal yr BP). In this presentation we compare the faunal changes with pollen, plant macrofossil and coprophilous fungi records from 5 localities in the Carpathian Region (Kokad, Nagymohos, Lake St Anne, Lake Brazi, Kardoskút Fehér Lake). Biome and quantitative climate reconstructions are used to compare the timing of the faunal changes in connection with the ongoing vegetation reorganization of the Carpathian Region. Our results suggest that the population size of large herbivores decreased in the Great Hungarian Plain (GHP) considerably after 17 700 cal yr BP, when *Artemisia* steppes and steppe tundra vegetation declined, while boreal forest tree abundance increased rapidly in the lowlands. The same boreal forest expansion was delayed, and took place around 16 200 cal yr BP in the surrounding low Carpathian mountain zone. Our results suggest that the vegetation responded quickly to the initial warming after the LGM. T_{JJA} reached 14-15 °C already at 19 000 cal yr BP. Cave sediments from central Hungary show the decline of *Microtus gregalis* and *Dicrostonyx torquatus* populations at 16 200 cal yr BP and the expansion of *Microtus arvalis*. The Heinrich-1 cooling was discernible both in the pollen and mammal records: *Juniperus communis* expansion, boreal forest retreat and resurging dominance of *Dicrostonyx torquatus* characterised this period between c. 16 200 - 16 800 cal yr BP, while the pollen based T_{JJA} reconstruction suggested ~1.5 °C summer cooling. The Late Glacial showed the expansion of deciduous forest trees (*Corylus*, *Tilia*, *Ulmus*, *Quercus*) in the GHP and minimal vegetation response to the YD cooling in the lowlands.

Absolute dating suggests that *D. torquatus* disappeared from the Carpathian Basin at ~ 16 640 cal yr BP, *Mammuthus primigenius* at ~ 16 125 cal yr BP, *Rangifer tarandus* at ~15 195 cal yr BP and *Microtus gregalis* at ~13 340 cal yr BP, while *Ochotona pusilla* survived into the Early Holocene, but likely disappeared around 11 000 cal yr BP.

These data overall suggest that the collapse of the large herbivore fauna slightly preceded the terrestrial vegetation change and thus likely facilitated it via restricted grazing and the accumulation of plant biomass.

Ecological flexibility of the Pleistocene Sumatran serow and the possible cause of local extinction of the Himalayan goral in Thailand

Kantapon Suraprasit^{1,2}, Rasmi Shoocongdej^{3,4}, Yuichi I. Naito^{5,2}, Jean-Jacques Jaeger⁶, Yaowalak Chaimanee⁶, Athiwat Wattanapituksakul⁴, Hervé Bocherens^{2,7}

¹Department of Geology, Faculty of Science, Chulalongkorn University, Bangkok, Thailand. ²Department of Geosciences, Biogeology, University of Tübingen, Tübingen, Germany. ³Department of Archaeology, Faculty of Archaeology, Silpakorn University, Bangkok, Thailand. ⁴The Prehistoric Population and Cultural Dynamics in Highland Pang Mapha Project, Princess Maha Chakri Sirindhorn Anthropology Centre, Bangkok, Thailand. ⁵Nagoya University Museum, Nagoya, Japan. ⁶PALEVOPRIM, UMR CNRS 7262 INEE, Université de Poitiers, Poitiers, France. ⁷Senckenberg Research Centre for Human Evolution and Paleoenvironment, University of Tübingen, Tübingen, Germany

Abstract

Two taxa within the subfamily Caprinae: Sumatran serow (*Capricornis sumatraensis*) and Chinese goral (*Naemorhedus griseus*) are common today in the mountainous areas and forests of Southeast Asia. The co-occurrence of these two species, in addition with a locally extinct Himalayan goral (*N. goral*) that is restricted to the Indian subcontinent and China today, is documented from several Pleistocene fossil sites in Thailand. In some Pleistocene Southeast Asian sites, previous studies on the carbon isotope composition have shown differences in dietary signatures, either pure C₃ or C₄ plants, for the species of *C. sumatraensis*, leading to the question of whether it was a grazer or browser. Moreover, diet and habitat preferences of both species of *Naemorhedus* (*N. griseus* and *N. goral*) have never been isotopically investigated. Here we reconstructed the diets and habitats of these three Pleistocene sympatric taxa through the isotopic analysis of carbonate in tooth enamel in order to identify the exact habitat of *C. sumatraensis* and to test the species co-occurrence patterns. For a long-term history perspective, we analyzed caprine fossils from four sites in Thailand, ranging from a Middle Pleistocene (Pha Bong, undated fauna), Khok Sung (≈200 ka, MIS7), and Thum Wiman Nakin (>169 ka, MIS6) to latest Pleistocene age (Tham Lod Rockshelter, 32 to 12 ka, MIS2), as well as some Holocene specimens. Our carbon isotope analysis reveals different ecological patterns between *Capricornis* and *Naemorhedus*. During the Pleistocene glacial-interglacial cycles and the Holocene, *C. sumatraensis* had a wide range of diets and habitats varying from pure C₃ to C₄ vegetation, while both *Naemorhedus* species from all Thai fossil sites fed on pure C₄ plants or a mixture of both types and shared chiefly an open landscape habitat. The isotopic results suggest that *C. sumatraensis* has been a greater ecological generalist than *Naemorhedus*, in both diet and habitat. The Sumatran serow *C. sumatraensis* was more ecologically flexible in diet and habitat during the Pleistocene, compared to its recent population, reflecting that the modern wildlife habitat is likely constrained due to the human impact on the Thai ecosystems. In addition to the human hunting and besides the interspecific competition, the loss or reduction of grasslands after the latest Pleistocene, when rainforests became dominant, certainly contributed to an extirpation of *N. goral* in Thailand.

O-0124

Holocene history of 'non-native' tree taxa in Ireland

Susann Stolze^{1,2}, Thomas Monecke¹

¹Colorado School of Mines, Golden, USA. ²Institute of Arctic and Alpine Research, University of Colorado Boulder, Boulder, USA

Abstract

The occasional occurrence of pollen of *Abies*, *Acer*, *Carpinus*, *Fagus*, *Juglans*, *Picea*, and *Tilia* in Holocene deposits from Ireland has largely been attributed to sample contamination, reworking of older pollen, or long-distance transport. Therefore, these tree taxa are generally considered as 'non-native' to Ireland. To test this assumption, we examined more than 500 Holocene pollen records from across Ireland for the occurrence of 'non-native' tree pollen types. The palynological evidence was summarized in a database, using G.F. Mitchell's Irish pollen zones for biostratigraphic assignment. The Holocene presence of 'non-native' tree pollen types was recorded in over 38% of Irish pollen archives. *Carpinus* and *Tilia* pollen were documented since the Boreal period. Pollen of *Acer* and *Fagus* were first recorded in the Irish Neolithic, whereas *Juglans* pollen has occurred since later prehistoric times. Both *Abies* and *Picea* pollen occur since the Afforestation period. The palynological evidence presented here implies that the presence of individual 'non-native' tree pollen in Holocene records from Ireland cannot be simply explained by contamination, reworking, or long-distance transport. Although the 'non-native' tree pollen do not show closed pollen curves or high pollen abundances prior to the Afforestation period, the large number of pollen archives from across the island suggests that 'non-native' trees formed part of the Holocene vegetation. Based on these results, a revision of the phytogeographic status of the 'non-native' tree taxa in Ireland is proposed. *Carpinus* and *Tilia* are considered as being native, while *Acer*, *Fagus*, and *Juglans* represent archaeophytes. *Abies* and *Picea* are neophytes.

Spatiotemporal trends in subfossil chironomid diversity: A robust recorder of climate and environmental change?

Stefan Engels¹, Andrew Medeiros², Yarrow Axford³, Stephen Brooks⁴, Oliver Heiri⁵, Larissa Nazarova⁶, Tomi Luoto⁷, Dave Porinchu⁸, Roberto Quinlan⁹, Angela Self⁴

¹Birkbeck University of London, London, United Kingdom. ²Dalhousie University, Halifax, Canada. ³Northwestern University, Evanston, USA. ⁴Natural History Museum, London, United Kingdom. ⁵University of Basel, Basel, Switzerland. ⁶University of Potsdam, Potsdam, Germany. ⁷University of Helsinki, Helsinki, Finland. ⁸University of Georgia, Athens, USA. ⁹York University, Toronto, Canada

Abstract

Anthropogenic activities have led to a global decline in biodiversity, and monitoring studies indicate that insect communities have been particularly affected. There is a need for long-term (centennial or millennial scale) data to better understand natural dynamics and the processes that govern the observed trends in insect diversity. Chironomids (Insecta:Diptera:Chironomidae) are among the most abundant insects in lake ecosystems, are sensitive to environmental change, and as parts of their larval exoskeleton preserve well in lake sediment records, they provide a unique resource of centennial to millennial-scale information on insect population dynamics. Here, we analyse spatial and temporal trends in chironomid diversity, exploring the applicability of both taxonomic and functional diversity.

Our results show that July temperature (Tjul) is the environmental factor that is most strongly correlated to spatial trends in modern-day taxonomic diversity in regional datasets from Canada, Finland, Norway, Russia and Switzerland. We observe a strong increase in subfossil chironomid alpha diversity with increasing Tjul between 2.5-14°C, whereas in areas with Tjul >14°C alpha diversity stabilises or even declines, potentially due to human-related factors such as lake eutrophication.

A compilation of subfossil chironomid diversity records that span the last glacial-interglacial transition (LGIT), the most recent interval characterised by notable climate variability, further illustrates the sensitivity of chironomid faunas to summer temperature. We observe decreasing diversity during millennial-scale to centennial-scale cold intervals in the majority of the LGIT records. A compilation of records that span the current interglacial (Holocene) show that during intervals when the amplitude of temperature change was relatively muted, site-specific factors such as vegetation and soil development have a more pronounced influence on chironomid fauna, obscuring the chironomid diversity-temperature relationship.

These results illustrate the effects of regional climate change and local natural factors and anthropogenic activities on subfossil chironomid taxonomic diversity in both space and time. However, they do not enable determination of whether the impact of climate variability on chironomid community composition is limited to changes in number of extant species, or if there were fundamental changes to community composition, e.g. through changes in the food web. Analysis of diversity trends within functional classes related to feeding- or habitat-preference shows no class-specific relationship to temperature in the Norwegian training set, and we gained little additional information on past ecosystem dynamics when analysing functional diversity trends in a subset of our LGIT records. To move forward with analysing functional diversity using subfossil chironomids, we need to: (a) increase the count sums of our samples; (b) better link our subfossil taxonomy to the Linnaean taxonomy; and (c) produce more data on modern-day chironomid ecology.

O-0126

Greater tree species richness in eastern North America compared to Europe is does not translate to functional trait space differences

Alejandro Ordonez, Jens-Christian Svanning
Aarhus University , Aarhus, Denmark

Abstract

Our aim in this study was to determine if differences in species richness between currently climatically similar regions correlate to dissimilarities in functional diversity. Using classic functional traits defining distinct ecological strategies, we described the trait spaces of European and eastern North American tree floras. The trait space of each region was described based on the occupied area, species accumulation pattern, and the trait-space size, dispersion, and clustering. We then evaluated if the species richness differences between these two climatically similar regions correlate to the dissimilarities in occupied areas and species accumulation pattern; as well as differences in the trait-space attributes. Differences in species richness between climatically similar regions do not necessarily result in functional dissimilarities. Regardless of eastern North American having a larger trait-space, occupied areas and species accumulation patterns converged. Although in both regions species clumped towards the trait-space centroid, we observed statistically significant differences between Europe and eastern North America in the dispersion and clustering but not in size the trait space. Positional convergence between European and eastern North American trait spaces suggests that this species richness anomaly does fully translate to the functional space. Our results suggested that species accumulation within a region occurs within a climatically restricted trait space, and not via trait space expansion. Moreover, the consistent aggregation of species towards the trait-space centre aligns with the idea of a directional selection towards a generalised morphology, which might provide the best way to interact with a broad array of environmental conditions.

The Cameron Hills ice streams of southern Northwest Territories, Canada: a closer look

Roger Paulen¹, John Menzies², Emrys Phillips³, Chris Stokes⁴, Rod Smith⁵

¹Geological Survey of Canada, Ottawa, Canada. ²Brock University, St. Catharines, Canada. ³British Geological Survey, Edinburgh, United Kingdom. ⁴Durham University, Durham, United Kingdom. ⁵Geological Survey of Canada, Calgary, Canada

Abstract

The Cameron Hills ice streams in southwestern Northwest Territories and northern Alberta are unique for the western sector of the Laurentide Ice Sheet in that unlike other ice stream corridors in the region, they formed atop an upland instead of within topographic lowlands (e.g., Great Slave Lake and Hay River ice streams). Two distinct, cross-cutting sets of megascale glacial lineations (MSGSL) occur in the Cameron Hills upland; an earlier south-southwest flow largely preserved along the southeastern flank of the upland that was then crosscut by the southwest flow (IS #145 of Margold et al., 2015). Spectacular bedforms commence at the eastern leading edge of the Cameron Hills and many extend >15 km in length, and have impressive length:width ratios of 75:1 or greater. There are conflicting interpretations on the nature and formation of these bedforms in terms of ice bed hardness and their erosional versus depositional nature of the MSGSL formation. Previous interpretations on the Cameron Hills MSGSL were wholly derived from remote sensing data.

A field investigation was conducted in 2018 within a single elongate bedform on the Cameron Hills to determine the strain signature and associated microstructures imparted by the palaeo-ice stream on the laterally extensive till formed at its bed. Micromorphological samples were collected to document the nature of sediment deformation, the spatial variations in the microfabrics, and the ductile shear zones and deformation fronts within the till. Samples were also collected from the Hay River ice stream (IS#176 of Margold et al., 2015), a lowland till plain adjacent to the Cameron Hills near the Alberta-Northwest Territories border, for micromorphological fabric comparison between the upland and lowland ice streams. A detailed micromorphological study of the till sequences beneath the Cameron Hills and Hay River ice streams is used to unravel the complex deformation histories recorded by these glacial sequences, and investigate the potential factors controlling fast ice flow in these contrasting palaeo-ice stream settings.

On a macroscale, the tills formed beneath many palaeo-ice streams are massive, lacking any visible signs of stratification and/or glacial tectonic deformation structures. As a consequence, micromorphology is increasingly being used as a primary tool for the analysis of these subglacial sediments, which provides far greater detail on their depositional and deformation histories recorded by these sediments than previously obtained from just macroscale studies.

O-0128

Microsedimentology of tills near Ainet, Austria -were palaeo-ice streams in the European Alps underlain by soft deforming bed zones?

John Menzies¹, Jürgen Reitner²

¹Department of Earth Sciences, Brock University, St. Catharines, ON, Canada. ²Geologische Bundesanstalt /Geological Survey of Austria, Vienna, Austria

Abstract

Fast moving palaeo-ice masses within the European Alpine Ice Cap (EAIC) during the Last Glacial Maxima within the large valleys of the European Alps can be compared to ice streams that drained the larger Quaternary Ice Sheets in Europe and North America and the modern East and West Antarctic Ice Sheets. Unlike these continental-style ice sheets, the ice inundating the European Alps flowed first through confined bedrock valleys that, at close to the glacial maximum, acted in similar manner to ice streams in the North American Cordilleran Ice Sheet. Knowledge of the subglacial environments illuminates controls in basal ice activity in terms of overall ice sheet mass balance based upon a grasp of basal thermal regimes, sediment availability and rheology, as well as subglacial hydrological conditions.

Debate continues as to basal ice temperatures and sliding velocities as well as basal interface conditions whether on hard or soft beds in many inner and marginal zones of EAIC. Little mention exists as to the extent of soft sediment basal deformation although increasingly such conditions are known from several parts of the EAIS. In particular, in the Drau (Drava) ice stream, an upper branch of the large Sava Ice Stream, appears as a fast-moving ice mass that would likely be underlain by soft deforming sediment. It is the underlying microsedimentology of parts of the Drau Valley in the Lienz area of Austria that is the focus of this research.

Past research on tills has demonstrated that the use of microsedimentology and the examination of multiple microstructures reveals details of till sedimentology surpasses most macroscale examination of tills. The tills of the Drau Valley at Ainet occur from the valley bottom to high up on the valley side. Thin section examination of these tills reveals a detailed depiction of soft sediment deformation processes throughout the basal zones of this ice stream illustrative of temperate basal ice conditions. The tills exhibit the characteristics typical of ongoing active deformation while being emplaced and post-emplacment stress effects such that the evidence from Ainet supports the contention that most likely ice streams in the palaeo-EAIC were similar to those today in Antarctica and in the Quaternary ice streams of the Laurentide and North European Ice Sheets.

Why you should sweat the small stuff: microsedimentology and Snowball Earth

Marie Busfield¹, Daniel Le Heron²

¹Aberystwyth University, Aberystwyth, United Kingdom. ²University of Vienna, Vienna, Austria

Abstract

Microscopic analyses of glacial sediments are well-developed and increasingly widely utilised techniques in Quaternary studies, exposing a wealth of additional sedimentological and structural data which may not be visible at the outcrop scale. However, these techniques have been comparatively under-utilised in the ancient glacial sedimentary record. Here, we use numerous examples from Cryogenian (c. 700 million year old) glaciomarine successions in Namibia, Australia, Scotland and the USA to illustrate the successful application of traditionally Quaternary analysis techniques to pre-Quaternary glacial sedimentary rocks. In northern Namibia, beautifully preserved shear structures and plasmic fabrics provide the first evidence of subglacial deformation in the region, and attest to mobile, warm-based ice masses on the 'globally frozen' Snowball Earth. These deformation structures also aid in unpacking longstanding debates regarding the glacial origin of diamictite-rich facies versus accumulation via rift-related mass flows. In northern Scotland, similar debates ensue, where normally-graded facies do attest to sediment gravity flow emplacement, but ice-rafted debris only visible at the micro-scale confirm a direct glacial input as well. Ice-rafted debris are also only detected microscopically within iron formations in South Australia, demonstrating that these are syn-glacial as opposed to the post-glacial rusting of the seas argued under traditional Snowball Earth hypotheses. Meanwhile, in the western USA, microsedimentology is essential in distinguishing sediment gravity flow deformation from proglacial glaciotectonic deformation, and in identifying the first regional evidence of ice-contact conditions during Cryogenian glaciation. These microscopic data can therefore shed light on the primary mode of deposition of glacial sediments, on the dynamics and basal thermal regime of depositing ice masses, and on the location of grounded ice margins in the pre-Quaternary record, demonstrating the importance of sweating the small stuff even when exploring potentially global scale ice ages.

Sheared clast and enveloping plasmic fabric in the subglacially deformed Chuos Formation, from the Cryogenian record (~720 Ma) of northern Namibia.

Lateglacial lacustrine sediments in Peary Land, northernmost Greenland

Jaap J.M. van der Meer¹, Kurt Kjaer²

¹School of Geography, QMUL, London, United Kingdom. ²Center for Geogenetics, Natural History Museum of Denmark, Copenhagen, Denmark

Abstract

During reconnaissance Quaternary geological mapping in northernmost Greenland we encountered substantial lacustrine sediments, dated to between 16 and 12 KA BP. These sediments started to accumulate in inland embayments of an ice shelf in the Lincoln Sea between Ellesmere Island and northern Greenland.

Micromorphological analysis of a set of thin sections from the lacustrine sediments revealed that they should be classified as rhythmites, not annual varves. The sedimentology is quite complicated. Most astonishing is the widespread occurrence of organic material (most likely mosses) in the sediments, associated with widespread bioturbation. Astonishing, because it is not clear where the plant material came from so early in the lateglacial and which organisms are responsible for the bioturbation.

We will present further sedimentological data on the lacustrine sediments and a comparison with other, non-lacustrine rhythmites.

Dynamic retreat of the Eden-Stainmore palaeo ice stream of the last British-Irish Ice Sheet

Bethan Davies¹, Stephen Livingstone², David Roberts³, David Evans³, Delia Gheorghiu⁴, Colm O Cofaigh³

¹Royal Holloway University of London, Egham, United Kingdom. ²Sheffield University, Sheffield, United Kingdom.

³Durham University, Durham, United Kingdom. ⁴SUERC, Glasgow, United Kingdom

Abstract

During the Last Glacial Maximum, ice streams of the last British-Irish Ice Sheet (BIIS) controlled the discharge of ice and sediment from various dispersal centres. Deglaciation was characterised by shifts in ice-divide location and internal ice-sheet dynamics resulted in flow switches and dynamic changes in the configuration of ice streams, and hence significant modification of their landform signatures. We present new geomorphological mapping and 11 ¹⁰Be cosmogenic nuclide ages from the Stainmore Gap and Eden Valley, constraining regional dynamic ice-stream retreat following the LGM in northern England. These data allow us to provide temporal constraints on glaciodynamic ice-flow phasing, by linking ages to flow-sets and stillstands recorded in the glacial geomorphological. In our new palaeo ice-sheet reconstruction, we identify complex decoupling of ice in the Vale of York/Mowbray, which was characterised by early retreat of the North Sea Lobe and a minor re-advance of Stainmore ice into the space vacated prior to ~20 ka. This was followed by rapid recession of the central Stainmore Gap, which was ice-free by 18.0 ± 0.5 to 19.8 ± 0.7 ka. The Stainmore Gap Ice Stream retreated contemporaneously with the Tyne Gap Ice Stream, which became ice-free in its eastern sector by 18.4 ± 0.8 ka and in its central sector by 17.4 ± 0.7 ka and the Vale of Eden, with the southern edge at Crossby Ravensworth Fell becoming exposed between 19.2-20.3 ka. The implication is that the northwards ice-flow reversal in the Vale of Eden, which became a fast flow tributary of the Irish Sea Ice Stream, occurred while the Stainmore and the Tyne Gap ice streams were still active and therefore must have been associated with the development of a N-S ice divide down the western spine of the northern Pennines and then across Howgill Fells. This ice divide migration likely triggered the rapid collapse of eastward ice flow corridors as their catchment areas contracted. Our new age constraints suggest that the central sector of the BIIS rapidly collapsed back up into upland dispersal centres between 20 - 17.5 ka.

New Constraints on Late Pleistocene Sea Levels across Western Scotland with Implications for the Wester Ross Readvance

Alexander Ray Simms¹, Louise Best², Ian Shennan³, Dillon Osleger¹, Lorraine Lisiecki¹, Juliet Sefton³, Jeremy Lloyd³, Amy Lightowler³

¹University of California Santa Barbara, Santa Barbara, USA. ²University of Gloucestershire, Cheltenham, United Kingdom. ³Durham University, Durham, United Kingdom

Abstract

Reconstructing the past behavior of ice sheets through the Late Pleistocene provides a means for understanding how ice sheets respond to climate change. Following the last glacial maximum, the British Ice Sheet retreated in response to warming and global sea-level rise. The retreat of the ice sheet over northwest Scotland is partly reflected in local records of sea-level change as well as moraines left behind within the landscape. We provide new constraints on the relative sea-level record of northwest Scotland based on two newly cored isolation basins. A record of magnetic susceptibility from one of these basins closely tracks climate changes recorded in the Greenland ice cores and is used to tune our age model from one of the basins. The new sea-level index points suggest sea level was 17.26 ± 0.10 m at 14.9-15.8 ka within Glac Bhuidhe and 12.65 ± 0.05 m at 15.7-16.1 ka with Loch Bad n h-Aclaise, both near the town of Gairloch in northwestern Scotland. Neither basin provides evidence for a “double-dip” in sea level during meltwater pulse 1-A as some models of glacial-isostatic adjustment predict for northwestern Scotland. As both basins lie within the limits of moraines associated with a regional readvance known locally as the Wester Ross Readvance, they constrain the age of the glacial event to greater than 15.8 ka. This age is within error of some rescaled cosmogenic ages and older than most previous models and point to a pre-Bølling Allerød age for the readvance, suggesting it may correlate to the Killard Point Readvance in Ireland and/or Heinrich Event 1. Furthermore, the basin stratigraphy records other regional climate events including the Younger Dryas and Bølling Allerød.

Geomorphological and seismostratigraphic evidence for multidirectional polyphase glaciation of the northern Celtic Sea.

Zsuzsanna Tóth^{1,2}, Stephen McCarron^{3,2}, Andrew Wheeler^{1,2}, Stefan Wenau⁴, Stephen Davis⁵, Aaron Lim¹, Volkhard Spiess⁴

¹University College Cork, Cork, Ireland. ²Irish Centre for Research in Applied Geosciences, Dublin, Ireland. ³Maynooth University, Maynooth, Ireland. ⁴University of Bremen, Bremen, Germany. ⁵University College Dublin, Dublin, Ireland

Abstract

A Quaternary stratigraphic succession preserved offshore Southeast Ireland (between Dungarvan to Hook Head) records a sequence of depositional and erosional events that supports regional glacial event models derived from nearby coastal sediment stratigraphies and landforms. Multichannel seismic and Sparker data are presented and reveal a five-fold event stratigraphy. A regionally widespread, largely acoustically massive facies (SU2) interpreted as the 'Irish Sea Till' infills an uneven, channelized bedrock surface overlying irregular mounds and discontinuous pockets of weakly stratified deposits (SU1) in bedrock lows that are likely remnant, earlier Pleistocene diamicts and associated sediments. SU2 is truncated throughout the study area by a strong, horizontal reflector and overlain by a thin, stratified acoustic facies (SU3), suggestive of the development of a regional ice dammed palaeolake or smaller ponded water bodies after the recession of ice. On the near shore bedrock platform to the north, a north to south oriented linear narrow ridge at seabed is interpreted as an esker, and represents southward flowing subglacial drainage associated with a restricted ice sheet advance onto the Celtic shelf postdating the SU1-SU3 seismostratigraphy. Onshore LIDaR data reveal drumlin orientations that corroborate the southerly advance of ice into the Celtic Sea from the mainland. The evidence supports palaeoglaciological models derived from nearby coastal localized sediment sequences comprising an LGM-aged cross-shelf Irish Sea Ice Sheet flow from the east, followed by proglacial subaqueous deposition, and finally an episode of offshore-directed Irish Ice Sheet ice flow at a regional scale. The offshore topography marks a new limit for a restricted Late Midlandian Irish Ice Sheet advance from an inland ice dispersal centre onto the Celtic Sea shelf offshore County Waterford.

Cultural Dynamic at the Initial and Early Upper Palaeolithic of Altai Mountains

Natalia Belousova

Institute of Archaeology and Ethnography SB RAS, Novosibirsk, Russian Federation

Abstract

This article presents the results of determining the technological and typological characteristics and the general trend of the Kara-Bomian and Ust-Karakolian cultural tradition's development at the IUP and EUP of Altai Region (50,000–30,000 uncal yrs BP). One of the priority areas of research was the study of the structural organization of the cultural deposits of the Kara-Bom (excavation area 4) and Ust-Karakol-1 (excavation area 2) Upper Paleolithic sites, which were used as a reference for the reconstruction of cultural dynamics. The analysis of these complexes opens up the possibility for the study of homogeneous stone industries, the specification of their technical and typological variability and the subsequent verification of regional cultural and chronological schemes.

As a result of the study, we proposed new schemes of the cultural and stratigraphic division of the Upper Paleolithic deposits of Kara-Bom and Ust-Karakol-1 sites. We found that layers 6–4 of Kara-Bom include two horizons with archaeological material (cultural horizons UP1 and UP2) instead of the six habitation levels noted earlier. Lithological layers 11–8 of the Ust-Karakol-1 site contain a single horizon with archaeological material (cultural horizon EUP1), instead of the four levels noted earlier. We have proved that the content of the elements of blade-point Middle Paleolithic technology in the EUP1 cultural horizon of Ust-Karakol-1 site is a consequence of the disturbance and mixing of cultural deposits of the Middle and Upper Paleolithic. The analysis of archaeological complexes of the Kara-Bom site shows that the list of technological and typological characteristics of the industries of the early stage of the Kara-Bomian tradition's development is significantly reduced in the industry of the later stage. This was manifested in the disappearance of the volumetric component in the blade production (flat-faced cores) and a series of tool-markers and technologies (points with ventral base thinning, truncated-faceted pieces, pecking technique etc.).

New data clarify the existing cultural and chronological model of the cultural tradition's development in the early stages of the Upper Paleolithic of the Altai region. We found out that the Kara-Bomian and Ust-Karakolian traditions represent evidence of generally different episodes of human habitation, rather than synchronous ones, as previously supposed. The Kara-Bomian assemblages belong to a chronological interval of 46,000–31,000 uncal yrs BP. The industries of the Ust-Karakolian tradition are clearly fixed in the region not earlier than 35,000 uncal yrs BP and find similar analogies in assemblages of the middle stage of the Upper Paleolithic of the region. The technological tradition's development of this period was aimed at the microlithization of stone tools, the disappearance of non-volumetric elements in the blade production and the improvement of prismatic technology.

We are grateful to the RFBR (grant 18-39-00167) for supporting our research.

New data on Initial Upper Paleolithic in Central Asia: Ushbulak site (Kazakhstan)

Anton Anoiikin¹, Vladimir Kharevich¹, Galina Pavlenok¹, Aliona Shalagina¹, Zhaken Taimagambetov²

¹Institute of Archaeology and Ethnography of the Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation. ²National Museum of the Republic of Kazakhstan, Astana, Kazakhstan

Abstract

Initial Upper Paleolithic assemblages were initially identified on the basis of the archaeological materials from the sites of Boker Tachtit and Ksar Akil in the Levant. Nowadays, such assemblages have been reported from many regions of Eurasia including Near East, and Central Asia: Altai Mountains, Transbaikalia, Mongolia, and North China. A typical IUP assemblage has been recently found in Kazakhstan (Ushbulak).

Ushbulak (the northeastern part of the Shilikty Valley) is a stratified site (8 lithological layers; 7 cultural layers). According to recovered lithic assemblage and its features, as well as the stratigraphic position of the complexes, and associated faunal remains, three major cultural and chronological units have been tentatively established, including the Holocene assemblage (layer 1), the UP assemblage (layers 2–4), and the IUP assemblage (layers 5–7).

The most significant number of artifacts was discovered in the layers 5–7 (14000 items). The debitage assemblages from these layers represent primary knapping targeting blade production by parallel uni- and bidirectional methods of prismatic core reduction. Blade cores with the opposite semi-tourné platforms predominate in core collection. Core trimming elements correspond well to the available cores. The majority of core trimming elements (crested and semi-crested, plunging, and marginal laminar spalls) illustrates laminar prismatic and sub-prismatic reduction.

The tool assemblage includes several types, such as end-scrapers on large blades, including those with ventral thinning of the base, notched tools, truncated-faceted tools, truncated blades, burins on blades, point with basal trimming, strangled blades, biface and burin-cores.

Based on the composition of the lithic industry, layers 5–7 can be defined as a lithic workshop near raw material outcrops.

These features, supplied by dates 45250–44000 calBP from layer 6 allow us attributing these layers 5–7 to the Initial Upper Paleolithic and considering Eastern Kazakhstan as a region between synchronous sites of the Initial Upper Paleolithic in Altai Mountains (Kara-Bom site, Ust-Karakol-1 site and others), Dzungaria (Loutoshi site, Tongtiandong site) and Northern Mongolia (Tolbor-4 site, Tolbor-21 and others).

Chronological sequence of the Initial and Upper Paleolithic in Mongolia and its relationship to ecosystem changes during MIS3

Masami Izuho¹, Hitoshi Hasegawa², Gunchinsuren Byambaa³, Tsogtbaatar Batmunkh³

¹Department of History and Archaeology, Tokyo Metropolitan University, Tokyo, Japan. ²Department of Global Environment and Disaster Prevention, Kochi University, Kochi, Japan. ³Institute of History and Archaeology, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia

Abstract

In this paper, we investigate the possible correspondence between the chronological sequence from the Initial to Early Upper Paleolithic (IUP-EUP) and the ecosystem changes during MIS 3 in Mongolia. With progress of Upper Paleolithic research across Eurasia and beyond, in the last decade, we are beginning to gain a clearer picture of even the IUP-EUP phenomenon at the onset of the Upper Paleolithic. IUP in its broad sense can be summarized as follows: (1) IUP assemblages are distributed extensively from North Africa to Northeast Asia, (2) the dates likely fall within the range of 50,000-40,000 Cal yr BP, and (3) the stone tool technology is characterized by blade-based primary reduction with elements of the Levallois technique. In northeast Asia, following the period with extensive distribution of IUP assemblages with many common cultural characteristics found across continents, the EUP assemblages appeared displaying higher regional diversity continuing until about 30,000 Cal yr BP. Therefore, one of the main current research objective is to reconstruct the variability and chronology of relevant assemblages of several smaller regional IUP-EUP clusters that are discovered, for example, in southern Siberia and northern Mongolia. IUP-EUP sites found in these regions, at the northeastern tip of their distributions, challenge our current understanding of lithic technology as having broad similarities and local evolutions.

Recent fieldwork in northern Mongolia conducted in the Selenge River Valley System provides relatively high-resolution datasets for reconstructing the origin and evolution of local IUP-EUP assemblages in Mongolia. The ages of IUP-EUP sites in Mongolia fall within the interval of 45-33,000 Cal yr BP, though the change of cultural phenomena are not yet clear. Those ages seem slightly younger than those from other regions, but this age-estimate may still contain several thousand years of error due to the difficulty in accurately determining ages at these sites. The difficulties are mainly derived from its preservation condition because these sites are subject to several agencies of post depositional disturbance; these sites are situated at higher terrace or colluvium slope-wash. Obtaining site-based geochronology with careful examinations of the geological contexts will provide a better platform for us to obtain reliable chronological sequence. This will also allow us to understand change in past human-behaviors during IUP-EUP in Mongolia, providing a local perspective. On the other hand, high-resolution datasets to reconstruct the local paleoenvironment have been compiled recently in Southern Siberia and even in Mongolia although they are not sufficient to cover the entire area. Our comparisons of those data show clear association between the chronological sequences and regional environmental and landscape changes in Mongolia, while awareness of problems and limitation.

O-0137

The presence and absence of IUP in China: Implications for modern human dispersal across Eurasia

Xing Gao

Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China

Abstract

The emergence of Initial Upper Paleolithic Industries in China is a very complicated research issue, regional variability is obvious in archaeological records in the vast area during the transition from the Early to the Late Paleolithic. While the presence of Levalloisian-like technocomplexes and large blade assemblages from a few Paleolithic sites in North China, such as the Shuidonggou in Ningxia, Luotuoshi and Tongtiandong in Xinjiang, Jinsitai and Sanlongdong in Inner Mongolia, signaled the beginning and existence of Initial Upper Paleolithic industries in part of the region, lithic assemblages from many other sites in North China were largely dominated by traditional simple flake tools. In Central and South China, Levalloisian and blade products are totally absent throughout the Paleolithic, leaving the vast space for the prevailing of pebble-tool-tradition until the Neolithic. What is the dynamic for such technological variation? Environmental restrictions? Different adaptation strategies? Occupation by different human groups? These questions have puzzled archaeologists for a long time. This paper will summarize the diversity of the early Late Paleolithic industries in China and try to offer some interpretations to the complexity of Paleolithic development in the region, including the possibility of different trajectories of modern human origins and evolution.

Variations in core reduction strategies in the IUP assemblage at Shuidonggou locality 1, northern China

Feng Li¹, Steven Kuhn²

¹Institute of Vertebrate Palaeontology and Palaeoanthropology, Chinese Academy of Sciences, Beijing, China.

²Department of Anthropology, University of Arizona, Tucson, USA

Abstract

The term Initial Upper Paleolithic (IUP) is generally used to describe the earliest Upper Paleolithic assemblages with Levallois elements in blade production in many regions of western Eurasia, Central Asia, and China. Many researchers consider the IUP techno-complex as transitional from Middle Paleolithic to Upper Paleolithic, primarily on the basis of the Levallois-like features of blade production. In fact, IUP assemblages may contain evidence for multiple strategies for manufacturing blades, including prismatic, Levallois, and burin core methods. Little attention has been paid on the relations of different core reductions within IUP assemblages. Are they independent reduction strategies employed with varying frequencies, or could cores have transitioned from Levallois to prismatic (or vice versa) during reduction? Shuidonggou locality 1, one of the few IUP sites in northwestern China, has yielded a large assemblage of cores and blades, and has figured prominently in discussions of technological diffusion and modern human dispersals in northern Asia. In this paper, we analyze the 3-D models of cores from Shuidonggou locality 1, constructed using a CT-scanner. We apply simple metric as well as geometric morphometric approaches to investigating the relationship between Levallois and non-Levallois cores and core reduction. In addition to casting new light on the nature of blank production at Shuidonggou locality 1, our findings are relevant to research on “transitional” lithic technologies in general.

Abstract

A specific blade technology associated with the Initial Upper Paleolithic (IUP) suddenly occurred in Central and Northeast Asia during the Greenland Interstadial 12 (Kuhn and Zwyns, 2014), but where, how and why this phenomenon emerge is still unclear. In Siberia and in Mongolia, the IUP marks a definitive shift toward blade and bladelet-based lithic assemblages that overall characterize the onset of the Upper Paleolithic in the steppe belt and to the farther north. In the Yellow River Basin, at the southeastern edge of this phenomenon and also at the southern border of the northern biogeographic zone in China, the site of Shuidonggou (SDG) tells a different story. Although a handful of loci have yielded evidence for IUP technological systems (SDG1, SDG2 and SDG9) (Brantingham et al., 2002; Li et al., 2013; Peng et al., 2014), human occupations that followed the IUP occupations show the return of a flake-based assemblage configuration at the expense of the blade technology (Li et al., 2013). Here we present a techno-typological analysis of the SDG2 assemblages (cultural layers 3 to 1a) excavated between 2014 and 2016 and that cover the time span between ca. 32 ka cal BP to 20 ka cal BP. In the material studied, none of the defining features of the IUP blade technology subsists, and instead we see the rapid re-establishment of technological practices commonly observed in the region preceding the appearance of the IUP. On the one hand, a closer look at flaking patterns shows that although technological change occurred through time, it does not lead back to blade productions. Finished products remain poorly standardized, although significant temporal variations are illustrated by the import/export of semi-finished products (Lin et al, 2019). Also, method and flaking techniques illustrate a degree of diversity that contrast with the use of a generic label such as 'core and flakes'. However, our analysis also underlines similarities in the selective treatment of raw material types that may reflect long-lasting regional signatures (e.g. specific use of the SDG resources). At the regional level, our results provide insight that helps clarify the temporal changes in the lithic technology at SDG2, with evidence for versatile subsistence strategies but also convergence in raw material exploitation. At a more global level, the SDG2 sequence help illustrate a complex history of technological changes at the border between two strikingly different paleoenvironmental ecozones (Dennell, 2008; Norton et al., 2010)

O-0141

Lost in Space? Current trends, challenges and potentials in strontium isotope archaeology

Kate Britton

University of Aberdeen, Aberdeen, United Kingdom. Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

Abstract

More than thirty years after the first ground-breaking work in the field, strontium isotope applications are ever-increasing in the archaeological sciences, and in particular in bioarchaeology. From larger studies tracking the mobility of past populations to individual (and even seasonal) movement histories, strontium isotope analysis is proving to be a valuable means of exploring the past and answering archaeological enquiries at a range of scales. In addition to numerous studies on human remains, isotope zooarchaeology has flourished as a sub-field, including diverse strontium isotope applications to both domestic fauna and remains of wild animals from Pleistocene sites. In this talk, the highlights and challenges of strontium isotope applications in archaeology will be explored, with a particular focus on the difficulties of translating isotope ratios into spatial data within a meaningful, archaeological interpretive framework. The position of strontium isotope analysis in bioarchaeology now and into the future will be contemplated, and key research priorities discussed.

The PleistoHERD model: Linking intra-tooth strontium isotope profiles and isoscapes using computational modelling to reconstruct *Rangifer* palaeomigrations

Mael Le Corre¹, Joshua Wriath¹, Vaughan Grimes², Steeve Côté^{3,4}, Kate Britton¹

¹Department of Archaeology, School of Geosciences, University of Aberdeen, Aberdeen, United Kingdom.

²Department of Archaeology, Memorial University of Newfoundland, St. John's, Canada. ³Caribou Ungava, Département de Biologie, Université Laval, Québec, Canada. ⁴Centre d'Etudes Nordique, Université Laval, Québec, Canada

Abstract

Reconstructing the movement palaeoecology of archaeologically-important prey-species, such as reindeer, is crucial to the study of ancient landscapes and ecosystems, and for gaining a better understanding of the decisions, movements and hunting strategies of past human groups. Traditionally inferred from the behaviour of modern analogue species, our ability to reconstruct ranging behaviours and seasonal movements in the past has greatly improved with the development of isotope techniques that target incrementally developed tissues preserved in the archaeological and palaeontological record, such as tooth enamel. Strontium ($^{87}\text{Sr}/^{86}\text{Sr}$) and oxygen ($\delta^{18}\text{O}$) isotope provide information on the location individuals foraged during tissue formation. Isotope analysis of sequentially-sampled tooth enamel can be used to evidence seasonal migratory behaviour of ungulates, and to provide an indication of possible seasonal ranges (e.g. summer or winter range). However, more nuanced approaches that link intra-tooth isotopic profiles and isoscapes, are required in order to reconstruct past migratory routes across landscapes and seasonal range use. Here, we present the methodological framework for an isoscape-based model which will assess the distribution and migratory movements of *Rangifer* from their intra-tooth $^{87}\text{Sr}/^{86}\text{Sr}$ and $\delta^{18}\text{O}$ isotope data, the PleistoHERD model. Our model integrates intra-tooth and landscape isotope data using GIS analysis and movement modelling methods from modern ecology. In developing the model, we use intra-tooth isotope profiles from modern migratory caribou from the Rivière-aux-Feuilles herd, Québec, Canada, alongside creating a working $^{87}\text{Sr}/^{86}\text{Sr}$ isoscape, based on the age and nature of the lithology of Québec, supplemented by bioavailability strontium isotope data from modern plants, and refined using Random Forest modelling. Preliminary isotope analyses of the second and third molar indicated variations in $^{87}\text{Sr}/^{86}\text{Sr}$ isotope values, reflecting the seasonal migratory behaviour of the individuals during their first 18 months of life. A Bayesian spatial assignment approach is used to identify the origin of every intra-tooth sample from each individual, and produce a time-series probability distribution map for each caribou. Caribou movements are then modelled throughout the time-series distribution map to identify potential winter and summer ranges and migration routes. Finally, in order to refine and discriminate potential migration routes, we use habitat suitability models to take into account the impact of topography, hydrography and landcover on caribou movements. The comparison of reconstructed seasonal movements with real migratory movements, assessed from 30 years of telemetric survey of the Rivière-aux-Feuilles herd, will allow us to validate the model. The implications of the PleistoHERD model, and its interdisciplinary approach, for the use of strontium isotope analysis in both archaeology and palaeoecology will be explored.

Abstract

The main goal of this paper is to reconstruct the spatial scales and patterns of organization of human mobility across a diverse array of ecological and altitudinal settings across the southern Andes (32°-34° S) during the last 2500 years. This project is designed to sample different biogeographic regions from the Pacific coast in Chile to the eastern Andean lowlands in Argentina (Figure 1). To achieve this long-term goal, we present advances in the following two specific goals of the project.

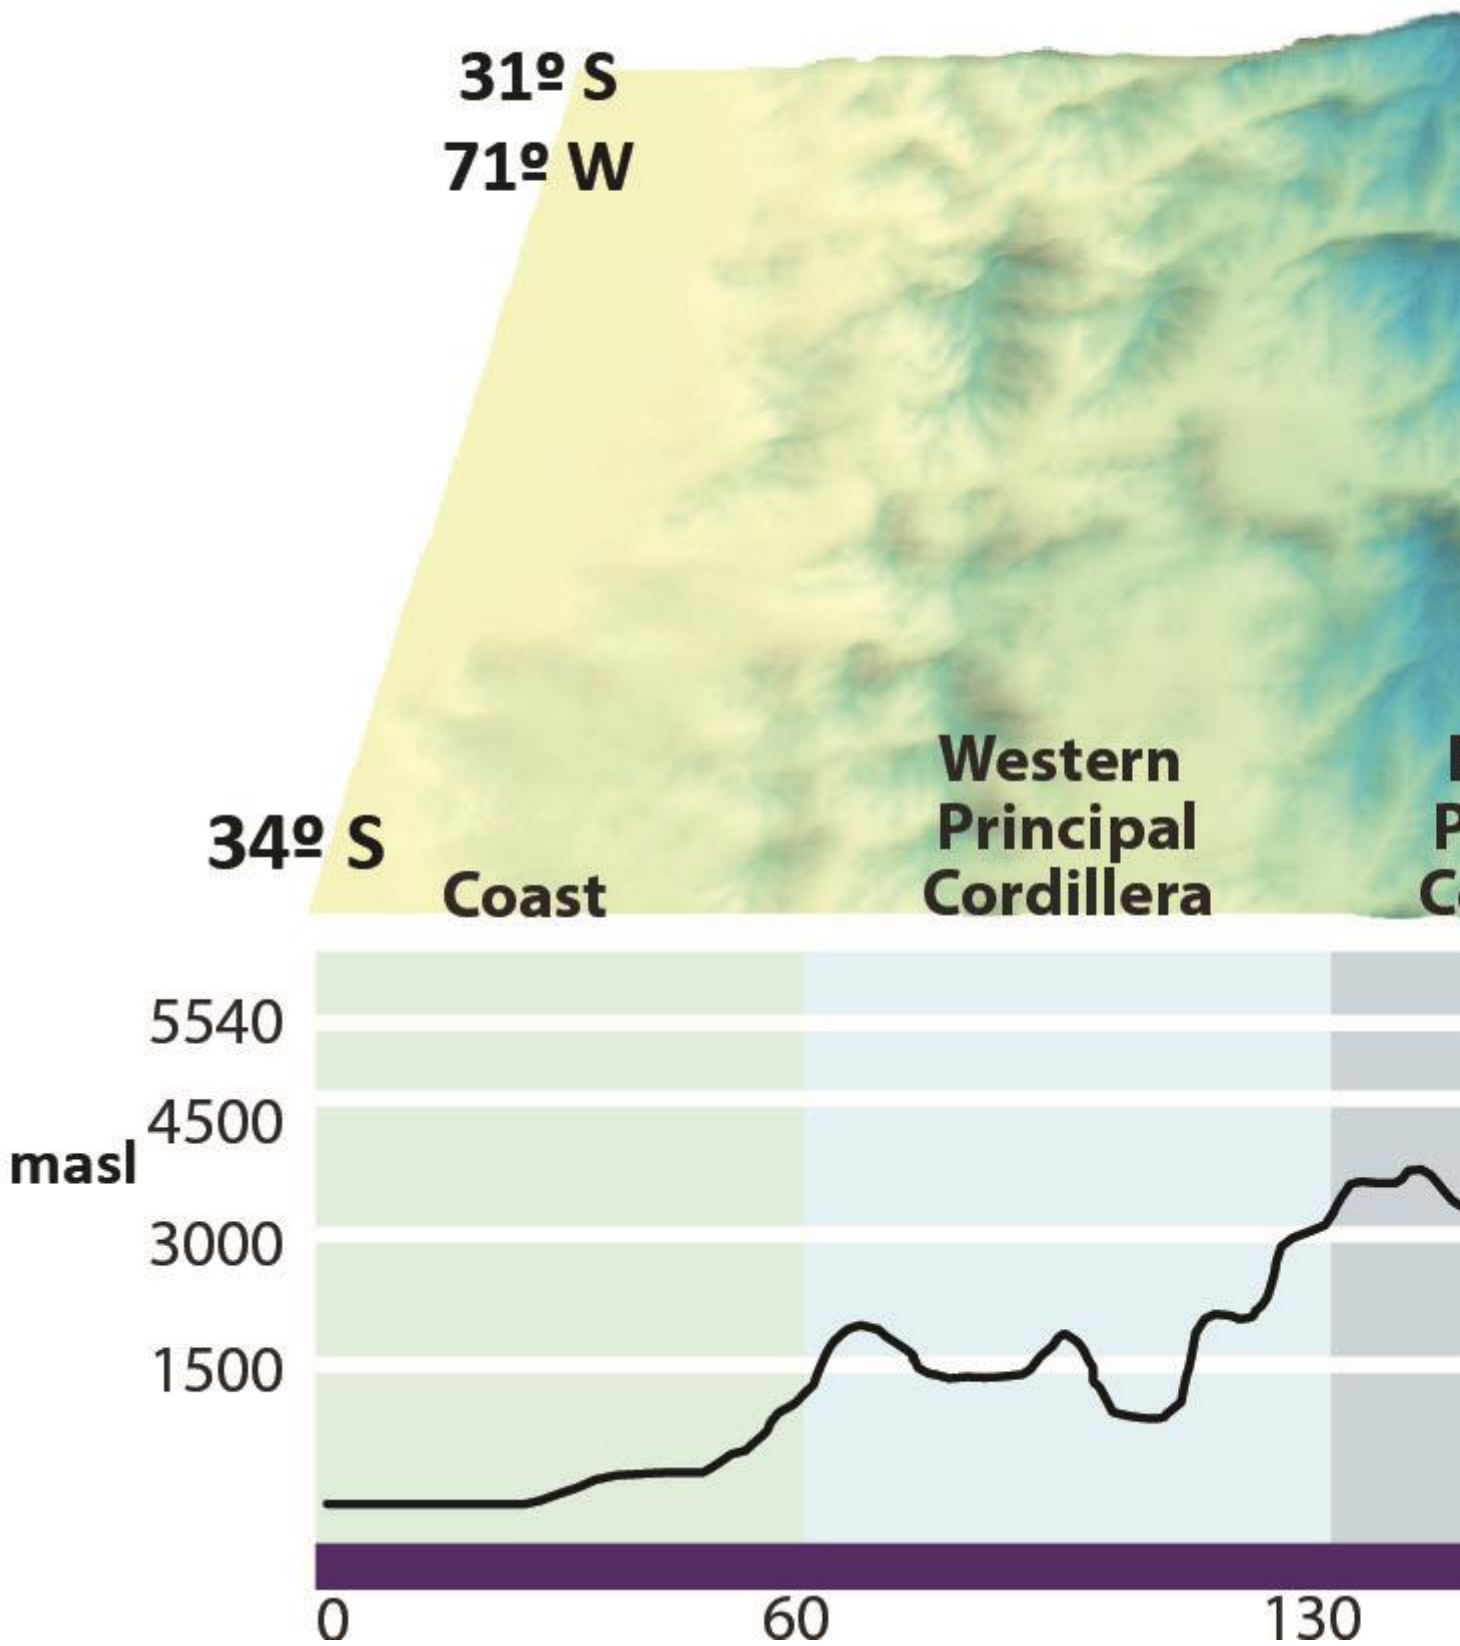

Figure 1. Cross-section of the southern Andes.

Firstly, we seek to build a framework of bioavailable strontium isotopes ($87\text{Sr}/86\text{Sr}$) as expressed in the main Andean geological units, which span from the Pliocene to the Lower Paleozoic: a) marine Sr in the Pacific coast; b) Coastal Cordillera (Cretaceous); c) Western Principal Cordillera (Miocene-Oligocene); d) Eastern Principal Cordillera (Cretaceous-Jurassic); e) Frontal Cordillera (Permian-Triassic); f) Precordillera (Lower Paleozoic); and e) Active Foreland (Quaternary) (Figure 2). To achieve this goal, we analyze plants and rodent samples from modern and archaeological contexts. This is the first attempt to apply such an approach in the southern Andes.

Figure 2. Geological framework for the southern Andes.

Secondly, by analyzing strontium isotopes in human bone and teeth samples from archaeological contexts, we reconstruct place of origin and death, providing an analytical window for the study of individual life histories, combining the realms of quotidian ranges of human movement and social processes, such as conflict and migration, which disrupt this pattern of daily life. We focus on the analysis of human remains from the last 2500 years, witnessing the most intense processes of socio-demographic and economic change, including an apparent reduction in the intensity of mobility, first presence of archaeological cemeteries, the origins of agro-pastoral economies, and the geographic expansion of the Inka Empire.

From a methodological perspective, we develop a preliminary comparison of strontium and oxygen isotopes ($18\text{O}/16\text{O}$), revealing a divergent pattern: while oxygen isotopes for human samples from distant regions in western Argentina overlap widely, there are important differences in strontium isotopes, hence suggesting that strontium provides a finer tracer of human mobility across this geologically complex Andean landscape. Our strontium results will be briefly compared to those produced by colleagues for the south-central Andes of southern Peru, northern Chile, and western Bolivia, in an attempt to learn about the spatial resolution achievable in different Andean geological settings. In synthesis, by integrating the results for bioavailable strontium and human tissues in the context of a biogeographic framework, this project (National Geographic HJ-136R-17) presents the first assessment of sociocultural variation, scales of human territories, and patterns of social interaction across the southern Andes.

Traveling monastic paths: A study of mobility and religion in medieval Ireland using radiogenic strontium and oxygen isotope analysis

Elise Alonzi

University College Dublin, Dublin, Ireland. Arizona State University, Tempe, USA

Abstract

Monasteries were powerful social institutions in early and late medieval Ireland that took drastically different forms over time. Medieval historical records, such as annals and Saints' Lives, and archaeological data, such as the layout of monastic buildings, suggest that small communities of monks at early medieval Irish monasteries followed ascetic or austere ways of life. Contrastingly, historical and archaeological sources indicate that monks at late medieval monasteries, founded by English and continental religious orders, lived in large communities and interacted with lay or non-religious people. Historical texts also record that high-status Irish monks and nuns traveled throughout Ireland, Scotland, England, and continental Europe. However, documents record little information about lower status monks and lay people. Thus, it is unknown how frequently people traveled as part of monastic life and how frequently local individuals participated in monasticism. This study leverages unique burial contexts of 88 individuals at five Irish monastic sites spanning nine centuries (8th-16th centuries AD) through biogeochemical analysis of human bones and teeth based on two isotopic systems (radiogenic strontium and oxygen) compared to a geological baseline of plant samples, to uncover patterns of medieval Irish mobility in connection to the changing practices of Irish monasticism.

The building of Qin-Han Empire: insights from strontium isotopes of sacrificial animal tooth enamel

Zihua Tang¹, Xueye Wang¹, Xianglong Chen², Jing Yuan²

¹Institute of Geology and Geophysics, CASS, Beijing, China. ²Institute of Archaeology, CASS, Beijing, China

Abstract

The domesticated cattle and horses were introduced to north China as early as the second millennium BCE, and played vital roles in subsequent China's wars and farming. However, supplies of these livestock are still hampered by the lacks of direct evidence and suitable methods. A newly excavated Xuechi site, a state-level ritual venue for the Qin-Han dynasties, exposed abundant sacrifice animals, providing a valuable opportunity to approach this issue. Here we analysis the enamel $^{87}\text{Sr}/^{86}\text{Sr}$ value of 10 cattle and 19 horses from different sacrificial pits of the site. As the whole, the cattle and horses bear the similar $^{87}\text{Sr}/^{86}\text{Sr}$ values and no statistically significant differences are found between pits. By contrast, the $^{87}\text{Sr}/^{86}\text{Sr}$ values of the livestock are obviously higher than those of local snails and surface water, strongly suggest that the analyzed livestock were not raised on the immediate locality of the site. Inferred from river water $^{87}\text{Sr}/^{86}\text{Sr}$ values, the regional baseline map for bioavailable $^{87}\text{Sr}/^{86}\text{Sr}$ values further suggests that some livestock (cattle 7/10, horse 5/19) probably derived more than one hundred kilometers away. These extensively consumed livestock found from the Xuechi site suggests a social network behind them, as supported by historical documents. Moreover, the increase in standard deviation of $^{87}\text{Sr}/^{86}\text{Sr}$ values of cattle tooth enamel shows robust correlation to the trajectory of Chinese states, implying that the variability of $^{87}\text{Sr}/^{86}\text{Sr}$ values of sacrificial tooth enamel is a potential tool to track the formation of empire.

Origins of the people in the Iron Age Levänluhta water burial, western Finland.

Laura Arppe¹, Heli Etu-Sihvola¹, Kristiina Mannermaa², Anna Wessman²

¹Finnish Museum of Natural History, University of Helsinki, Helsinki, Finland. ²Department of Cultures, University of Helsinki, Helsinki, Finland

Abstract

With ~100 exceptionally well preserved skeletons, the Levänluhta water burial (ca. 400-800 CE) is one of the foremost Iron Age sites in Finland, situated ca. 50 km inland from the Baltic Sea coast in western Finland. Since 2011 it has been the target of multidisciplinary studies including modern archaeological (Wessman et al. 2018), osteological, isotopic and genetic investigations (Sikora et al. 2018; Lamnidis et al. 2018) aiming to arrive at a holistic understanding of the site and those buried there.

To study the origins of the people buried in Levänluhta, who are almost entirely women and children, tooth enamel from 16 individuals was sampled for ⁸⁷Sr/⁸⁶Sr analysis. Local bioavailable ⁸⁷Sr/⁸⁶Sr values (0.7238-0.7384) were evaluated using environmental sampling of surface waters and small mammal bones. Some of these data are included in the aDNA study of Sikora et al (2018). The studied humans yielded ⁸⁷Sr/⁸⁶Sr values from 0.7103 to 0.7313. Six individuals showed ⁸⁷Sr/⁸⁶Sr values (0.7268-0.7313) consistent with local Sr levels. Ten individuals showed lower values (0.7103-0.7207), out of the range of local environmental samples. Four of these had ⁸⁷Sr/⁸⁶Sr values <0.715, distinctly different from the observed local baseline and the relatively high ⁸⁷Sr/⁸⁶Sr levels common for the Levänluhta area bedrock.

Three scenarios are considered in the interpretation of the origins of the apparent “non-local” individuals. Their ⁸⁷Sr/⁸⁶Sr levels are consistent with origins from e.g. the Baltic countries, northern Poland and Germany, southern Sweden, and Denmark, all underlain by Phanerozoic sedimentary rocks. However, immigration within Finland can't be excluded. Although high ⁸⁷Sr/⁸⁶Sr values typical for the Precambrian rocks constituting most of the Fennoscandian Shield are expected throughout Finland, also regions with bedrock ⁸⁷Sr/⁸⁶Sr ratios <0.715 have been modeled to occur. A third, alternative scenario arises from the possibility of heavy usage of aquatic resources from the brackish northern Baltic Sea with current ⁸⁷Sr/⁸⁶Sr values at 0.7094-0.7096. Due to the influence of strong isostatic uplift, the coastal waters were only at a ~25 km distance from the site during the Iron Age and attainable via the Kyrönjoki river. Incorporation of Baltic fish and seals, would result in lower ⁸⁷Sr/⁸⁶Sr values of consumers than expected based on local terrestrial/freshwater resources only. Despite the site's inland location, Baltic resources were likely significant for prehistoric subsistence in the area highlighting the need to carefully consider how we determine values defining “local”.

Strontium isotopes reveal new insights into the complex life history of modern and ancient fish in California

Malte Willmes, Levi S. Lewis, James A. Hobbs
University of California, Davis, Davis, USA

Abstract

The San Francisco Estuary is the largest estuary along the west coast of the United States and a vital link in California's water supply. It provides a complex, dynamic and productive habitat but over the last centuries has been highly altered and degraded by human impacts. This resulted in the loss of numerous ecosystem functions and in the rapid decline of many native fish species, causing significant conflict about the use of limited freshwater resources.

Comprehensive life history and migratory patterns of impacted species are needed to guide future conservation and water management efforts. Fish otoliths (ear bones) consist of continuously-accreted calcium carbonate, thus providing a life-long archive of the environmental conditions each individual has experienced. Strontium isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$) in fish otoliths can be used to reconstruct the use of different watersheds in freshwater systems and the use of habitats with varying salinities in estuaries. Thus, they can be used as a powerful tracer to reconstruct migration, habitat utilization, and life history diversity in both modern and ancient fishes (Fig. 1).

We applied strontium isotope analysis to several threatened and endangered fish species in the San Francisco Estuary, including the iconic Chinook Salmon and the threatened Longfin and Delta Smelt to quantify and reveal their life history diversity across the recent drought and flood periods. We have also examined similar patterns in archaeological Chinook Salmon otoliths collected from Native American middens to examine life history complexity in the Estuary prior to the Gold Rush in the 1850s.

Our findings show that strontium isotope analysis greatly enhances our understanding of the diversity of live histories utilized by each species. Furthermore, by combining life history reconstructions with environmental data (temperature, fresh-water outflow), we can investigate the underlying drivers and mechanisms of movement patterns, which can lead to more effective water management and conservation efforts.

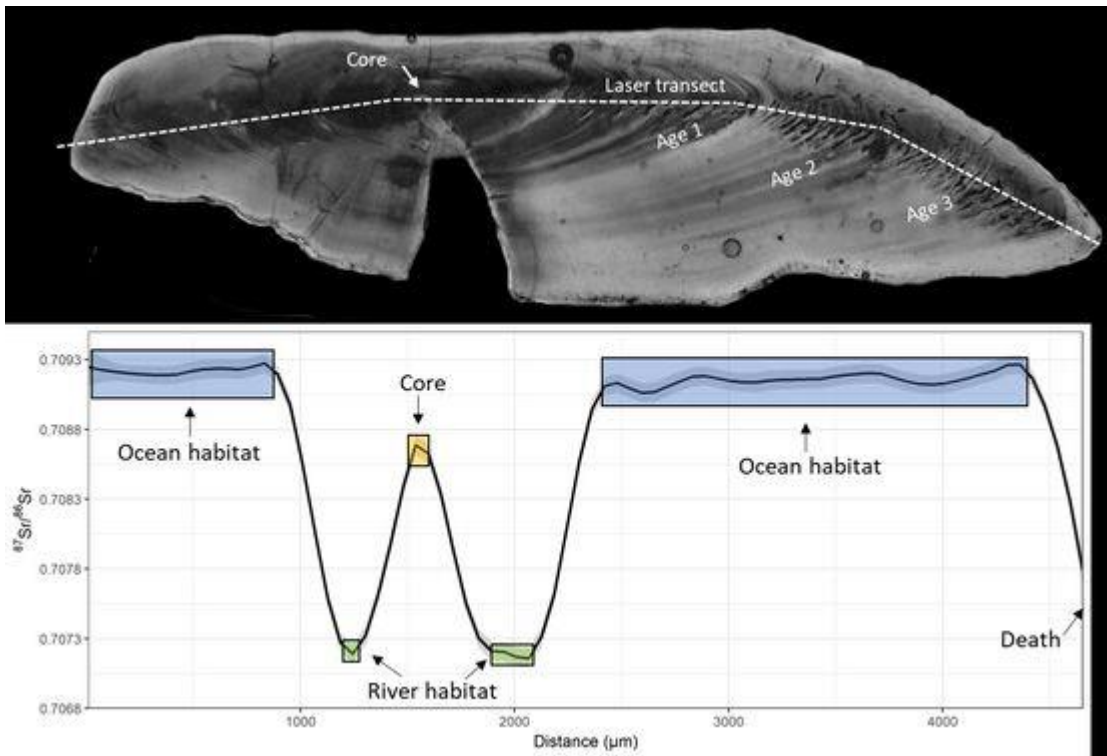

Fig. 1: Otolith cross-section and strontium isotope profile of a 3-year-old Chinook Salmon (*Oncorhynchus tshawytscha*). Variation in strontium isotope values reflects natal riverine habitat, rapid migration through the estuary, multiple years spent in the coastal ocean as an adult, and a return to freshwater habitats to spawn prior to death.

Collaborative RESPONSE to Rapid Climate Change Impacts on Greenlandic Heritage

Thomas McGovern
CUNY, New York, USA

Abstract

Both the scientific record and local and world cultural heritage are threatened by accelerating climate change, especially evident in the circumpolar north. Science and Heritage organizations are joining with local communities to respond to these threats and this paper presents one such partnership building upon multiple seasons of archaeological and paleoecological research and a community focused field school in SW Greenland. The RESPONSE Project Greenland is an international collaborative project sponsored by the *North Atlantic Biocultural Organization* (NABO, www.nabohome.org), the *Integrated History and Future of People on Earth* program (IHOPE, <http://ihopenet.org/global-environmental-change-threats-to-heritage-and-long-term-observing-networks-of-the-pas/>) and the *Humanities for Environment Circumpolar Observatory* program (<https://hfe-observatories.org/observatories/circumpolar-observatory/>) with funding support from the US National Science Foundation. It involves an international interdisciplinary team of researchers from Greenland, US, Canada, Denmark, Norway, Poland and the UK, host Greenlandic institutions, field school students and indigenous scholars in a coordinated effort to rescue an archaeological and paleoecological record threatened by both accelerated marine erosion and rising soil temperatures. The “melting middens” phenomenon is now well documented by the Danish REMAINS project which has established the biochemical tipping point that transforms excellent organic preservation in stratified archaeological sites into unrecoverable mush in a few years. The work of the 2011-18 NSF NABO Comparative Island Ecodynamics project has underscored the extent of the damage: of 97 sites tested only three retained significant organic preservation. The new NABO RESPONSE project will work to rescue excavate archaeological midden deposits, Norse cemeteries, and Colonial era mission settlements while expanding the ongoing Greenland National Museum and Archives site survey and documentation program. The RESPONSE project also will work to extend the paleoecological record through bog and lake coring and extensive geo-archaeological sampling of home fields to reconstruct long term human ecodynamics. It will also work to build Greenlandic capacities for further heritage rescue and conservation work and aid early career Greenlandic and international student engagement. The Swedish Bifrost (<https://hfe-observatories.org/projects/bifrost-online/>) environmental media project will document the work to provide professionally-produced digital resources for public communication and education on climate change.

When you can't save them all: cultural heritage loss on Alaska's North Slope

Anne Jensen

University of Alaska Fairbanks, Fairbanks, AK, USA. University of Alaska Museum of the North, Fairbanks, AK, USA.
Bryn Mawr College, Bryn Mawr, PA, USA

Abstract

Archaeological sites are important sources of data on past human behaviour, as well as valuable resources for paleoenvironmental reconstruction. They can also inform attempts to strengthen resilience and to adapt to environmental change in a sustainable and culturally appropriate way. Just as new methods increase our ability to access information from these sites, accelerating environmental change poses a dire threat.

Equally importantly, they are part of the tangible cultural heritage of descendant communities, and of humanity writ large. For indigenous peoples, many of whom have been subject to extremely rapid cultural change, often imposed from the outside, sites can be an important part of sustaining and even revitalizing cultures under pressure. This too is threatened by site loss.

The scale and urgency of the global threat requires new models for funding, education and recruitment of staff, engagement with the public and long-term curation of rescued samples.

This paper will describe the situation in the area of Utqiagvik (formerly Barrow), Alaska, where multiple important sites are under threat and some have already been lost entirely. Responses (both current and planned) will be highlighted, as will the challenges that are magnified by remote location and extreme climate.

Multiple approaches to investigating climate change impacts on coastal heritage in Ireland and Wales: The CHERISH project.

Sarah J. Davies¹, Louise Barker², James Barry³, Anthony Corns⁴, Kieran Craven³, Sean Cullen³, Toby Driver², Geoffrey A. T. Duller¹, Hywel Griffiths¹, Sandra Henry⁴, Daniel Hunt², Cerys Jones¹, Henry F. Lamb¹, Edward Pollard⁴, Helen M. Roberts¹, Patrick J. Robson¹, Robert Shaw⁴, Hollie Wynne¹

¹Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom. ²Royal Commission on the Ancient and Historic Monuments of Wales, Aberystwyth, United Kingdom. ³Geological Survey of Ireland, Dublin, Ireland. ⁴Discovery Programme: Centre for Archaeology and Innovation, Ireland, Dublin, Ireland

Abstract

The winter of 2014 was exceptionally stormy in the British Isles, with major damage on coasts exposed to the North Atlantic. Combined with the impacts of subsequent individual events, such as Ex-Hurricane Ophelia in October 2017, this recent stormy period has highlighted the vulnerability of coastal communities to current and future climate change. Attention has generally focused on impacts to infrastructure, property and communities, with less emphasis on implications for coastal heritage that are important from both a cultural and economic perspective. CHERISH (Climate, Heritage and Environments of Reefs, Islands and Headlands) is a five year, multi-disciplinary project supported through the Ireland-Wales Territorial Co-operation Programme (2014-2020) which is focusing on past, present and future climate change impacts on coastal heritage in Ireland and Wales.

Aerial survey, including high resolution LiDAR imagery is providing new details of the nature and extent of historic assets in understudied, remote areas such as the Welsh islands. Crop marks produced during drought conditions of summer 2018 have revealed previously unrecorded coastal archaeology within our study areas. The combination of aerial and ground-based survey, which includes high-resolution laser-scanning and geophysical survey enables detailed recording and monitoring of sites at risk from coastal erosion and storm impacts. Palaeoenvironmental records from coastal lakes and bogs are being developed to investigate long term patterns of storminess across the study area. Integration of palaeoenvironmental evidence with archaeological excavations and documentary records at key sites is revealing valuable insights into human-environment interactions in these dynamic coastal environments at a range of timescales. High-resolution mapping of the seabed around islands and headlands and detailed monitoring of selected submerged cultural heritage assets is being undertaken, representing an integrated approach to investigating onshore and offshore heritage and landscape change.

Data gathering on land, at sea and from air to investigate coastal heritage around the Irish Sea provides valuable baseline data for monitoring of risks to historic assets, helps to determine rates of loss at vulnerable sites, and sets contemporary risks within a long term framework of North Atlantic Holocene climate variability. Detailed evidence from selected case study sites offers mitigation towards the likely future loss of heritage assets, archaeological, and palaeoenvironmental archives. These case studies also represent opportunities to raise awareness of the implications of climate change for coastal communities, and provide an evidence base to inform management and policy decisions.

Understanding the Impacts of Climate Change on Cultural Heritage Buildings: A Case of UNESCO World Heritage Site, India

Shailendra K. Mandal¹, Supriya Rani²

¹National Institute of Technology Patna, Patna, India. ²Patna University, Patna, India

Abstract

Cultural heritage is not only an important part of a country's cultural identity but also a key driver of economic activity which can play an important role in a nation's economic and social resilience. Nevertheless heritage buildings are gradually becoming more vulnerable, due to physical decay and deterioration, effects of climate change, and human-induced impacts, such as poor or ineffective maintenance. An increased number of climate events, many of which are associated with the impacts of climate change, are posing considerable problems in managing and preserving cultural heritage around the world. Being exposed to a number of climate hazards and having a great cultural heritage, The Nalanda University ruins in state of Bihar in India presents a case study that provides the basis for the consideration of the strategies required for losing legacy of cultural heritage buildings. Through the commitment with practitioners responsible for the management of a range of cultural heritage sites, this paper identifies the challenges faced when considering climate change adaptation measures. It discusses that enhanced climate change adaptation and improved hazard mitigation strategies, involving a broad range of rightly trained stakeholders, are extremely important considerations when it comes to the assessment, maintenance and conservation of UNESCO World Heritage site.

O-0152

Sea Level Rise, Predictive Modeling and Heritage Resources in Delaware's Inter-Tidal Zone: Indicators from Shepard's Island

Heather Wholey, Daria Nikitina, Kyle Knox, Michael Powers
West Chester University, West Chester, USA

Abstract

The Delaware Bay is the second largest estuary along the U.S. Atlantic coast and is experiencing some of the gravest effects from Sea Level Rise. Most of the estuarine shoreline is fringed by salt marshes that have been developing for the past 2,000 years but are now being lost at a rate of up to an acre/day. The trend suggests that much of the Delaware Bay wetlands may convert to open water at a variable rate, and that about 10% of documented archaeological and historic resources will soon be inundated or surrounded by salt marsh. A multi-disciplinary pilot project targeted the Milford Neck portion of the Delaware Estuary. Sediment cores were extracted from the marsh adjacent to Shepard's Island, a dryland hummock surrounded by salt marsh, to document marshland border changes over time and to estimate future changes. An archaeological survey on the hummock itself yielded evidence for human occupation. Using stratigraphic data, ArcGIS modeling, and paleo-environmental and SLR history, we reconstructed the Holocene coastal landscape at Sheppard's Island and developed predictions for future changes. Existing predictive models suggest these hummocks within the intertidal zone are low probability for archaeological recovery. The Shepard's Island survey results contradict this and reveal that sites in these locations are on the front-line for experiencing adverse effects from SLR. These landscapes serve as harbingers for the impacts of environmental changes on cultural resources along the estuary.

Research on plant utilization and adaptation to environment of human of Yahuai cave site during the latest 20 ka BP

Yan Wu

Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China

Abstract

It is an important scientific problem in the study of the relationship between man and land to select the key areas and important periods of human evolution. South China has a unique geographical landscape pattern and unique vegetation and climate background, which is not only an important channel for the diffusion and migration of ancient humans but also an ideal refuge to avoid climate changes. It preserved the rich archaeological remains of the evolution and development of human beings, and provided a rare place for the adaptive strategies of human survival and the early environment. However, few plant utilization research works have so far been done in this area. In this paper, the Yahuai cave from Guangxi Zhuang Autonomous Region, South China is selected for investigation. The Yahuai cave site is a very important site in the prehistoric archaeology in South China and Southeast Asia, where a well-preserved ancient human skull fossil is found. We analyzed the continuous accumulation of ancient cultural and natural remains, and utilized AMS¹⁴C dating to reconstruct the chronological framework. Flotation and pollen analysis were first conducted to identify these samples. However, few macroremains and pollen were recovered from this site. Therefore, phytolith analysis was employed as an important research method in this project. By phytolith analysis of soil samples, we extracted the plant information and analyzed the human usage of plant resources. It is the first time that wild rice was found at 16000BP based on the phytolith record. The presence of wild rice is one of the essential elements for identifying the origins of rice cultivation and domestication. This finding provides a prerequisite for the origin of rice. Besides, Bambusoideae, and palm were also identified at different periods. A wide collection and utilization of plant resources from Yahuai cave site revealed the ways and strategies of human being's adaptation to the environment during the latest 20000 years.

O-0155

Quaternary stratigraphy solves engineering geology problems; two case histories from Utah, USA

James McCalpin

GEO-HAZ Consulting, Inc., Crestone, USA

Abstract

Two geologic hazard case histories from Utah, USA show the importance of understanding Quaternary stratigraphy in engineering geology investigations. The Eaglepointe landslide occurred on 05-AUGUST-2014 in a developed area of North Salt Lake City, Utah, USA and measured 150 m wide and 175 m long. The failed slope is underlain by ~ 20 m of lakeshore sands and gravels from pluvial Lake Bonneville (15.5 to 18 ka), which overlie altered Tertiary volcanic rocks. The style and orientation of the landslide are not compatible with the strike-and-dip of bedding in volcanic rocks (i.e., a translational slide or wedge failure). Four geotechnical boreholes had been drilled on the slope prior to 2014, and another 16 after failure. Boreholes revealed that a 2 m-thick weathering zone (paleosol) had developed on the volcanic rocks prior to their burial by the Bonneville shoreline sediments. The paleosol has lower shear strengths than the in-situ bedrock, and also forms a perched water table beneath the permeable Quaternary sandy gravels. At the landslide site the paleosol slopes north, in the direction of today's surface slope (not in the direction of bedrock dip), and forms the 2014 failure plane. The failure plane is thus controlled by a thin Quaternary paleosol (not bedrock), developed on a complex paleotopography of the Wasatch Range front (basal faceted spurs eroded by gullies), all buried by 20 m of Quaternary gravels. This subsurface complexity was not detected in pre-development geotechnical studies.

In the same year but 350 km farther south, the Chief Toquer [earthfill] Dam was being constructed on the footwall of the active Hurricane Fault. The cut-off trench exposed numerous normal faults in bedrock, but site engineers could not determine if the faults were active by regulatory definition (movement younger than 35 ka), which if true would have posed a major constraint. The dam footprint overlaps the active channel of a fault-parallel stream and three higher Quaternary terraces. Our soil chronosequence suggests Terrace 1 (oldest) is >125 ka, Terrace 2 >35 ka, and Terrace 3 Holocene, whereas OSL ages indicate T1 is ca. 50 ka, T2 35 ka, and T3 19 ka. None of the hundreds of bedrock faults visibly displace alluvium >35 ka, which covers 85% of dam length (therefore, faults there are not active). In the remaining 15% of the dam alluvium over the faults is <19 ka, so even though alluvium is not displaced, fault movement younger than 35 ka (but older than 19 ka) cannot be precluded. This example shows a weakness of using age-based definitions of hazard "activity", because the critical Quaternary isochron may not exist at your project site.

O-0156

Study on spatial-temporal distribution characteristics and forming mechanism of landslides in the Meigu River basin of China

Zhiqiang Yin¹, Dong Sun², Hai Shao¹

¹China Institute of Geo-environment Monitoring, Beijing, China. ²Chengdu Center of Hydrogeology and Engineering Geology, Sichuan Bureau of Geology & Mineral Resources, Chengdu, China

Abstract

The Meigu River basin, which is located in the uplift area of the Qinghai-Tibet Plateau, is characterized by the development of fault and folds. Due to special landform patterns, a large number of large scale landslides with complex genesis mechanisms that caused heavy damage. In order to reveal the temporal and spatial patterns and formation mechanisms of landslides controlled by this special landform with oblique valleys and anticline mountains, on the basis of investigation and comprehensive analysis in the Meigu River basin and using the interdisciplinary ways of Quaternary geology, engineering geology and tectonic geology, the temporal and spatial distribution characteristics of landslides in the basin, the relationships between the development position of landslides and active faults, folds, joints *etc.*, the main controlling factors of the engineering geological rock groups are susceptibility to landslide were all systematically studied, then have achieved the following conclusions: 1) The Meigu River Basin belongs to the coincident tectonic landform under the control of tectonic uplift, with typical features of oblique valleys and anticline mountains. There were 18 faults and 27 folds with a certain scale in the basin by field investigations, and there is a good correlation between the occurrence time of landslide and the active period of fault. 2) There are 161 landslides in the basin which is the most important types of geohazards in the basin, and the development and distribution characteristics of landslides are significantly different due to the differences in topography and geomorphology of the upper, middle and lower reaches of basin. These landslides are spatially distributed "along the river", "along the fault zone", and "oblique core". And there are mainly five development stages: middle and late Pleistocene, late Pleistocene, 200 a B.P., 1980s and 1990s and modern times. 3) Fracture activities, folds, joints, and soft interlayer in rock mass have unique control patterns over the landslides development process since the mid-late Pleistocene. Fault fractures and folds are the main controlling factors over landslides in the region. 4) T_3xj 、 J_2s 、 $T_{1-2}d$ of soft interlayer in sand-mudstone are the most prone sites for landslides (easy-slide rock mass groups), therefore, they are also the key areas for preventing landslide hazards in the future. All these results provide new technical theoretical support for landslide research and disaster prevention and mitigation in the similar regions of the plateau and surrounding areas.

Unprecedented riverbank collapse during Australia's 'Big Dry': a spin-off consequence of the River Murray's late Quaternary depositional history

Elyssa De Carli^{1,2}, Ian Rutherford³, Dan Penny², Tom Hubble²

¹The University of Wollongong, Wollongong, Australia. ²The University of Sydney, Sydney, Australia. ³The University of Melbourne, Melbourne, Australia

Abstract

Much of Quaternary science is about the genesis of sedimentary deposits and interpreting the depositional histories of environments to the present-day form. These are the deposits and legacy environments that civil engineers then work and build in (e.g. floodplains, coastal deposits, slope-deposits). In the northern hemisphere, there is a long relationship between engineers and Quaternary scientists around glacial and peri-glacial deposits, where Quaternary science helps to explain the spatial distribution, properties and mechanical behaviour of engineering materials (Groot & Griffiths, 2001). In Australia, this intersection is less common and obscured by nomenclature, with much of the overlap found in the 'regolith' literature (e.g. Taylor & McNally, 2001). Here we provide an example of an intersection between engineering and Quaternary science where a thorough understanding of geomorphology and depositional histories helped to solve a modern-day riverbank collapse problem.

During very low river levels in the Millennium Drought (1997-2011), known colloquially as Australia's 'Big Dry', long sections of river bank along the lower River Murray in South Australia collapsed, threatening many social and economic assets. Not only did these failures represent rapid geomorphic change in a reach that is normally considered very stable, but they also occurred during long periods of extremely low flows. This phenomenon is unusual and unprecedented as bank failures are typically associated with the recession of high-energy floods rather than with prolonged drought.

Geotechnical investigation found a soft clay deposit in the riverbank stratigraphy at four sites along the River Murray, concluding that "during periods of low river level it should be assumed that riverbank collapse could occur where the riverbanks are underlain by the soft clay" (SKM, 2010; Coffey, 2012). The origin of this geotechnically problematic unit and its regional extent was unknown. Subsequent drilling by our team revealed a fine-grained soft clay deposit dominated the Holocene upper valley-fill as a single stratigraphic unit over an 80km reach of river, between 10 to >50m thick in its down-valley extent. When placed within the context of the late Quaternary environment and the depositional history on an incised valley system, interpretation of physical and mechanical properties of the deposit identified a central basin environment evolving under highstand conditions. Mapping the extent of the stratigraphic unit/central basin within this geomorphic framework allowed us to determine and constrain the extent of the riverbank collapse hazard and predict where future bank-failures will take place along the lower River Murray, focussing management strategies during future low flows. A thorough understanding of Quaternary environments and their depositional histories is particularly useful to engineers at the interface of coastal and fluvial environments, considering that these environments and often complex stratigraphic units form the building foundations for most of the world's cities.

O-0158

Geological anomalies within the London Basin, United Kingdom; their engineering impact, morphology and possible formation theories.

Amy Flynn, Philip Collins, Peter Reading, Lorna Anguilano
Brunel University London, London, United Kingdom

Abstract

Engineering projects in London are increasingly using the subsurface, making it essential to understand the geological context. A number of geological anomalies within the London Basin have commonly been grouped together and named “drift-filled hollows” (DFHs). These are typically interpreted as closed depressions, developed into the local rockhead (mainly the London Clay Formation) and infilled with a melange of unconsolidated, superficial deposits, including Quaternary fluvial sand and gravel. DFHs are challenging to engineers due to the difficulty in identifying the features from the surface, the risk of missing the features during site investigations due to the limitations of boreholes, and their differing geotechnical properties compared with the predicted and surrounding clay strata. Potential risks include: differential settlement, possibly to nationally significant infrastructure and during sub-surface construction; tunnel face collapse; water ingress; and delayed timelines due to machine breakages. This can lead to increased costs and potential loss of life.

Information on over 80 DFHs within Central London has now been collated and assessed - the largest dataset compiled to date. The features range in size from 5-500m in width and up to 75m deep. Many of the deeper features breach to the local bedrock and have evidence of faulting associated within or surrounding the feature. Some also have a diapir of lower strata upwelling within the depression. A major outcome has been identifying the spatial and vertical variability between and within features using both CPTu and borehole samples, suggesting they reflect a range of processes.

The features are not just of significance to Civil Engineers, but to the earth surface processes community due to both uncertainty about the processes which led to their formation and their potential for palaeo-environmental reconstructions (Collins et al., 1996). Three main hypotheses have been proposed: fluvial scour at river confluences (Berry, 1979), periglacial activity through the formation of pingos (Hutchinson, 1980) and dissolution-related subsidence (Collins et al. 1996). These explanations remain problematic due to a lack of diagnostic physical evidence identified within borehole samples. This talk will focus upon the limitations of existing hypotheses, further possible formation hypotheses and the difficulties in studying these features due to both their variability and samples only being available through boreholes.

The Anthropocene and environmental sustainability: An investigation of rural to urban watersheds Black Hawk County (Iowa, U.S.A.)

Chad Heinzel¹, Joshua Balk², Mohammad Iqbal¹, Danika Patten³

¹University of Northern Iowa, Cedar Falls, USA. ²Black Hawk Soil and Water Conservation District, Waterloo, USA.

³AmeriCorps - Land and Water Stewards Project Coordinator, Cedar Falls, USA

Abstract

Two rural to urban tributaries, Dry Run Creek (DRC, HUC12) and Black Hawk Creek (BHC, HUC10) Watershed, to the Cedar River are located Northeastern Iowa. These streams are heavily influenced by agricultural runoff in its upper reaches then become heavily urbanized as they travel through the cities of Cedar Falls and Waterloo (pop. 109,157) before draining into the Cedar River. The streams are perennial, however most first-ordered segments have been agriculturally tiled increasing base-flow in second and third-ordered stream segments. A previous, 2005, DRC study identified factors that led to DRC being placed on Iowa's 303(d) impaired streams list, lack of aquatic diversity (2002) and high bacteria levels (2008). Recent, DRC and BHC watershed evaluations identified changes to their urban and rural reaches. As the watersheds' urbanization (population and/or agricultural) continues land use and bank stability are becoming significantly impacted/compromised. Comparative findings over the past twelve years indicate: Bank stability improved slightly, canopy cover decreased by 10%, point source drainage increased by 7%, urbanization increased by 22%, and stream variability decreased by 8%. Further laboratory investigations seek to characterize DRC's, physical (particle-size analyses) and chemical properties (aqueous - ICP-MS). Black Hawk Creek baseline stream data were also recorded for comparative analyses every two years.

Work by the Black Hawk County Soil and Water Conservation District, the Dry Run Creek Advisory Board, Iowa Department of Natural Resources, University of Northern Iowa and others have made positive impacts on local watersheds. Native vegetation (shade tolerant – prairie grass plugs), May 2018, were planted near the UNI Water Monitoring Well site, creating a natural buffer that seeks to decrease runoff and reduce bank erosion, increasing bank stability. The UNI bank stability site provides local communities an opportunity to view 'best practices'. Watershed (DRC and BHC) citizens are encouraged to participate in geologic and water monitoring or other conservation efforts: rain barrels, permeable pavers, rain gardens and prairie strip. One climate change outcome appears to be the intensification of precipitation events; three of the highest/intensity rainfall events in the past forty years were recorded in 2018. As urbanization and agricultural practices continue to reshape our watershed, understanding how these activities accentuated by a changing climate will alter DRC and BHC processes and habitats. Our primary goal is to build meaningful relationships between the Dry Run Creek Watershed Advisory Board, University of Northern Iowa, local preK-12 schools, local Water Management Authorities (WMA) and communities/citizens within the Middle Cedar Watershed. These efforts seek to improve our watershed's geo-ecological health through applied geoscience, education outreach, and political engagement; ideally leading to an environmentally sustainable present and future.

Assessment of flood vulnerability using GIS tools: A case study of the central High Atlas of Azilal (Morocco)

Fatima El Bchari¹, Abdellatif Souhel²

¹Polydisciplinary Faculty, Safi, Morocco. ²Faculty of Sciences, El Jadida, Morocco

Abstract

Climate change has increased the severity of weather-related natural disasters such as flash flooding, riverine flooding, coastal erosion, lightning and fires (IPCC,2012). The occurrence of extreme meteorological events is increasing as well in the area of the mountains of Morocco. Thus, this research considers the support provided by remote sensing and GIS data for the delineation of potential sites susceptible to natural hazards such as flash floods, storms, droughts, and landslides.

The present study focuses on an assessment of flood hazard areas in the High Atlas of Azilal (Morocco) where it has suffered from flood in every year with different extents.

Spatial analysis in GIS environment has been applied for the estimation of flood risk zones in which seven relevant physical factors have been selected namely, rainfall, slope, aspect, elevation, distance from stream, land use and lithology. The relative importance of physical factors has been compared in pairwise matrix to gain the weight values during the process of Analytical Hierarchy Process (AHP). The flood hazard zones have been mapped according to their weights. It has been Tillouguit, Tabant and Rbat region are identified as the high risk zones of flood.

Proposed methodology for the assessment of flood hazard and elaboration of maps of flood vulnerability by Analytical Hierarchy Process in GIS environment is a first step in development of the information system for integrated risk assessment from natural disasters.

Remote sensing application to the mapping of built-up areas exposed to flood and runoff hazards in sedimentary basin in Benin

Oussen AROUNA¹, Eric ALAMOU¹, Abib Guimmongui SABI OROU BOGO²

¹National School of Public Works, National University of Sciences, Technology, Engineering and Mathematics (NUSTEM), Benin, Abomey, Benin. ²Laboratory of Cartography, University of Abomey-Calavi, Benin, Abomey-Calavi, Benin

Abstract

The sedimentary basin made up of bar earth with a high clay content is subject to flooding and runoff phenomena despite significant investments made by donors, the Beninese government and local authorities to set up several stormwater treatment facilities. This research aims to determine the cause of the persistence of flooding and runoff in the sedimentary basin despite the existence of large stormwater treatment facilities. The methodological approach is based on remote sensing and the Geographic Information System (GIS). To this end, Quickbird images with a resolution of 0.6 m in panchromatic and 2.4 m in multispectral were used to extract the "built-up area" class using Ecognition software. The mapping of the areas exposed to flood and runoff hazards was carried out by simulating a ten-year return period rainfall (2-hour rainfall with an intensity of 50 mm/h) with the HEC RAS 2D modelling software on the basis of a Digital Elevation Model (DEM) developed from Shuttle Radar Topography Mission (SRTM) data at 1 arc/s. The intersection of the "flood and runoff hazard zone" layer with the "built-up zone" layer using QGIS software identified the built-up areas established in flood and runoff hazard areas. In total, 62% of built-up areas are built in natural stormwater flow paths and areas exposed to runoff. Flooding and runoff problems are then more related to the uncontrolled occupation of urban space than to the inadequacy of stormwater treatment facilities and the geological characteristics of the sedimentary basin.

Keywords: sedimentary basin, remote sensing/GIS, floods, runoff, Benin.

Dynamic of glacial to interglacial transitions inferred from multi-proxy analysis in ice cores

Amaelle Landais

LSCE/IPSL (CNRS/CEA/UVSQ/UPS), Gif sur Yvette, France

Abstract

Polar ice cores are unique climate archives providing continuous stratigraphy for the last 800 000 years with a relatively high temporal resolution (annual for the last 60 000 years). They are particularly well adapted to study the dynamic of the glacial to interglacial transitions and link with external and internal forcings (orbital configuration, greenhouse gases concentration). Indeed, they provide direct access to the past atmospheric concentration through air trapped in ice cores and a wealth of dating tools are available. Finally, the recent developments of ice core proxies now permit to have access to low latitude proxies in polar ice cores hence providing sequence of high vs low latitude events without chronological uncertainty on the same archive.

I will present recent developments for ice core dating and combination of low and high latitude proxies in ice cores. The sequence of events over several key transitions between glacial and interglacial periods (Termination I, Termination II, Termination III and Termination V) will be discussed based on recent and new ice core records showing the interplay between orbital forcing, greenhouse gases concentration and millennial scale variability at low and high latitude.

Human-induced marine ecological degradation: historical ecology and the Anthropocene

Moriaki Yasuhara

University of Hong Kong, Hong Kong, Hong Kong

Abstract

We analyzed published downcore microfossil records from 150 studies and reinterpreted them from an ecological degradation perspective to address the following critical but still imperfectly answered questions related to the Anthropocene: (1) How is the timing of human-induced degradation of marine ecosystems different among regions? (2) What are the dominant causes of human-induced marine ecological degradation? (3) How can we better document natural variability and thereby avoid the problem of shifting baselines of comparison as degradation progresses over time? The results indicated that: (1) ecological degradation in marine systems began significantly earlier in Europe and North America (~1800s) compared with Asia (post-1900) due to earlier industrialization in European and North American countries, (2) ecological degradation accelerated globally in the late 20th century due to post-World War II economic growth, (3) recovery from the degraded state in late 20th century following various restoration efforts and environmental regulations occurred only in limited localities. Although complex in detail, typical signs of ecological degradation were diversity decline, dramatic changes in total abundance, decrease in benthic and/or sensitive species, and increase in planktic, resistant, toxic, and/or introduced species. The predominant cause of degradation detected in these microfossil records was nutrient enrichment and the resulting symptoms of eutrophication, including hypoxia. Other causes also played considerable roles in some areas, including severe metal pollution around mining sites, water acidification by acidic wastewater, and salinity changes from construction of causeways, dikes, and channels, deforestation, and land clearance. Microfossils enable reconstruction of the ecological history of the past 10^2 – 10^3 years or even more, and, in conjunction with statistical modeling approaches using independent proxy records of climate and human-induced environmental changes, future research will enable workers to better address Shifting Baseline Syndrome and separate anthropogenic impacts from background natural variability.

The impact of watershed restoration on marine sediment dynamics in coastal and coral reefs environments, US Virgin Islands

Sarah C. Gray¹, Carlos Ramos-Scharrón², Gregg Brooks³, Rebekka Larson³

¹University of San Diego, San Diego, CA, USA. ²University of Texas, Austin, TX, USA. ³Eckerd College, St. Petersburg, FL, USA

Abstract

Terrigenous sediment derived from unpaved roads is a significant stressor to coral reefs in the high-relief island of St. John, US Virgin Islands. The 10.7 km² Coral Bay watershed was the focus of a NOAA-ARRA watershed restoration program completed in 2011, which included: sediment retention structures, road drainage improvements, and limited road paving. A seven-year terrestrial-marine monitoring program to assess the effectiveness of this restoration at multiple spatiotemporal scales measured: (a) terrestrial erosion and runoff-sediment yields; (b) time integrated (sediment traps) and high resolution (nephelometers) marine terrigenous sedimentation and turbidity at shoreline and coral reef sites; and (c) sediment "residence time" using short-lived radioisotopes (SLR) in developed/restored and minimally developed sites.

Watershed erosion, sediment yields, terrigenous sedimentation, and coral exposure to sedimentation stress were significantly greater below developed compared to minimally developed watersheds. Restoration program paving reduced road-segment-scale erosion rates to 4-29% of pre-paving rates, but watershed modeling showed that ~90% of the ~110 Mg yr⁻¹ reductions were due to sediment retention ponds. In the marine environment, resuspension contributed more to turbidity and deposition than shorter lived (hours) runoff plumes, and limited the ability to resolve changes post-restoration in the potential exposure of corals to sedimentation stress. However, ⁷Be activity measured in offshore reef sediment traps suggests that a relatively short (months) time scale of connectivity between watershed and reef sedimentation.

Due to resuspension, statistically significant pre- vs. post- restoration reductions in marine sedimentation were not measured. However, significant decreases in % clay and terrigenous sediment were found below the restored watersheds post restoration. These data suggest that % clay (rather than reduced total sedimentation) may be a more sensitive tracer of effective restoration, which targets sediment input from unpaved roads.

Lessons learned from the Coral Bay watershed restoration and monitoring program may serve to inform the development of effective management and monitoring strategies that may be applied to other areas with similar ephemeral hydrologic behavior. Long term (several seasons) integrated terrestrial- marine monitoring is essential to quantify the habitat impact of watershed restoration and must include regular coordination and data sharing between a multidisciplinary team of scientists, community members, and the sponsors.

Climatic and human impacts on Si cycling in the Chesapeake Bay

Carla Nantke¹, Patrick J. Frings², Johanna Stadmark¹, Markus Czymzik³, Daniel J. Conley¹

¹Geology Department, Lund University, Lund, Sweden. ²GFZ, GeoForschungsZentrum Potsdam, Potsdam, Germany.

³IOW, Leibniz Institute for Baltic Sea Research, Rostock, Germany

Abstract

Coastal marine ecosystems form the transition zone between the terrestrial and marine Si cycles. Short residence times make the nutrient cycles in coastal zones sensitive to local to global changes in environmental conditions and human disturbances. Si isotopes help us to link variations in the terrestrial Si cycle triggered by climate change and/or human activity.

The Chesapeake Bay, an estuary on the North American East Coast, is a well-suited study site with a constrained settlement history (European settlement around 250 a BP). Different sedimentary proxies record the influence of climate variations, land-use changes and altered nutrient fluxes since ~12,000 a BP. To investigate variations in Si fluxes during the Holocene we measured biogenic silica (BSi) concentrations and $\delta^{30}\text{Si}$ in hand-picked centric diatoms from two sediment cores: one located proximal to the main inflow Susquehanna river, the other closer to the Atlantic. $\delta^{30}\text{Si}_{\text{diatom}}$ varies between 0.8 and 1.7 ‰ in both sediment cores.

Calculated Si budgets for the modern Chesapeake Bay suggest 90% of Si consumption by diatoms, a much higher rate than previously assumed for estuarine systems. However, different trends at both core sites indicate the importance of regional influences like water-mixing conditions and Si inputs from the watershed. BSi fluxes for both sediment cores are mainly coupled with erosion events caused by sea-level rise and deforestation. Human activity modified Si cycling in the Chesapeake Bay: Variations in $\delta^{30}\text{Si}_{\text{diatom}}$ together with an increase in BSi fluxes since European settlement ~250 a BP indicate a distinct influence on the coastal Si cycle. Land-use changes in the watershed are likely to be the major cause altering Si budgets in the Chesapeake Bay.

Superimposing processes linked to climate change (precipitation, vegetation, sea-level) or human activity (agriculture, damming and nutrient supply), are difficult to disentangle in the complex Chesapeake Bay system. Lake sediments hold a great potential to provide high resolution-records of terrestrial Si fluxes to better distinguish individual processes influencing terrestrial Si fluxes.

Benthic foraminifera as potential proxies for environmental monitoring: A study from parts of south east coast of India

Jayaraju Nadimikeri

Yogi Vemana University, KADAPA, India

Abstract

India has 7,516 km of coastline, of which the mainland accounts for 5,422 km. As the coastal environments across the World have become very friendly for human development and diversity hence the high degree of pollution is expected in these places. Rivers which debouch into the Bay of Bengal after flowing long distance along the course collecting huge outlets of various domestic, industrial, agricultural and aquaculture contaminants from the estuaries at the Bay. Contaminants derived from river runoff have been shown to accumulate in estuarine sediments, reaching concentrations potentially capable of causing biological. Demonstration of effects, however, is difficult due to strong natural environmental gradients and the effects of past and present point source of contamination. The increased usage of pesticides and fertilizers in both agriculture and aquaculture sectors along the coastal tract of Andhra Pradesh has been one of the reasons for this environmental stress. The abundance, diversity, temporal and spatial distribution and test morphology of foraminifera in this environment can provide a proxy to reveal the present degree of pollution in the coastal environments of the study area, when related to the concentrations of heavy metals (Fe, Mn, Pb, Ni, Co, Cu). Recent benthic foraminiferal assemblages have been used as proxies to monitor the effects of pollution on the marine marginal waters. Benthic foraminifers are increasingly used as bio-indicators of environments at different levels of investigation. Community structures provide information on ecological conditions, especially in the highly changing parallel environments while some species are sensitive to species environmental parameters. Distributions of benthic foraminifers were significantly related to those of environmental variables and were ordinated along the axes that correlated both natural environmental variables and pollutants. Test morphology may also be related to environmental characteristics and is sometimes used as bio-indicator. For example, the size and density of the pores are considered as an indicator of the dissolved oxygen concentration. Recently, morphological abnormalities are increasingly taken as proxies. Morphological abnormalities of fossil and Recent foraminiferal tests have long been reported. This paper is to monitor the pollution effects on biota of the parts of south east coast of India. In order to avoid further damage to this coastal fragile ecosystem immediate safety measures have been suggested to the policy makers, public etc.,. This paper attempts to provide action plans for the policy makers to frame ideologies for the protection of the coastal environment.

Stable strontium isotopes ($\delta^{88/86}\text{Sr}$) as a salinity proxy in the lagoon-estuarine environments

Yuexiao Shao¹, Juraj Farkaš^{1,2}, Luke Mosley¹, Jonathan Tyler¹, Deborah Haynes¹, Briony Chamberlayne¹, Bronwyn Gillanders¹

¹University of Adelaide, Adelaide, Australia. ²Czech University of Life Sciences, Prague, Czech Republic

Abstract

Strontium (Sr) isotopes have been widely used in large-scale ecosystem and hydrological studies. Specifically, the $^{87}\text{Sr}/^{86}\text{Sr}$ is commonly used for tracing radiogenic processes such as water source mixing, while the newly employed stable $^{88}\text{Sr}/^{86}\text{Sr}$ (noted as $\delta^{88/86}\text{Sr}$) is sensitive to isotope fractionation processes such as carbonate formation. Combining the two isotope signatures in carbonate sediment archives and ambient water adds potential to reconstruct paleo-hydrology in carbonate-producing coastal environments. Importantly, the stable $^{88}\text{Sr}/^{86}\text{Sr}$ has been applied in recent years in coastal environments with fresh to marine salinity conditions, very few studies were conducted in hypersaline environments.

The Coorong hydrological system (Fig. 1), located ~100 km southeast to Adelaide, represents a unique 'natural laboratory' to calibrate novel and traditional isotope tracers in due to its unique geomorphology and large salinity gradient in water bodies ranging from fresh to hypersaline (from ~0 PSU to ~120 PSU, Fig. 2). This study aims to assess the radiogenic and stable Sr isotope ratios (i.e., $^{87}\text{Sr}/^{86}\text{Sr}$ and $\delta^{88/86}\text{Sr}$) in the Coorong lagoon waters, inorganic carbonates and bivalve shells *Arthritica helmsi* from sediment cores, and hence explore the potential of these isotope tracers to be used to reconstruct the paleo-hydrology in the Coorong throughout the recent thousands of years.

Figure 1: A map showing the Coorong Lagoon and Lower Lakes at the terminal end of the Murray River (i.e. Murray Mouth estuary) in South Australia (modified from Shao et al., 2018).

Hydro-geochemical signatures for the identification of seawater intrusion in paleobeach aquifer of Cox's Bazar city and its vicinity, Bangladesh

Ashraf Ali Seddique¹, Harue Masuda², Ryo Anma³, Yoriko Yokoo⁴, Yuta Shimizu⁵

¹Jatiya Kabi Kazi Nazrul Islam University, Mymensingh, Bangladesh. ²Osaka City University, Osaka, Japan. ³Tokushima University, Tokushima, Japan. ⁴Doshisha University, Doshisha, Japan. ⁵National Agriculture and Food Research Organization, Hiroshima, Japan

Abstract

In order to better understand the encroachment of seawater into the groundwater system a total 115 groundwater samples were collected in an area of $\sim 7\text{km}^2$ in Cox's Bazar paleobeach and its vicinity, from different *types of tubewells, which included hand pump fitted bore wells (<50m depth), moderately deep energized bore wells (50-100m depth) and deep bore wells (>100m depth)* during June 2013. A combined hydro-geochemical indicators, selected trace elements (Sr and B) and in addition to d^{18}O and d^2H were used in this study. Results show that the high values of EC (202 to $6730\mu\text{S}/\text{cm}$) and TDS (135 to $4509\text{mg}/\text{l}$) are found in groundwater of wells closer to the coast and few wells from the northern and central part of the study area. The cross plot of HCO_3/Cl and TDS shows that groundwater along the paleobeach and some isolated areas are saline with $\text{TDS} > 1000\text{mg}/\text{l}$, associated with high ratios of Cl/TDS (0.065). The groundwater facies generally evolves from freshwater (Ca-Mg-HCO_3) to saline water (Na-Cl) type with an intermediate Ca-Mg-Cl type indicating that the aquifer system interacts with seawater and undergoes cation exchange. Results also reveal that the area affected by marine water intrusion has ionic ratios of Br/Cl (0.0006 to 0.0021) similar to seawater (0.0015) with some higher values. Groundwaters along the paleobeach and some isolated areas, low ionic ratios of SO_4/Cl (0.01 to 6.53) and Na/Cl (0.20 to 152.09), relative to marine ratios (0.05 and 0.86 respectively), are also observed. Groundwaters with Seawater Mixing Index > 1.0 and $\text{TDS} > 1000\text{mg}/\text{l}$ constitute about 20% of the studied groundwaters and have relatively high $\delta^{18}\text{O}$ ($> -4.0\text{‰}$) values and the linear relationships between TDS and most of the ions, including B and Sr, and the chemical signature of the saline plumes (e.g., marine SO_4/Cl , Na/Cl and Br/Cl ratios) suggest that mixing processes control the chemical composition of the seawater within the aquifers. However, these geochemical variations also reveal that the quality of potable water has deteriorated to a large extent due to seawater intrusion along the paleobeach, migrating inland toward the heavily groundwater exploited areas from the coast line and may entail various future health hazards.

Key Words: Cox's Bazar, Paleobeach, Coastal groundwater, Seawater intrusion

O-1007

Climatic and anthropogenic controls on sediment sources, fluxes, and transport pathways to and across a formerly glaciated coastal zone

Christopher Hein, Elizabeth Canuel, Justin Shawler

Virginia Institute of Marine Science, College of William & Mary, Gloucester Point, USA

Abstract

Climate change and human modifications of linked riparian and coastal landscapes have altered the provenance, temporary storage reservoirs, and transport rates of sediments delivered to the coast, causing time-varying sediment fluxes to estuaries, wetlands, and beaches. This study explores the role of changing climate, sea level, and anthropogenic land use on sediment delivery to, and across, the formerly glaciated Merrimack River drainage basin and Plum Island barrier-backbarrier system (northern Massachusetts, USA) across multi-decadal to multi-millennial timescales. Using a suite of sediment cores collected across this barrier island and associated estuary, sedimentologic, bulk organic, biomarker, and organic and inorganic stable- and radio- isotopic proxies were used to reconstruct paleo-environmental changes and quantify time-varying sediment fluxes to the coastal zone following de-glaciation. Our results document that the source of sediment ($\sim 850 \times 10^6 \text{ m}^3$ total) delivered to the backbarrier bays, tidal flats, and marshes of Plum Island shifted from direct fluvial, to mixed estuarine and marine during a period of gradual deceleration of sea-level rise throughout the Holocene. This barrier-island system has remained relatively stable (progradational, aggradational) throughout the last 3500 years in response to continued sand inputs from the Merrimack River. However, low sediment accumulation rates (0.2 – 2.8 mm/yr) throughout the mid-to-late Holocene in the Merrimack River estuary and low modern total suspended sediment (9.0 – 15.0 mg/l) in the modern Merrimack River reflect an upstream landscape stripped of fine sediment by repeated Pleistocene glaciations; this presents a threat to continued health of backbarrier marshes as sea-level rise accelerates. In recent centuries, it is the human impact that has controlled coastal sediment delivery: for example, land clearing and river/coastal engineering increased estuarine sediment accumulation rates by an order-of-magnitude during the 17th to 19th centuries in response to enhanced terrestrial sediment inputs. However, this effect was muted by sediment trapping behind artificial rock walls and dams. Most recently, urbanization and suburbanization of the watershed led to the accumulation of mixed-grain sediment with different terrestrial and marine influence across the estuary. Simultaneously, continued delivery of sand to the ocean-side beach, allowed the island to remain in equilibrium with rising sea level. Together, these data demonstrate the complex and time-varying patterns of sediment delivery to, and across, the paraglacial, river-influenced coastal zone in response to natural and anthropogenic changes in drainage basin sediment production and transport, and downstream changes in sea level, coastal morphology, and land use. Further, they highlight the need to develop feasible sustainable paths for management that balance natural processes and societal needs and constraints.

North Atlantic radiocarbon constraints on ocean circulation and air-sea gas exchange over the last deglaciation

Andrea Burke¹, Rosanna Greenop¹, Rhian Rees-Owen¹, James Rae¹, Paula Reimer², Tim Heaton³

¹University of St Andrews, St Andrews, United Kingdom. ²Queen's University Belfast, Belfast, United Kingdom.

³University of Sheffield, Sheffield, United Kingdom

Abstract

Paleoclimate records from the North Atlantic show some of the most iconic records of abrupt climate change during the ice ages. Here we use radiocarbon as a tracer of ocean circulation and air-sea gas exchange to investigate potential mechanisms for the abrupt climate changes seen in the North Atlantic over the last deglaciation. We have created a stack of surface radiocarbon reservoir ages over the past 20,000 years from the North Atlantic, using new synchronized age models from five sediment cores refined with thorium normalization between tie-points. This stack shows consistent and large reservoir age increases of more than 1000 years from the Last Glacial Maximum into Heinrich Stadial 1, dropping abruptly back to approximately modern reservoir ages at the onset of the Bolling-Allerod. We use the intermediate complexity earth system model cGENIE to investigate the potential drivers of these reservoir age changes in order to further our understanding of the climatic changes occurring at these times and improve regional radiocarbon calibration.

O-1009

Exploring the phase relationship and mechanics of Dansgaard-Oeschger signals between the Northern and Southern hemispheres

Kirsten Tempest, W. Richard Peltier, Deepak Chandan
University of Toronto, Toronto, Canada

Abstract

At present, the matter of the connection between the Northern and Southern hemisphere in regards to Dansgaard-Oeschger (D-O) events during the MIS3 period and the deglacial interval itself are still far from clear. Our interest is in the mechanism whereby these intensely fluctuating temperature signals, evident in Greenland ice cores, are transmitted southwards to their Antarctic counterparts.

Recently Peltier and Vettoretti succeeded in producing a comprehensive model of glacial climate variability [1] which correctly captured the Dansgaard-Oeschger mode of millennial timescale climate change. This employed the CCSM4 global climate model with unique modifications, allowing for further understanding of this mechanism involved. A major result of this paper is the identification of what is apparently the correct bipolar seesaw behavior. In particular it is noted that there is an essentially perfect correlation between the sea surface temperature variability in the Southern Ocean encircling Antarctica and that of the air temperature above Antarctica (Figure 3e of [2]) as it shows that the signals are propagating from the Northern hemisphere to the Southern hemisphere via an oceanographic pathway as one would expect. In this paper we compare the air temperature signals over a series of D-O cycles predicted for both the Northern and Southern hemispheres by the comprehensive model at the locations of ice core extraction: NGRIP site on Greenland and the Epica Dronning Maudland (EDML) and WAIS divide (WDC) sites on Antarctica. The phase lag of the signal between the hemispheres is noted and we comment on the differences, if any, between our model results and those obtained by other groups based upon the data. [3]

Using this successful model, we are in the process of tracking these predicted D-O signals from the Northern to Southern hemisphere in order to illustrate the mechanism involved in the transmission of the signal. The mechanism potentially involves the Deep Western Boundary Undercurrent: an extensive southward flowing channel hugging the Eastern coast of the Americas. Whereby the signal is thought to travel from the tip of Greenland into the Southern Ocean. At which point it would be captured by the strong Antarctic Circumpolar Current (ACC), transporting the signal around Antarctica and thereby extending the time before the signal emerges at the surface of the southern ocean and thence via an atmospheric pathway into the Antarctic ice cores. This paper will report upon our progress in understanding this oceanic transportation mechanism.

Data and Modeling Evidence for multiple Episodes of abrupt Mass Loss from the Antarctic Ice Sheet during the last Deglaciation

Michael E. Weber¹, Nicholas R. Golledge², Christopher J. Fogwill³, Peter U. Clark⁴

¹University of Bonn, Steinmann-Institute, Bonn, Germany. ²Antarctic Research Centre, Victoria University of Wellington, Wellington, New Zealand. ³School of Geography, Geology and the Environment, University of Keele, Keele, United Kingdom. ⁴College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, Corvallis, OR, USA

Abstract

Global mean sea level rose ~134 m (Lambeck et al., 2014) during the last deglaciation (~19,000 and ~8,000 years ago). A better understanding of the contribution of the Antarctic Ice Sheet (AIS) to this sea-level rise may inform projections of global mean sea-level rise in a future, warming world. Earlier sea-level projections for the 21st century (IPCC, 2013) did not include potentially large contributions from the AIS, however, recent ice-sheet models (DeConto and Pollard, 2016) indicate that future AIS collapse could be substantial, approaching deglacial dynamics. Although modeling evidence suggests that once initiated, ice retreat may continue for centuries (Feldmann and Levermann, 2015; Golledge et al., 2015), there has been no direct evidence; neither is it clear how fast those dynamics would unfold.

Here we summarize data from Iceberg Alley that indicates repeated and rapid AIS mass loss during deglaciation, dubbed Antarctic Ice Sheet Discharge (AID) events (Weber et al., 2014). Similar behavior was simulated independently by ice-sheet modeling (Golledge et al., 2014), and geologic and glaciological records suggest step-wise retreat of 400 km in the Ross Sea sector of the West AIS (Bart et al., 2018), and ice-elevation drawdown in the Weddell Sea sector of the East AIS in excess of 600 m (Fogwill et al., 2017). Major retreat events occurred during times of global meltwater pulses, indicative for a possible AIS contribution of Meltwater Pulse 1A of several m. Flux rates of iceberg-rafted debris indicate that onset of each AID happened very fast, usually within one or two decades, and continued for centuries. Accompanying ice-sheet modeling indicates a close relationship of iceberg calving and grounded ice-mass loss on decadal to multi-decadal time scales.

This newly detected, substantial deglacial dynamics of the AIS contradicts earlier assessments (Bentley et al., 2010; Mackintosh et al., 2014) and the postulated rapid pace challenges current ice-sheet and climate models (Feldmann and Levermann, 2015; Golledge et al., 2015) and needs to be tested against them. Our findings for the changing past raise concerns that current instabilities observed for large parts of the West AIS (Rignot et al., 2014) may indeed indicate irreversible retreat that is already on the way.

Also, we will show first results from upcoming IODP-Expedition 382 (Iceberg Alley; March 20 to May 20, 2019); during with a number of new, high-resolution sediment sequences will be recovered to provide novel insight into ice-sheet ocean interactions and to constrain the findings obtained so far.

Collapse of Eurasian ice sheets 14,600 years ago was a major source of global Meltwater Pulse 1a

Jo Brendryen^{1,2,3}, Haflidi Haflidason^{1,2}, Yusuke Yokoyama⁴, Kristian Agasøster Haaga^{5,2,3}, Bjarte Hannisdal^{5,2,3}
¹Department of Earth Science, University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway. ³K.G. Jebsen Centre for Deep Sea Research, University of Bergen, Bergen, Norway. ⁴Atmosphere and Ocean Research Institute, University of Tokyo, Tokyo, Japan. ⁵Department of Earth Science, University of Bergen, Bergen, Norway

Abstract

Rapid sea-level rise caused by the collapse of large ice sheets is a global threat to human societies. In the last deglacial period, the rate of global sea-level rise peaked at more than 4 cm/yr during Meltwater Pulse 1a, which coincided with the abrupt Bølling warming event ca. 14,650 yr ago. However, the sources of the meltwater have proven elusive, and the contribution from Eurasian ice sheets (EIS) has until now been considered negligible. Here we revisit the deglacial chronology of the marine-based sectors of the EIS using a new reconstruction of the radiocarbon content of Norwegian Sea surface water. We utilize the ¹⁴C reconstruction as a regional calibration curve to recalibrate marine ¹⁴C dates from the EIS deglaciation. We show that marine-based sectors of the EIS abruptly collapsed at the Bølling transition and lost an ice volume of between 4.5 and 7.9 m sea level equivalents (95% quantiles) over 500 yr. During peak melting 14,650 - 14,310 yr ago, Eurasian ice sheets lost between 3.3 and 6.7 m sea level equivalents (95% quantiles), thus contributing significantly to Meltwater Pulse 1a. A meltwater flux of 0.2 Sv over 300 yr was injected into the Norwegian Sea and the Arctic Ocean during a time when proxy evidence suggests vigorous Atlantic meridional overturning circulation. Our new reconstruction of the EIS deglaciation shows that a marine-based ice sheet comparable in size to the West Antarctic ice sheet can collapse in as little as 300-500 years. The new precise deglacial chronology enables us to address the chain of events leading to the EIS collapse, and to evaluate the influence of meltwater runoff on ocean circulation and climate.

Using simplified physical models to predict ice sheet melting and response as climate changes

Victor C. Tsai¹, Alexander A. Robel²

¹California Institute of Technology, Pasadena, USA. ²Georgia Institute of Technology, Atlanta, USA

Abstract

Over the last few decades, large-scale ice sheet models have improved dramatically and are now being used to accurately hindcast recent ice sheet mass loss from the Greenland and West Antarctic Ice Sheets, and also the collapse of the Laurentide Ice Sheet. However, while these large-scale models attempt to include much of the known physics relevant to ice mass loss, the complexity of these processes often requires a number of key processes to be modeled with empirical relations or data assimilation rather than with equations based on first-principles physics. While such an empirical approach is useful within the range over which data is available, it is unclear how accurate these models are when applied to either future or past warming scenarios or geometries unlike those observed. Here, we discuss three ways in which simplified but physically motivated models can be used as alternatives to help make less precise but potentially more accurate predictions of ice sheet mass loss. First, we describe a simple two-equation model of two ice sheets intersecting in a saddle and show that this simplified system predicts acceleration of ice mass loss due to the positive height-mass balance feedback and saddle geometry; the model can therefore explain saddle region collapse of the Laurentide-Cordilleran system that more complex models have shown could be responsible for Meltwater Pulse 1A. One benefit of the new simplified model is that it makes straightforward predictions as to what parameters most affect the speed of collapse. Next, we describe a simple alternative to the positive degree day (PDD) model based on a simplified one-dimensional energy conservation equation; despite the simplicity of this PDD alternative, it performs better than the PDD model while still only using surface air temperature as an input and thus does not require the numerous parameters of a typical energy balance model. Finally, we describe how simple physical considerations of friction near a marine grounding line suggest that the standard Weertman sliding parameterization of basal sliding should be modified in a very specific way that is at odds with how it is done in most ice sheet models; instead of water pressure modifying Weertman sliding directly, it should be accounted for in a separate frictional equation. In all three of the models described, simplified but physically motivated reasoning leads to qualitatively different predictions of ice sheet mass loss with climate change as compared with when more traditional empirical laws are used, suggesting that these simplified models provide useful insight about ice sheet behavior in future or past climates very different from what has been observed.

Nature and timing of deglaciation in Changme Khangpu valley, Sikkim Himalaya, India

Manasi Debnath¹, Milap Chand Sharma², Hiambok Jones Syiemlieh¹, Pankaj Baghel³, Parvendra Kumar⁴, Arindam Chowdhury¹

¹North-Eastern Hill University, Shillong, India. ²Jawaharlal Nehru University, New Delhi, India. ³Inter University Accelerator Centre, New, India. ⁴Dr. HS Gour Central University Sagar, Sagar, India

Abstract

The Changme Khangpu (CK) glacier in the Sikkim Himalaya has been selected for study the palaeoclimate through proxy of glacial landforms and glacial sediment assemblages. The main axis of CK valley trends N-S and modern glacier restricted at an altitude between 5900 and 4810 m a.s.l. (27.9583 N, 88.6844 E). Lack of previous studies and spectacular preserved landforms within the 4.5 km downstream from the present glacier snout of CK captivating, and raises the importance to portrait the glacial geomorphology and reconstruct the palaeoclimate of this monsoon dominated valley. We used SRTM DEM, Sentinel-2A satellite imageries, GPS, sedimentological analysis and field technique to map the glacial landforms and glacial sediment assemblages. The ¹⁴C isotope AMS dates of glacio-fluvial and glacio-lacustrine deposition were obtained to reconstruct palaeo phases of climate. Two main glacial phases have been identified by latero-frontal moraines from the mapping. The sedimentation in a form of rhythmite archives were dated to be 31.47 ± 0.15 Ka Cal BP, situated at 1.7 km from present glacier snout. This indicates that this glacier retreated at a slower pace, similar to in present-day glacier snout variability. This retreating phase was appears to be interrupted by the local glacial cooling phase, demarcated prominently by a huge latero-frontal moraine, enclosing the present glacier periphery. Primary glacial sedimentation was continuously redistributing under the paraglacial slope processes, signifying an inverted age of dated sedimentation. The younger talus scree, younger debris rampart are major paraglacial features overlying the palaeo-rhythmites, enhancing the modification of primary sedimentation. Chronological analysis of glacio-fluvial archive from a trench indicate towards oscillating nature of environment from 14.05 ± 0.17 to 3.45 ± 0.06 Ka Cal BP. The sediment grain size variation during the period of 7.75 ± 0.05 ka to 5.49 ± 0.04 Ka Cal BP signifies interrupted environmental condition. This study suggests that valley slope derived paraglacial processes inhibited the preservation of primary glacial sediments and geomorphic features in such environments.

Episodic massive acceleration of Northern Hemisphere ice sheet retreat during the last deglaciation caused by the marine ice sheet instability

Aurélien Quiquet¹, Christophe Dumas¹, Didier M. Roche^{1,2}

¹Laboratoire des Sciences du Climat et de l'Environnement, Gif-sur-Yvette, France. ²Vrije Universiteit Amsterdam, Amsterdam, Netherlands

Abstract

During the last deglaciation (19 ka BP-11 ka BP) sea level rose by about 120 m with a mean rate of a few centimetres. However, natural archives for past sea level change record episodic abrupt sea level rises as fast as 4 metres per century (e.g. Deschamps et al., 2012).

Several mechanisms can explain such accelerations in ice sheet retreat: i) ice stream surges due to internal thermo-mechanical oscillations (e.g. MacAyeal, 1993; Calov et al. 2002) ; ii) strongly negative surface mass balance due to surface elevation feedbacks (e.g. Gregoire et al., 2012; Abe-ouchi et al., 2013) ; or iii) oceanic destabilisation of the grounding line position for marine ice sheets (e.g. Pollard et al., 2016). If the first two processes have been generally put forward to explain Northern Hemisphere retreat, the role of marine ice sheet instability have not been quantified yet, despite the fact that models used at the millennial timescale have considerably improved the representation of this process (Schoof, 2007; Tsai et al., 2015).

Here, using a coupled ice sheet – climate model (Roche et al., 2014; Quiquet et al., 2018), we show that we reproduce episodic massive accelerations of Northern Hemisphere ice sheet retreat during the last deglaciation due to the marine instability. Both the Laurentide and the Eurasian ice sheets are potentially affected by these instabilities which are strongly re-inforced by bedrock deflection. If ice sheet geometry evolution is largely sensitive to climate forcing, such events systematically occur in the course of the deglaciation. Our results suggest that the marine ice sheet instability is an important mechanism to explain Northern Hemisphere ice sheet waning, highlighting the major role of oceanic forcing for ice sheet evolution.

Abstract

During the Upper Pleistocene (MIS 5-2), abrupt climate changes repeatedly altered paleoenvironments across the Iberian Peninsula. Within this context, humans adapted and transformed their environment. Artifact and bone assemblages from palimpsests and high-resolution sites reflect human-environment interactions. Polar ice cores record global scale temperature and sea-level changes on annual time scales for the entire Upper Pleistocene. Deep-sea sediment cores off Iberia record regional and continental scale climate and environmental changes at centennial and millennial time scales. Terrestrial sediment traps, including lakes, bogs, and caves, record local and regional scale records at similar temporal scales. For western Iberia, Lapa do Picareiro, a cave site in central Portugal, provides a diachronic record of MIS 3 and 2 human occupation and environmental change. The cave contains a unique, continuous, 10.5 m stratified sedimentary sequence spanning 60,000 years of the Upper Pleistocene, making it an ideal locale to track long-term human response to paleoenvironmental change. The sedimentary sequence of Picareiro contains Middle and Upper Paleolithic occupations, extremely rich faunal assemblages, and subtle variations in particle size and geochemistry that record changes in the climate, hydrology, and morphology of the cave environment. Age control is provided by over 60 radiocarbon dates. Sedimentological analyses including magnetic susceptibility link the cave deposits with global scale records of Upper Pleistocene climate from the Greenland ice cores and regional-scale ones from deep-sea cores off Portugal. Stratified lithic artifact assemblages reveal technological changes that correlate with climate and environmental shifts recorded in the North Atlantic. Taphonomic analyses of the faunal remains inform on local paleoenvironments and human diet choice during MIS 3 and 2. We draw on these data to synchronize abrupt climate changes and human adaptive responses during the Upper Pleistocene.

Symbolism in late European Neandertals: Paleoenvironmental and evolutionary contexts

April Nowell¹, Melanie Chang²

¹University of Victoria, Victoria, Canada. ²Portland State University, Portland, USA

Abstract

Discussions of Neandertal behavior tend to focus on the identification of species characteristics in what we might refer to as an “ethological” approach. This is understandable because such an approach is both conservative and objective. At the same time, given the close biological relationship of Neandertals to modern humans and the likely complexity of their behavior based on this relationship, a broader, more “ethnographic” approach may be useful. Reconstructions of Neandertal population structure, behavior, and lifeways rarely take into account the possibility – or rather, probability – that Neandertal populations were themselves structured by cultural or ethnic distinctions, like all known modern human populations, past or present. Based on a detailed review of the archaeological, paleoenvironmental and genetic evidence, we argue that (1) the capacity for symbolic behavior was shared by Neandertals and modern humans, and therefore may also have characterized the Last Common Ancestor of these hominins (with concomitant implications for our understanding of the Denisovans); and (2) that the apparent increase in archaeologically-visible symbolic behavior after ~48,000 BP may reflect increased needs for social differentiation among late European Neandertals due to environmental and within-group pressures, and not necessarily changes in cognition or in response to encounters with anatomically modern humans. We conclude that while Neandertals exhibited many aspects of “modern behavior” throughout their lifespan as a species, it is only after 48,000 BP that a unique confluence of environmental and social pressures may have prompted them to codify their inter- and intra-group behavioral and cultural variation in a more durable visual media.

Abstract

One of the joint issues in archaeology and paleoenvironment is the impact of climate changes on human populations and their means of adaptation. Determining the impact of climatic changes on past human populations is difficult and aims to do try to find coincidences between a climatic event and a cultural transition. However, the identification of a concomitance is undermined by the uncertainties inherent in the chronologies of archaeological sites (dating methods) and by the resolution of environmental data. Our study focuses on improving the temporal resolution of these environmental data for southwestern France, a region that has provided abundant studies on cultural traditions since the Middle Palaeolithic.

Pollen grains and spores preserved in marine sediments are good tracers of environmental changes and our study was carried out using a deep-sea core collected in the Bay of Biscay. This analysis made it possible to study at very high-resolution (100-300 years), the environmental changes in southwestern France between 44,000 and 35,000 years before the present. We then compare our results with the chronology of cultural transitions in the southwestern France to detect a coincidence between both, and see whether climate changes may have been really a part in the development of these cultural transitions.

Our very high-resolution pollen study and other climate tracers preserved in the same samples allowed us to detect several climate phases and associate them with the main climate events in the North Atlantic Ocean and Greenland, i.e. Dansgaard-Oeschger cycles and Heinrich events. In addition, we were able to observe three phases during the Heinrich 4 stadial, which were identified in very high-resolution studies of Greenland ice cores, but also in deep-sea cores from the Iberian margin. In the current state of research and despite the difficulties mentioned above, we can begin to see possible concomitances emerge. This work will be continued during the thesis.

The causes and effects of the earliest Levallois in Britain

Aaron Rawlinson, Luke Dale, Mark White, David Bridgland
Durham University, Durham, United Kingdom

Abstract

The change from Acheulean technology to the use of the Levallois technique is often used to define the Lower-Middle Palaeolithic transition (c. 300,000 – 250,000 BP) and is considered the only major technological innovation during the Middle Pleistocene. The correlation of MIS 9 and MIS 7 with the terrestrial record in Britain has revealed that this is not a static division in the archaeological record but a longer and more dynamic process. This has allowed a more detailed examination of the changing environments of Britain and its effects on the archaeology found. Research into MIS 9 is examining the Proto-Levallois phenomenon alongside some of the earliest Levallois evidence at sites such as Purfleet and explores whether the new technology was ubiquitous in Britain during the interglacial or if its presence is geographically or temporally constrained. Key elements in this discussion include the timing of early Levallois technology and its relation to the preceding Acheulean. This was previously thought to have been a rapid transition, but evidence from MIS 9 reveals a period of overlap with the Acheulean similar to patterns seen in other regions.

This paper will examine why the change in technology occurred after a long tradition of handaxe manufacture. MIS 9 is often considered to be a turning point for Palaeolithic technology, but the paper will ask whether this can be linked to environmental changes during the MIS 9 interglacial and what effects Britain's glacial cycles might have had on the development of Levallois technology.

To change or not to change... Mesolithic societies in the Wojnowo Region, western Poland

Iwona Sobkowiak-Tabaka¹, Krystyna Milecka², Lucy Kubiak-Martens³, Dominik Pawłowski⁴, Beata Janczak-Kostecka², Robert Kostecki², Przemysław Bobrowski¹, Magdalena Ratajczak-Szczerba²

¹Institute of Archaeology and Ethnology, Polish Academy of Sciences, Poznań, Poland. ²Institute of Geoecology and Geoinformation, Adam Mickiewicz University, Poznań, Poland. ³Biax Consult, Zaandam, Netherlands. ⁴Institute of Geology, Adam Mickiewicz University, Poznań, Poland

Abstract

The problem with the perception of past societies as being largely dependent upon environmental conditions and climate changes is especially significant in reference to hunter-gatherers. For a long time these groups were treated as technologically undeveloped and focused mostly on procuring food. But numerous recent studies show that hunter-gatherer societies were able to apply various strategies for survival in constantly changing natural conditions, i.e. the development of Federmesser groups on the North European Plain during almost the entire Late Glacial. Moreover, these communities were likely to affect local surroundings.

In our paper we focus on the Wojnowo Region, located in the western part of Poland. The richness and diversity of excavated settlement remains located along the edge of the Obra river valley allow the region to be defined as a 'persistent place', an area occupied through centuries or even millennia because of the extremely favorable settlement conditions. Detailed analysis of multi-proxy data – archaeological, palaeobiological (pollen, plant macroremains, Cladocera, diatoms), geomorphological and geochemical - enabled reconstruction of both environmental conditions and human impact on the landscape. From the radiocarbon dating of burnt bones we were able to observe multiple occupation episodes which were completely invisible in the archaeological record.

Moreover, the aforementioned region is an extremely good example of an area where Mesolithic hunter-gatherers "survived" deep into the Late Neolithic. This phenomenon was observed on several archaeological sites and confirmed by radiocarbon determinations.

We would like to discuss the factors affecting human behavior in the distant past, both environmental and cultural (i.e. cultural transmission, transformation). Why, on the one hand, did some societies, witnessing frequent and sharp environmental shifts, show flexibility, apply different subsistence strategies, and develop? And, on the other hand, why did other societies not change their hunting-gathering way of life, even though around them completely different patterns had prevailed?

Climatic reconstruction between Bond events 4 and 3, implicating the rise/fall of the society at the Sannai-Maruyama site

Hodaka Kawahata

AORI, the University of Tokyo, Kashiwa, Japan

Abstract

The Sannai-Maruyama site (5.9–4.2 cal. kyr BP), one of the most famous and well-studied mid-Holocene (mid-Jōmon) archaeological sites in Japan, existed in Bond events 4-3. The north Mesopotamian civilization and the Yangtze River civilization in China showed similar decline. It was characterized by the exceptionally largest settlement community by the hunter–fisher–gatherers of 90,531 Jōmon sites in Japan.

Temperature is an important environmental parameter. At a glance, 2 groups of proxies for temperature estimates may give contradicting implications. For example, alkenone sea surface temperature and the assemblage of pollen suggest that warm (cold) and cold (warm) environments in the former (latter) half in the period of Bond events 4-3, respectively. Food availability influenced by the climate might control the prosperity/collapse of the site. Chestnuts and horse chestnuts were important food in the Jōmon people and proposed to be protected by *hansaibai* (the word is *hanand Saibai*, half and cultivation, respectively) (Nakao, 1976; Kitagawa and Yasuda, 2004). Especially northernmost Honshu is close to the northern limit of *Castanea* distribution.

Sedimentary cores were collected in Mutsu Bay near the Sannai-Maruyama site. Proxy #1, including alkenone temperature and assemblage of Ostracoda and coccoliths, generally suggests that the temperatures in early-summer peaked around 4.8-4.3 cal. kyr BP with minima in 5.9 and 4.1 cal. kyr BP. Proxy #2, including $\delta^{18}\text{O}$ value of benthic foraminifera, alkenone flux and relative abundance of pollen, suggested annual-based warm environments in 6.0-5.0 cal. kyr BP. In whole, both proxy groups propose that Jōmon people at the Sannai-Maruyama site generally enjoyed improved life in warm climate between Bond events 4 and 3.

Northward shift of westerly jet, in association with strengthened East Asian Summer Monsoon, influencing prosperity/collapse of the human societies in Far East Asia, could bring relatively warm climate in 6.0-4.3 cal. kyr BP, when the Sannai-Maruyama site flourished between Bond events 4 and 3.

It is suggested that high population density at the Sannai-Maruyama site could be supported by effective *hansaibai* in *Castanea crenata* (chestnuts) and *Aesculus turbinata* (horse chestnuts) to the less amount. Actually the production density per area of chestnut, one of the highest of fruits a tree produces in calorie, is as high as one quarter of the rice production density. Effective *hansaibai* in *Castanea* dominated forest could support high population density at the site. Cooling episodes at Bond event 3 could result in the decline of *hansaibaion* chestnuts, leading to the collapse of the site. Recent results from compiled archaeological-site map with the number of ruins and pit dwellings and from mitochondria DNA haplotype are in more favor of the contention that people were dispersed without no/little change of population across the Bond event 3.

Abstract

Reaching to over 4000 m in altitude, the Bale mountains of south-central Ethiopia comprise the most extensive area of Afro-alpine and sub-alpine Ericaceous vegetation in Africa and host an exceptionally high number of endemic species. Previous pollen analyses of a sediment core of the glacial lake Garba Guracha, located at 3950 m altitude, indicate shifts of the Ericaceous and the Afroalpine belt in relation to climatic changes during the Holocene and imply that the ecosystem has been shaped by natural expansion and contraction of vegetation zones (Umer et al. 2007). At the same time, the significance and timing of the onset of anthropogenic impact, e.g. through grazing and through cutting and burning of *Erica* scrub, is debated.

From Lake Garba Guracha we have retrieved sedimentary ancient DNA targeting the last 4000 years and focussing on plants and diatoms. Positive results were retrieved from nearly all samples. The vegetation revealed by the DNA is characterized by Afro-alpine species in all but the lowest sample, which shows a high number of reads assigned to *Erica arborea* - absent in the younger samples with ages less than 4000 yrs BP. This supports the previously postulated timing of the contraction of the Ericaceous zone, while, in contrast to pollen, it provides a local picture of the vegetation and reveals a high diversity in herbs and forbs, including endemic taxa. Diatom taxa identified by DNA experience a distinct turnover during the time period analysed, and, together with the aquatic plants, can elucidate lake ecosystem history. Interestingly, sequence data of plants was more consistent between PCR replicates than that of diatoms. Consistency in the plant data between replicates was high to an age of about 2500 yrs BP, while for diatoms, degradation as deduced from rates of success and reproducibility was not as clearly linked to depth. Thus, despite signals of DNA degradation, the results clearly demonstrate that authentic and informative DNA data can be retrieved over millennial timescales from Afro-alpine sites.

Evaluating the potential of environmental DNA metabarcoding in analyses of ancient DNA from contrasting lakes in tropical Asia

David Taylor¹, Sujatha Kutty², Joeline Lim³, Letisha Fong¹, Wayne Bannister¹, Rudolf Meier²

¹Department of Geography, National University of Singapore, Singapore, Singapore. ²Department of Biological Sciences, National University Singapore, Singapore, Singapore. ³Biology Department, Queen's University, Kingston, Canada

Abstract

DNA metabarcoding is used to infer the species composition of an environmental sample by extracting, amplifying, sequencing, and analysing target genomic regions, or short sequences of environmental DNA (eDNA) that can be used to distinguish between taxonomically different organisms. The set of techniques comprising DNA metabarcoding allows for the study of all barcode genes recovered from an environmental sample (hence the prefix “meta”). Relying on high-throughput sequencing of bulk samples, and access to an appropriate DNA nucleotide library for identification, DNA metabarcoding potentially can be applied even to degraded target material. The set of techniques therefore has great potential for the study of ancient DNA (aDNA), particularly where the focus is on the reconstruction of past biotic assemblages and/or the environments they represent. This paper evaluates the potential of DNA metabarcoding to dated sediment sequences from three contrasting freshwater lakes in Singapore and the Philippines. The oldest of the sediment sequences covers the last ca 1000 years, while the oldest sediment samples in the youngest date to about 120 years ago. In particular the paper tests the ability of DNA metabarcoding to reproduce results from conventional palaeolimnological analyses of the remains of chironomids and diatoms. The application of DNA metabarcoding to aDNA still faces many challenges, owing mainly to the small quantities of DNA involved, its often highly fragmented and degraded nature, the diversity of possible sources and the high likelihood of contamination. Currently, barcode-based identifications are heavily dependent on sequence availability in public databases, such as **NCBI Genbank** and the **Barcode of Life Data System**, where information from tropical Asian species is relatively sparse. The paper demonstrates the important role played by a major barcoding effort targeting extant tropical Asian taxa in identifying the source of aDNA in lake sediments. Although there have been relatively few palaeolimnology-based studies in tropical Asia, the sediment-based remains of chironomids and diatoms have been extensively used in other parts of the world as proxies of past variations in lake water quality, particularly temperature, nutrient and oxygen availability and pH. Preliminary results are highly promising. These results and their implications for tropical palaeolimnology – and for applications of palaeolimnological results, such as in the setting of restoration targets, the evaluation of possible regime shifts and the determination of local histories of invasive taxa – are discussed.

⁶CEED, University of Oslo, Oslo, Norway

Abstract

For the Alps, the pollen analysis of lake and peat bog deposits has for a long time been used to reconstruct the vegetation and land use history. In the last five years, more local records of vegetation cover were obtained in the Northern French Alps, using the emerging DNA metabarcoding approach. Focusing also on mammal DNA, this approach allows the reconstruction of the pastoral history. The combination of these two proxies provided a better understanding of the long-term interactions between the vegetation cover and human activities in the Alps. Similar approach is now developed for all the Alps in the framework of the ECOGEN project, also presented in this session.

This paper will present a reconstruction of the landscape changes from a sediment core retrieved in lake Gers (1540 m a.s.l., Northern French Alps). The palaeoecological record, based on the analyses of environmental DNA and pollen, spans the last 4600 years (5.8 m long core). Our ambition is not to compare the pollen and DNA data, but to combine them to develop a more detailed and realistic vegetation reconstruction.

Pollen and DNA analyses highlight similar "core taxa" (e.g.: *Picea*, *Alnus*, *Acer*...), which are still currently present in the catchment area. Moreover, both pollen and DNA data reflect a similar dynamic of the main vegetation groups. Both proxies agree to indicate a quite stable and mainly forested vegetation from 4600 to 1000 cal. years BP, and a major shift in vegetation occurring at 1000 cal. years BP. However, for this shift, pollen and DNA bring different views on the community composition (due to spatial, taxonomic and taphonomic differences). Pollen shows a significant decrease in tree cover and a change in plant community composition. This deforestation signal is also observed via the DNA, but is less pronounced. The DNA highlights a significant increase in the taxonomic diversity of herbaceous plants. This major change at 1000 cal. years BP was triggered by the development of pastoral activities (cow, goat and sheep) reconstructed from mammal DNA and coprophilous fungi analyses.

Overcoming enzymatic inhibitors in sedimentary ancient DNA (sedaDNA) extracts to maximize recovery for targeted enrichment and PCR metabarcoding

Tyler Murchie¹, Melanie Kuch¹, Emil Karpinski¹, Tara Sadoway², Duane Froese³, Hendrik Poinar¹

¹McMaster University, Hamilton, Canada. ²University Health Network, Toronto, Canada. ³University of Alberta, Edmonton, Canada

Abstract

Two major limitations in palaeoenvironmental metagenomics are DNA loss during extraction and the carryover of prolific enzymatic inhibitors. PCR metabarcoding can overcome some degree of inhibition through repeated silica-based purifications along with the addition of various substances (BSA, increased polymerase concentrations, etc.) during thermocycling. But this technique can be vulnerable to differential amplification rates and a subsequent bias in taxonomic profiles if there was substantial DNA loss with overly thorough inhibitor removal treatments during extraction. Alternatively, sedaDNA extracted with techniques designed to maximize ancient DNA recovery are prone to the carryover of enzymatic inhibitors (contingent on variations in the sedimentary matrix), which can result in failed PCR amplification or failed adapter ligation during library preparation, impeding shotgun sequencing or targeted enrichment strategies.

Our goal with this series of experiments was to evaluate various inhibitor removal treatments for their ability to reduce the carryover of enzymatic inhibitors in sedaDNA extracts while maximizing endogenous palaeoenvironmental DNA that can successfully undergo library adapter ligation. Four previously studied (via metabarcoding) Yukon sediment cores (two permafrost, two lake sediments) were tested using homogenized sediment inputs in triplicate. Our optimized extraction protocol was then directly compared with the DNeasy Powersoil DNA Extraction kit (one of the most commonly used extraction strategies in sedaDNA research along with the DNeasy PowerMax Soil Kit) following manufacturer specifications. Both extraction methods for each of the cores were then further processed for shotgun sequencing, targeted enrichment (enriching for animal whole mtDNA and plant cpDNA barcoding loci), and PCR metabarcoding. High-throughput sequence data derived from each combination of these techniques are compared here, as well as that of metabarcoding sequence data previously derived from these core samples. Preliminary quantitative PCRs indicate an up to 7-fold increase in total DNA recovery among the four core samples (average 3.6-fold) with our alternative extraction protocol, and up to a 5.6-fold increase in 'endogenous' library adapted *trnL* chloroplast DNA (with an average 3-fold increase).

Abstract

A Southwest-Northeast gradient of African diversity crosses modern European populations, with a maximum in Spain [1, 2]. It is unclear whether this gradient is the consequence of gene flow from Africa into Iberia in the Islamic period (as suggested by some analyses of nuclear DNA in modern populations [2, 3]), or of a much older contact, 10000-8000 years before present (as suggested by studies of uniparental markers, [4, 5, 6]). Here we typed whole ancient genomes from 4 Middle Neolithic and Bronze Age (~4000 yBP) individuals from Spain and Portugal, and found one of our samples from Southern Spain to belong to an undisputable Sub-Saharan mitochondrial lineage (L2a1). To test whether this finding reflects an isolated episode, or a sizable process of prehistoric gene flow from Africa, we analyzed a large genomic dataset of prehistoric samples. Our analysis at nuclear DNA detected small, but not insignificant, levels of Sub-Saharan African affinity in ancient genomes dating back to the Copper Age; and this similarity was stronger in the samples coming from the Mediterranean, than from the Atlantic, watersheds of Iberia. No similar pattern is present, as far as we could test, in other regions of Europe. In agreement with archaeological data, we interpret our results as evidence of an early migration process from Sub-Saharan Africa directly into the Iberian Peninsula. To our knowledge, this study is the first to report direct evidence of African gene flow into prehistoric Europe, following a Western route, likely across the Strait of Gibraltar.

ECOGEN: a project to examine ecosystem changes and species persistence over time using lake sediment DNA

Peter D. Heintzman¹, Dilli P. Rijal¹, Sandra Garcés Pastor¹, Kelsey Lorberau¹, Youri Lammers¹, Charlotte L. Clarke², Mary E. Edwards², Antony G. Brown^{1,2}, Kari Anne Bråthen¹, Inger G. Alsos¹

¹University of Tromsø – The Arctic University of Norway, Tromsø, Norway. ²University of Southampton, Southampton, United Kingdom

Abstract

We can predict potential future ecosystem impacts by examining the effects of analogous past changes. Within the past 12,000 years, there have been periods of both dramatic and relatively minor climate changes that are comparable to the range of predicted future scenarios. Additionally, human land-use impacts have been varied and widespread across Europe during this interval. Palaeoecological records, such as lake sediments, can inform how these drivers of change impacted past ecosystems. Traditionally, pollen has been used to infer ecological changes in sediment records, but its low taxonomic resolution precludes a detailed understanding of turnover and succession events. In contrast, ancient DNA recovered directly from lake sediments (*sedaDNA*) often yields species-specific information thereby mitigating this issue.

The ECOGEN project is using lake *sedaDNA* to examine the principle drivers of past ecosystem changes (climate and human land-use impacts), principally targeting vascular plants and key herbivores. The project focuses on two major regions: Northern Norway and the European Alps. Both regions have been affected by climatic changes, but the former is far less impacted by past human land-use changes than the latter. The large scale of the project (two regions and up to 40 lake sediment records) also allows for extensive testing of wet-lab and bioinformatic methodologies related to *sedaDNA* analysis.

In this talk, we will outline our major project findings so far, including full vascular plant records from many of our analysed sediment records from Northern Norway. These show distinct regional signals of succession and turnover. Ecological succession in the earliest Holocene tends to be rapid, with diverse plant communities appearing very soon after the Pleistocene-Holocene transition, which indicates swift responses to this short period of severe climatic change. Several records located near archaeological sites also show evidence of human land-use changes, as demonstrated by the appearance of disturbance indicators.

These initial findings demonstrate the efficacy of our approach, and they lay the foundation for large-scale regional comparisons to disentangle past drivers of ecosystem change that would improve our predictions of the near future.

⁷Institute of Biochemistry and Biology, University of Potsdam, Potsdam, Germany

Abstract

Future warming is proposed to result in loss of alpine plant diversity, which has important implications for vast alpine areas on the Tibetan Plateau. However, long time-series that confirm such a relationship are lacking from this region. Lakes represent useful archives to record long-term ecological change; yet, classical vegetation proxies such as pollen or macrofossil are not suitable indicators for plant diversity change. Here, we present an ancient plant DNA record of the past ~18,000 years, derived from sediments of Lake Naleng in the Hengduan Mountains – a biodiversity hotspot on the southwestern Tibetan Plateau in China. Furthermore, we simulated species richness using information from a modern vegetation database and temperature-related habitat changes. We found that overall plant diversity (i.e. richness) is highest when the lake catchment area is mainly covered by alpine meadows (at the end of the last glacial cycle and during the late Holocene) while diversity is low in warm phases with expanded forests (such as during the early and mid-Holocene, and presumably in the future), or during cold phases characterized by scarce vegetation and upland glaciation (such as shortly after the Last Glacial Maximum). While absolute diversity of each alpine plant family is highest during periods when it is most abundant, the relative diversity is highest when alpine meadows have a maximum extent and therefore offer a large variety of habitats. By analogy to our observed and simulated vegetation composition of former warming phases, alpine diversity will strongly decrease due to alpine habitats loss in a warmer future. Even if human impact will inhibit the invasion of forests and restrict the artificial stabilization of alpine meadows, grazing in alpine meadows will likely not cause a naturally high alpine plant diversity as suggested by analogy to the observed plant diversity change in the course of late Holocene human impact. To our knowledge our record represents the first proof of diversity-area-relationship concept from the past.

Development of the Holocene East Asian Monsoon – Evidence from Singapore and links to the Australasian Monsoon

Patrick Moss¹, Alan Ziegler², Robert Wasson², Trinh Nyguyen³, Jocelyn Hui²

¹The University of Queensland, Brisbane, Australia. ²National University of Singapore, Singapore, Singapore.

³National University of Singapore, Singapore, Singapore

Abstract

Nee Soon (1°24'N, 103°48'E) is a freshwater swamp forest that covers an area of 0.87 km² on north-eastern Singapore and is the only remaining swamp forest area on this highly urbanised island. The site occupies the lower portion of several shallow valley systems that eventually drain into the Seletar River and situated less than 10 m above present day sea level. Initial palynological analysis of sediment from this site revealed a record that extended into the last glacial period and parts of the Holocene (Taylor et al., 2001). The presence of montane pollen suggesting substantially cooler conditions, which extended into the early Holocene. During the mid-Holocene there is evidence of rising sea-levels, which is followed by falling sea-levels in the late Holocene. Fires, determined from charcoal analysis, were observed across the entire sequence. More recently 14 sediment cores were collected across the site to provide a more comprehensive picture of the sedimentology of the last remaining peat swamp forest in Singapore and to build on the initial analysis undertaken by Taylor et al. (2001). Subsequently, palynological analysis and radiometric dating has been undertaken on key facies of these sediment cores to provide further insight into the late Quaternary environments of the Nee Soon site, as well as improving the age model/stratigraphy of the sediment. Key findings support Taylor et al. (2001) study that the last glacial was cooler, with the site dominated by open taxa and greater representation of montane taxa. There is an increase in lowland forest taxa and decline in burning around 14,000 years ago that supports the development of the East Asian monsoon at this time and appears to strengthen in the early Holocene to become the dominant precipitation feature for this site onwards. These findings suggest that the precipitation increase occurred at a similar time to the Australasian monsoon development in north-western Australia (Field et al., 2017) but earlier than in the Wet Tropics of northeast Australia (Moss et al., 2017). In addition, variability in precipitation appears to be much less than in northern Australia and may be related to the equatorial location at the site that limits the influence of the El Niño Southern Oscillation phenomenon and other potential drivers of climatic variability.

Holocene Climate across the ITCZ, Hainan Maar Lake records vs. NE Queensland

henk heijnis¹, hong yan², John Dodson³, Mark Burrows⁴, Zhang Wenchao²

¹ANSTO, Sydney, Australia. ²Institute of Earth Environment, Chinese academy of sciences, XiAn, China. ³Institute of Earth Environment, Chinese academy of sciences, XiAn, China. ⁴Australian National University, Canberra, Australia

Abstract

The Asian/Australian monsoon is a coupled climate system through the cross-equatorial flow over the tropical Pacific-Indian Ocean and the migration of the Inter-tropical Convergence Zone (ITCZ). We present differences and correlations between a key sites from Hainan Island (China) and the Atherton tablelands, NE Queensland (Australia). Both sites have good chronological control and have been analysed using high resolution micro- XRF. We aim to explain the significance of the 9.2 ka, the 8.2 ka, the 2.8 ka and the Little Ice Age climate events in both regional and global context and its significance on the Asian/Australian monsoon system.

The following geochemical proxies including the ratios of Rb/Sr, Rb/K, Zr/Rb and Si/Ti were analysed using an X-ray fluorescence (XRF) core scanner.

O-1031

Tracking abrupt climatic changes of the Holocene using organic sediments from NE Australia

Mark Burrows¹, Henk Heijnis², Simon Haberle¹, Patrica Gadd²

¹Australian National University, Canberra, Australia. ²Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

Sediment cores recovered from Bromfield maar provide a continuous, high resolution record of climate variability through the Holocene for northeastern Australia. X-ray fluorescence (XRF-Itrax) is used in the generation of a long-term record of relative precipitation, supported by a suite of established proxies including humification, macrocharcoal and pollen. Together, these proxy data allow precise identification of wet and dry shifts in a sedimentary sequence comprised of laminated organic-rich muds, gyttja and peat.

In this presentation we describe and provide new interpretations on changes in the Early Holocene as recorded at Bromfield maar, with particular emphasis on laminated organic-rich muds at 4.80m (9.2 ka) and 4.42m (8.3 ka). Additional changes are detected in the Late Holocene peat sequence at 1.37m (2.9 ka) and 1.28m (1.5 ka).

Abrupt climate change events as identified in this study are significant as they allow the correlation of sedimentary records from sites throughout the wet tropics of Australia. The detection of these abrupt climate events also signals possible correlation with records from terrestrial sites across the Southern Hemisphere and potentially, the Northern Hemisphere. Such correlations may prove useful in demonstrating teleconnections, linking climates at a global scale.

¹Yunnan Normal University, Kunming, China. ²Nanjing Institute of Geology and Paleontology, Chinese Academy of Sciences, Nanjing, China. ³Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, China

Abstract

A modern pollen dataset used in this study consists of 75 surface samples from ponds, lakes, and reservoirs in Northwest Yunnan, Southwest China. Climatic data for each site, including monthly, seasonal and dry/rainy seasonal, as well as mean annual temperature and precipitation, were derived from observational data (1961-2010) of 20 meteorological stations in this region using linear interpolation method. Canonical correspondence analysis (CCA) was used to reveal the climatic parameters that best reflect the main patterns of variation in this modern pollen dataset, and to detect anomalous observations. Results of CCA indicate that mean annual precipitation (MAP), precipitation in dry season (November-April) (P_{ds}), and January temperature (T_{jan}) are three climatic parameters controlling the variation of this modern pollen dataset in Northwest Yunnan. Pollen-climate transfer functions for MAP, P_{ds} , T_{jan} were developed using the weighted-averaging partial least squares (WA-PLS) regression models. According to the performance of WA-PLS regression models, 3-component WA-PLS models were selected respectively for these three climatic parameters with low RMSEP (the root mean square error of prediction), low maximum bias, and high coefficient of determination (r^2) between observed and predicted values (RMSEP=48.7, 17.9 mm, and 1.0 °C; Maximum Bias=79.8, 37.1 mm, and 1.6 °C; r^2 =0.6, 0.6, and 0.74 for MAP, P_{ds} and T_{jan} , respectively).

Transfer functions for MAP, P_{ds} and T_{jan} were then applied to a fossil pollen record from Lugu Lake in Northwest Yunnan to reconstruct paleoclimate in the catchment of this lake. Quantitative estimates of paleoclimate show that MAP and P_{ds} fluctuated around 1000 and 110 mm (their present values), but T_{jan} is 0.8-4.3 °C lower than the present (5 °C) during 15000-12800 a BP (cal. a BP). From 12800 to 11500 a BP, MAP and P_{ds} were ca. 50 and 25 mm higher than the present, and T_{jan} increased to be the present level. Three climatic parameters at 11500-9100 a BP reached their maxima throughout the last deglaciation and Holocene. MAP, P_{ds} , and T_{jan} were 136-350, 35-139 mm, and 0.4-1.2 °C higher than today, respectively. From 9100 to 5500 a BP, both MAP and P_{ds} decreased, but they still were higher than the present, whereas T_{jan} declined to be the level slightly lower than the present. Three climatic parameters gradually decreased to be lower than the present from 5500 to 2500 a BP. After 2500 a BP, the catchment of Lugu Lake experienced a persistent period of low precipitation and temperature. On the average, MAP, P_{ds} , and T_{jan} were 94, 4 mm, and 1.9 °C lower than the present, respectively. Our quantitative estimates of MAP reveal a temporal pattern of precipitation variability associated with the strength of the Southwest Asian Monsoon during the last deglaciation and Holocene.

O-1034

A Late Pleistocene and Holocene vegetation and environmental record from Shuangchi Maar, Hainan Province, South China

John Dodson, Yan Hong, Jianyong Li
Institute of Earth Environment, Xi'an, China

Abstract

Shuangchi is a maar in the volcanic province of tropical northern Hainan Island, South China. A radiocarbon dated record of pollen, charcoal, organic carbon and some fossil algae provides a discontinuous record from its sediments cover the last 20,000 years. The fossil record is broken in places by abrupt pulses of inorganic material washed into the basin from the crater walls, presumably during periods of high magnitude storms. These samples also return anomalous radiocarbon ages. Last glacial maximum was marked by forest but with a high component of grassland, suggesting a drier and cooler climate than today. Forest recovery was rapid from about 9500 years ago and a peak in tropical rainforest taxa persisted until about 5000 years ago and this appears to represent peak warming in the region. From about 5000 years ago until present there is evidence of human impact, and fire was a tool used to clear forest. The human impact signal varies across Hainan which suggests that the level of human resource use was localised at least for several millennia. Human impact signals appear to be widespread from about 2000 years ago.

¹Max Planck Institute for Meteorology, Hamburg, Germany. ²California Institute for Technology, Pasadena, USA.

³University of Reading, Reading, United Kingdom. ⁴Australian Bureau of Meteorology, Melbourne, Australia

Abstract

Asian and Australasian monsoons are investigated in Coupled Model Intercomparison Project phase 5 simulations for mid-Holocene and future climate scenario rcp8.5. These two climates show interesting characteristics for monsoon dynamics: while the boreal summer inter-hemispheric contrast strengthens in both climates, the austral summer contrast only strengthens in mid-holocene and weakens in the future. Therefore, Asian monsoon is stronger than present day in both climates, while the Australasian monsoon is weaker in the past and stronger and wider in the future. Mechanisms determining monsoon responses in these two climates are investigated by decomposing the moisture budget in thermodynamic and dynamic components. Under future global warming, the intensification of the Asian monsoon results from a dominant thermodynamic effect (increased moisture) over the weakening of the circulation. In contrast, in the past the strengthening of the circulation (dynamic component) determines most of rainfall response. The Australasian monsoon is stronger in the future because of the thermodynamic component and it is weaker in the past because of the weakening in the tropical atmospheric circulation. Changes in net energy input over land versus ocean explain the different Asian and Australasian monsoon response. Our results highlight that temperature indices are poor indicators of the monsoonal response which is particularly sensitive to the radiative forcing. Therefore, the monsoon response is better constrained by the integrated energy balance, which accounts for changes at the surface as well as at the top of the atmosphere. The circulation is intensified where the anomalous net energy input is positive and weakened where it is negative.

¹Department of Geography, University of Cambridge, Cambridge, United Kingdom. ²School of Earth Sciences, Addis Ababa University, Addis Ababa, Ethiopia. ³Berkeley Geochronology Center, Berkeley, USA. ⁴Institute of Geography Education, University of Cologne, Cologne, Germany. ⁵Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom. ⁶ Institute of Geosciences, University of Potsdam, Potsdam, Germany

Abstract

The role played by changing climates and environments in the behaviours and dispersal of modern humans since their first appearance in Africa 300-200 thousand years before present (ka BP) is much debated. Recent theories are shaped by marine and terrestrial records of abrupt and extreme climate variability and on-going landscape changes, alongside archaeological evidence for increasing adaptability through time. Archaeological sequences and tropical climate records, on such long timescales, are often difficult to date directly and to correlate precisely, meaning that testing for relationships between modern human behaviours and their changing environments is extremely challenging.

A 280 metre sediment core from the Chew Bahir palaeolake in the southern Ethiopia Rift provides a continuous terrestrial archive reaching back ~600 ka BP, from which past climate and local environmental conditions have been reconstructed spanning the entire interval of modern human evolution. Layers of volcanic ash (tephra) within the Chew Bahir record provide key age-estimates within the site's age-model and also allow precise and direct correlations to some of the most important early modern human archaeological sites in Ethiopia, including the Kibish Formation. Using these tephra isochrons, the Chew Bahir palaeoclimate record provides critical insight into both the contemporary regional climate and local environmental conditions within which our ancestors were living in eastern Africa.

O-1037

The impact and significance of tephra deposition on a Holocene forest and lake environment in the North Cascades, Washington, USA.

Joanne Egan¹, Timothy Allott², William Fletcher², Christine Lane³, Jeff Blackford⁴, Douglas Clark⁵

¹Edge Hill University, Ormskirk, United Kingdom. ²The University of Manchester, Manchester, United Kingdom.

³University of Cambridge, Cambridge, United Kingdom. ⁴University of Hull, Hull, United Kingdom. ⁵Western Washington University, Bellingham, USA

Abstract

Volcanic activity can be a driver of short-term climate change and can impact on aquatic and terrestrial ecosystems at various temporal and spatial scales. However, the environmental impacts of tephra deposition are poorly understood. The palaeoenvironmental records from lakes and bogs, are essential tools used to investigate the nature and duration of the environmental response to tephra deposition, as continuous monitoring in active volcanic terrains is rare and few have the decadal durations required to measure environmental changes. Nonetheless, while several multi-proxy studies have indicated significant impacts, others have been ambiguous, reaching no clear consensus due to the difficulty to distinguish from background variability. High-resolution diatom and pollen stratigraphies from mid-Holocene sediments taken from fringe and central locations in Moss Lake, a small lake in the foothills of the Cascade Range, Washington, have been analysed to investigate the impacts (and duration) of tephra deposition on the aquatic and terrestrial ecosystem. Up to 50 mm of tephra was deposited from the climactic eruption of Mount Mazama 7958-7795 cal yr BP. The significance of tephra impacts independent of underlying long-term trends was tested using partial redundancy analysis. Tephra deposition caused a significant local impact on the terrestrial ecosystem, reflected in the fringe core by changes to open habitat vegetation (Cyperaceae and Poaceae) and reductions in aquatic macrophytes (*Myriophyllum spicatum*, *Potamogeton* and *Equisetum*). There was no significant impact of the Mazama tephra detected on the pollen record of the central core. Changes in this core are potentially climate driven. Overall, significant tephra fall was demonstrated through high resolution pollen analyses indicating a local effect on the terrestrial environment, but there was no significant impact on the regional forest independent of underlying environmental changes. The diatom response from both cores indicates a significant change in habitat type following blanket tephra deposition, with a decline in tychoplanktonic *Fragilaria brevistriata* and *Staurosira venter* and epiphytic diatom taxa indicating a reduction in aquatic macrophyte abundance, in agreement with the pollen record. Additionally, the central core shows an increase in tychoplanktonic *Aulacoseira* taxa, interpreted as a response to increased silica availability following tephra deposition. However, partial redundancy analysis provides only limited evidence of direct effects from the tephra deposition, and only from the central core, but significant effects from underlying environmental changes associated with climatic and lake development processes. The analyses highlight the importance of duplicate analyses (fringe and central cores), multi-proxy approaches and vigorous statistical analyses for the robust evaluation of ecosystem change following tephra deposition.

O-1038

Tephrostratigraphic studies on Lopevi volcano, Vanuatu

Vincent Neall

ACTIV, Palmerston North, Vanuatu. Massey University, Palmerston North, New Zealand

Abstract

The previously inhabited island of Lopevi, in Vanuatu, has shown regular volcanic activity since Cook's first sighting in 1774 AD. Nine episodes of volcanic eruptions are recorded between 1863 and prior to 1960 AD. Six pre-1960 AD. eruptive episodes, separated by buried soils, are preserved as tephras in a continuous stratigraphic sequence at the westernmost bay of the island, providing a fundamental record with which to elucidate a previously unknown order of lava flows and diamictons elsewhere on the island. This account provides further stratigraphic correlations and discoveries along the southern coast, from a 2005 expedition to Lopevi by the authors.

West of the previous village of Holen, lava flows and diamictons have been emplaced by eruptions in 1939, and subsequent to 1960 AD., extending the coastline and burying older deposits. However east of Holen, to the extinct peak of Mot Mot, at the south-eastern corner of Lopevi, there is a 3 km-long coastal exposure showing at least 4 major diamictons (and further less significant ones), interbedded with at least 3 pre-1960 AD. lava flows in valleys incised within the sequence.

Attempts at radiocarbon dating fossil crab shell and fibrous charcoal have proved fruitless. To aid with surface dating of recent deposits we established a curve of breast-height circumference of *Casuarina equisetifolia* trees, which grow on many of the dated surfaces. This proved useful as a relative dating technique for dating surfaces of unknown age over the last century.

The oldest diamictons appear closest to the south-east corner of the island between the December 2001 lava flow and the extinct Mot Mot, where they appear to be younging westwards. Further westwards, a sequence of four variably thick diamictons are interpreted to be the products of pyroclastic block-and-ash flows due to the presence of charcoal and cauliflower breadcrusted volcanic bombs. This sequence will be described in detail.

Immediately east of Holen is a 4 m-thick diamicton, which eastwards overlies a 1 m+ scoria containing anthropogenic materials. These included the blade of a presumed bone-handled knife, a piece of shattered green glass interpreted as a fragment of a bottle, a 4 cm-long gastropod, which was presumably a local food source, and oven-stone manuports. From 1943 AD. aerial photography this diamicton must precede the 1939 eruption because of the extensive vegetative cover at that time. The surface soil shows 1.2 m of overlying scoria, which we interpret as having been deposited in 1939 AD. We interpret this diamicton to have been emplaced during the 1922 AD. eruption when 500 persons were evacuated from the island. The next underlying unit, a lava flow, was probably emplaced during the 1908 AD. eruption when lava is reported to have descended to the sea.

Tephrochronology in south-Cappadocia (Turkey): first evidence of regular eruptions from LGM to Roman period, and impacts/non-impacts on human settlements

Catherine Kuzucuoğlu^{1,2}, Ségolène Saulnier-Copard¹, Damase Mouralis^{3,1}, Ali Gürel⁴, Jean-Pascal Dumoulin^{5,6}, Alain Riveron¹, Jean-François Pastre¹, Martin Godon⁷

¹Laboratoire de Géographie Physique, LGP-UMR 8591 / CNRS, 92195 Meudon cedex, France. ²Paris 1 University, 75005 Paris, France. ³IDEES (UMR 6266), Rouen Univ, 7 rue Thomas Becket, 76781 Mont Saint-Aignan cedex, France. ⁴Department of Geology Engineering, Halis Demir University, Nigde, Turkey. ⁵Laboratoire de Mesure du Carbone 14 (LMC14), LSCE/IPSL, CEA-CNRS-UVSQ, 91191 Gif-sur-Yvette, France. ⁶Université Paris-Saclay, 91191 Gif-sur-Yvette, France. ⁷IFEA Pôle Archéologie, IFEA, USR 3131, , Beyoglu, Istanbul, Turkey

Abstract

In the frame of Turkish-French research cooperation in geo-archaeology, palaeo-environment and palaeoclimate, 19 cores and 6 sections in lake/marsh/river sediments have been studied in connection with archaeological researches in south-central Anatolia. The cores and sections have been studied at four locations: (1) The Melendiz river terraces (Aksaray); (2) The Çiftlik Plain (Niğde); (3) the Bor Plain (Niğde); (4) the Ereğli Plain (Konya.). These geosystems belong to the southern part of the Volcanic Cappadocian Province (Melendiz river system and Çiftlik plain) and to the endorheic depressions lying north of the Taurus highlands (Bor and Ereğli plains). In the sequences presented, tephra layers of various thickness, grain size and lithic composition have been identified, characterized and dated. The results unveil very recent volcanic activity, and risk in the region.

State of the art

In the Hasandağ, researches have evidenced volcanic emissions at 35, 29, 15, 9, 3 to 0 kyrs ago (within at least 1 ka uncertainty: Pastre et al. 1997; Kuzucuoğlu et al. 1998; Schmitt et al., 2014) whereas an eruption (?) sketched on the wall of a Neolithic house is dated 8.4 kyrs ago (Mellaart, 1968; Hodder et al. 2006). In the Erciyes dağ, a rhyolitic activity is dated 9.5 kyrs ago (Hamann et al. 2010; Sarıkaya et al. 2018). Explosive activity is recorded in the Acıgöl caldera between 31 and 18 kyrs, while Late Glacial to Early Holocene tephras have been trapped in Acıgöl maar lake (Kuzucuoğlu et al. 1998; Roberts et al. 2001; Mouralis et al. 2003; Schmitt et al. 2011). No pyroclastite has been dated in the Karadağ (Ereğli-Konya).

New data

Sequences presented deliver numerous and very recent Cappadocian eruptions, and their impacts on populations as some of them have been collected in archaeological context. Eruptions (from different volcanoes?) occurred rather regularly within 3 to 1 kyrs intervals between at least 19.6 and 7.4 kyrs cal BP. Identified both in a core and in an archaeological site, a pumice fall is dated ca 2 kyrs ago. Such results are of tremendous importance as they show that:

- not only this remarkably regular magmatic activity in the region has been widely ignored,
- but populations lived together with eruptions from LGM to Mid-Holocene.

It is now clear that eruption risk must be considered seriously in the region, with monitoring installed over at least two volcanoes, the Hasan Dağ and the Erciyes Dağ.

This work is supported by archaeological projects led by Profs. Özbaşaran (Aşıklı), Bıçakçı (Tepecik-Çiftlik.), Godon (Melendiz), d'Alfonso (Kınık), Maner (KEYAR), with financial contribution from Artemis/INSU, ArchéoMed/INEE (PaléoMex), Halis Demir Univ. (A. Gürel), MAE's Melendiz archaeological mission (M. Godon), Labex Dynamite of Paris 1 University, and Laboratoire de Mesure du Carbone 14 (LMC14)

Post depositional processes: the environmental impact of plinian eruptions in Iceland

Lauren Shotter¹, Anthony Newton², Andrew Dugmore¹, John Stevenson³

¹University of Edinburgh, Edinburgh, United Kingdom. ²University of Edinburgh, University of Edinburgh, United Kingdom. ³British Geological Survey, Edinburgh, United Kingdom

Abstract

Large plinian volcanic eruptions have created key isochrones for classic tephrochronology and covered much of Iceland in thick tephra deposits. The long-term impact of these tephra falls on the environment, and the rate of recovery, is poorly understood. Tephra depth can be an important determinant of post-disturbance ecological processes and recovery, which can control the extent of discontinuations in the tephra record and classic tephra sequences. Deposits may be affected by a number of post-depositional processes which control thickness and distribution including slope processes, crust formation, and fluvial and aeolian erosion and remobilisation. Such processes, and their relationship to different plant communities, are important for understanding environmental response to the disturbance. In terms of environmental impact, rather than being a simple measurement, tephra depth could be considered a function of local vegetation (species, plant height, and growth stage), local topography, and season.

By utilising classic tephrochronology alongside palaeoenvironmental methods, the environmental impact of major plinian eruptions can be reconstructed. Within Iceland no such eruptions have occurred since people arrived in the late 9th century AD, so it is important that we explore their environmental impact in order to better understand the potential impact of future large plinian eruptions.

A number of sites are being investigated across Iceland, focusing on the Hekla 4 (c.4200 years B.P) and Hekla 3 (c.3100 years B.P) eruptions. These deposits have been recently remapped and so are significantly better understood than previously. Areas proximal to Hekla were buried under metres of tephra, and it may have taken thousands of years for a stable post-disturbance environment to form. At the other extreme, these layers are thin enough to have only temporarily impact the environment, if at all, and so the extent and length of the disturbance is likely to have varied with tephra depth amongst other controlling factors such as vegetation. By reconstructing the environment prior to, and after the eruption, we can investigate the extent of the impact and how long the environment took to 'recover' to pre-eruption conditions. We can also compare the disturbance between sites at different distances from the Hekla volcano, and at different altitudes, as well as investigating how different environments may have been affected. In doing so, a high-resolution temporal and spatial record of the impact of plinian eruptions in Iceland can be created.

The Early Holocene Saksunarvatn tephra: investigating the environmental effects of volcanic eruptions through annually laminated lake sediments

Marco Zanon¹, Ingo Feeser¹, Stefan Dreibrodt², Christel van den Bogaard³, Walter Dörfler¹

¹Institut für Ur- und Frühgeschichte, Kiel, Germany. ²Institut für Ökosystemforschung, Kiel, Germany. ³GEOMAR - Helmholtz Centre for Ocean Research, Kiel, Germany

Abstract

Due to its widespread coverage, the Saksunarvatn ash (ca. 10.2-10.3 ka cal. BP, Grímsvötn volcanic system) is regarded as an important stratigraphic marker to correlate multiple sedimentary archives between Greenland and northern continental Europe. While recent investigations revealed that the Saksunarvatn ash can't be considered the result of a single eruption, the relatively short interval between eruptive events, the spatial coverage and the total estimated amount of ejected material still raise questions concerning the duration and magnitude of any potential environmental repercussion.

Here, we make use of annually laminated sedimentary archives from northern Germany to investigate the potential influence of the Saksunarvatn event(s) on terrestrial and aquatic ecosystems. A single Saksunarvatn ash layer was identified in the lacustrine sequences of two distinct study-sites: Poggensee (Schleswig-Holstein) and Woseriner See (Mecklenburg-Vorpommern). Twenty sediment samples, each one spanning 2-5 years, were collected from the varved sequences of both sites, covering an interval of ca. 30-40 years before and after the deposition of the tephra layer.

Palynological and geochemical analysis conducted on these samples reveal a seemingly (multi)decadal episode of ecosystem disturbance occurring around the time of the ash deposition. The magnitude of this event, its proper delimitation in both archives and its relation with the multiple Grímsvötn eruptions will be evaluated within this presentation.

Abstract

The Tierra Blanca Joven (TBJ) eruption from Ilopango volcano, El Salvador is known to have been one of the largest eruptions in the Common Era. The date of the eruption is poorly constrained, ranging from approximately 255 CE to 536 CE, as many radiocarbon measurements plot on plateaus in the radiocarbon calibration curve. This uncertainty in the date means that the far-reaching impacts of the eruption are not known. However, there has been speculation that it may have caused the dense dry fog that was observed across Europe in 536 CE (Dull et al., 2010), and sulphur spikes in the polar ice cores have been attributed to the eruption (e.g., Zielinski, 1995). Here we present new results from a multi-faceted study into the eruption, which includes: glass chemistry data from all units within the deposits that help correlate deposits over more than 180,000 km²; precise wiggle-matched radiocarbon dates from a charred Mahogany tree stump that was found within the TBJ pyroclastic flow; the eruption parameters and the volume of magma erupted, which have been constrained using state-of-the-art dispersal models; and volatile compositions of the deposits that provide estimates of the amount of S and Cl released. These constraints allow us to provide a better assessment of the impacts of the eruption.

Constraining charcoal source area to better inform paleofire interpretations

Richard Vachula¹, James Russell¹, Yongsong Huang¹, Jarunetr Sae-Lim², Nora Richter¹

¹Brown University, Providence, USA. ²Washington University, St. Louis, USA

Abstract

Charcoal-based fire reconstructions inform perspectives on the response of fire regimes to changing climate, ecology, and management. In light of projected changes in global fire activity in response to future climate change, paleofire perspectives are increasingly important. Much previous work has sought to understand the processes affecting charcoal in sediments to develop more robust interpretations of fire records. Constraining charcoal dispersal and source area is essential to the reliable interpretation of charcoal records. Current estimates of source area and dispersal span a wide range, so our understanding of source area remains ambiguous, limiting our interpretations of charcoal records. We synthesize new work aiming to delineate charcoal source area and the spatial scale at which charcoal-based reconstructions record fire history. Firstly, we compile charcoal source area estimates from the published literature and show that these estimates span a wide range (from 10s of meters to 10s of kilometers) and demonstrate methodological biases (e.g. atmospheric and lake sediment traps, models, sediment cores). Using new quantitative geospatial techniques, we compare down-core charcoal accumulation with historical fire data to identify the spatial scales at which charcoal particles of different sizes reliably record fire history in two case studies: the montane forests of the Sierra Nevada, California, and the tundra ecoregions of Alaska, U.S.A. We find that our charcoal source area estimates in the Sierra Nevada (25, 35, and 150 km for charcoal particles >250, >150, and 63-150 μm , respectively) fall within the range of published estimates but that source area estimates in Alaska are much larger (0 to 150 km for charcoal particles >120 μm). The results of our Alaska case study suggest that an underlying paleofire assumption, that charcoal dispersal is dependent on particle size, does not always hold true. Finally, we present a kinematics-based dispersal model that incorporates variable particle size, density, and shape. We show that the model can explain the source area estimates and variability we see in our spatial analyses. In sum, our work offers new perspective in understanding charcoal source area and improves the interpretation of charcoal-based fire records. Our work also highlights the need to incorporate spatial analyses into the interpretation of paleofire records.

Calibration and validation of transfer functions for burned area and fire severity in the boreal forest

Andy Hennebelle¹, Julie Aleman¹, Pierre Grondin²

¹University of Montréal, Montréal, Canada. ²Ministry of Forests, Wildlife and Parks, Québec, Canada

Abstract

Charcoal particles preserved in lake sediments are commonly used for reconstructing fire return intervals (FRI) for assessing the fire regime. Yet, when analyzing fire-vegetation relationships, FRI is not always the most appropriate metric. Indeed, longer FRI are not always associated to late successional species while short FRI sometimes do not imply a dominance of early successional species. These discrepancies are only partly explained by taphonomical processes that affect the proxies, notably the production, the transportation and the deposition in the archive. More likely, other fire characteristics such as burned area and fire severity are important in explaining charcoal records and fire-vegetation relationships. Here our aim was to calibrate these fire characteristics against charcoal median surface recorded in traps located within 7 lakes of the western Québec boreal forest during 6 consecutive years. Fire severity was assessed by dNBR (differentiated Normalized Burn Ratio) calculated with LANDSAT images. We assessed charcoal dispersion by extracting fire characteristics at 3, 15, 30km from the lakes and charcoal deposition by analyzing fire characteristics the year of the fire and up to 5 lagged years. A Random Forest based methodology was used to distinguish fire variables that significantly contribute to explain charcoal measurements taken independently. Among those variables only the most relevant were kept for developing transfer functions that will enable to reconstruct fire characteristics. We found that charcoal median surface was related to fire severity and burned area occurring within 30km from the lake the year of the fire (lag 0). We subsequently created two transfer functions: one for reconstructing burned area ($r^2=0.7576$, P -value <0.001) and the other for fire severity ($r^2=0.7584$, P -value <0.001). These two transfer functions show that regional burned area and fire severity explain current year air-borne charcoal deposition. We will then further discuss the reliability of these transfer functions by testing them on sub-actual (last ~100 years) sedimentary charcoal data extracted from 11 lakes in the same vegetation context.

Abstract

Fire regime shifts under future climate change are difficult to predict, especially in the high-northern latitudes. There, modern fire regimes vary strongly between tundra, summergreen (larch-dominated) and evergreen (pine and spruce-dominated) boreal forests. Whether climate or vegetation are the main drivers of biome-specific fire regimes and the role of internal feedbacks with permafrost are highly debated. Yet, knowledge on past fire regimes and associated feedbacks in the high latitudes is scarce, especially on longer time scales beyond human interference.

Here, we study the long-term fire regime history of Chukotka, northeastern Siberia, using sediment core PG1351 from Lake El'gygytyn that covers the last 270,000 years. We focus on two glacial-interglacial transitions of similar summer insolation, but different global ice volume, and different vegetation composition. Multiple fire proxy records from the same samples allow to characterize the fire regimes of a warmer than modern (MIS 5e) and a cooler than modern interglacial (MIS 7e). We analyzed sedimentary charcoal from pollen slides that reflects various combustion efficiencies from regional sources, whereas the presence of the spores of *Gelasinospora* (a fungi indicative for fires) depends on the regional availability of fire-disturbed soils. In addition and for the first time, we provide long-term sedimentary records of the molecular fire markers levoglucosan, mannosan and galactosan from ultra-high performance liquid chromatography-high resolution mass spectrometry that indicate regional low-temperature biomass burning of varying burning conditions.

We find higher concentration and influx of all fire proxies during interglacials suggesting greater fire activity compared to the preceding glacials. Yet, proxy ranges, proxy record variability and ratios between the fire proxies of the two interglacials were significantly different, on both, millennial and centennial time scales. A comparison of fire proxies with available climate reconstructions from the same core and pollen-based vegetation reconstructions from the same samples suggests a strong dependence of fire regimes on regional biome configuration, but also on temperature and permafrost thaw. Hence, understanding long-term internal climate-vegetation-permafrost feedbacks is crucial for fire regime prediction in the future.

Using ATR-FTIR to quantify pyrolysis intensity as a proxy for fire severity in eastern Australia

Mark Constantine¹, Patrick Baker², Michael Bird³, Tim Cohen⁴, Brynn Hibert¹, Chris Majo¹, Anna McBeath³, Anne Rich¹, Xianglin Zheng¹, Scott Mooney¹

¹The University of New South Wales, Sydney, Australia. ²University of Melbourne, Melbourne, Australia. ³James Cook University, Smithfield, Australia. ⁴University of Wollongong, Wollongong, Australia

Abstract

There is significant uncertainty regarding past, present and potential future fire regimes in eastern Australia, and many of these questions require a longer baseline than is available from instrumental or historic records. Addressing such questions is also clearly often hindered by the ambiguity of charcoal as a proxy for fire. This ambiguity can result from the variability of charcoal formation, taphonomy can be uncertain and the delivery of charcoal into deposition environments can be dependent on the nature of the fire (severity, extent, distance to deposition site) and post-fire events. The inter-connected components of a fire regime can also influence charcoal accumulation and hence confuse the interpretation of any given record.

Here we apply attenuated total reflectance (ATR) Fourier-transform infrared (FTIR) spectroscopy to oven-produced charcoal formed at different temperatures (between 350 and 900°C) and to charcoal sampled in the field from fires of known severity. We show that we can discriminate IR spectra from these different 'pyro-intensities' using partial least squares regression.

We then apply these techniques to macroscopic charcoal (>250 micron) isolated from well-dated sedimentary sequences to consider 'pyro-intensity' over three temporal scales at sites in eastern Australia: (1) the last full glacial cycle at Thirlmere Lakes; (2) over the Holocene at sites in the Sydney Basin; and (3) over the last 500 years in Kosciuszko National Park.

The methods outlined represent a novel use of charcoal for considering changes to fire intensity and allow several contentious issues to be addressed about fire in eastern Australia. In this talk we focus on issues associated with the response of fire to climate change and variability, the human use of fire and the question *have fire regimes of the recent past increased in severity?*

Fire and fuel in Holocene northern Australian tropical savannas

Emma Rehn¹, Michael Bird¹, Cassandra Rowe¹, Sean Ulm¹, Craig Woodward², Geraldine Jacobsen²

¹James Cook University, Cairns, Australia. ²Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

Fire has a long history of interaction with Australian ecosystems but poses a growing risk as future climate change is predicted to lengthen fire seasons and increase extreme fire weather. Tropical savannas cover almost one quarter (1.9 million km²) of the Australian land mass, and fire occurs here almost annually. A greater understanding of past fire regimes, and their environmental context, is essential for management and planning in an increasingly fire-prone landscape. Despite the central importance of fire in savanna ecosystems, the region remains understudied in Australian palaeofire research. In light of this knowledge gap, this study combines established and emerging optical and chemical methods for charcoal analysis in the context of northern Australian tropical savannas.

This study presents three new Holocene palaeofire records from tropical savanna wetland sites in far northern Australia, each with diverse land-use histories. Three methods were applied to achieve a more comprehensive understanding of fire and fuels over time in tropical savannas.

1. Charcoal abundance is presented for four size classes covering a local signal (>250 μm and 250-125 μm) and surrounding regional signal (125-63 μm and <63 μm).
2. Particle morphology and aspect ratio are proposed indicators of fuel type (e.g. grass, leaf, wood). However, this technique derives primarily from temperate environments, notably from experimental burns and sites in the Northern Hemisphere. Our study tests methods developed in temperate, Northern Hemisphere settings on charcoal from the Australian tropical savanna. Fuel type data are discussed using a morphotype classification system, and a length-width ratio of ≥ 3.6 is used to identify macroscopic grass particles.
3. We demonstrate the application of chemical quantification of pyrogenic carbon (PyC) as well as isotopic identification of fuel type. PyC abundance determined using hydrogen pyrolysis and $\delta^{13}\text{C}$ composition (contribution of C₃ versus C₄ plants) are presented for the three sites and combined with the data generated using optical methods. All records are supported by ²¹⁰Pb and ¹⁴C chronologies and XRF core scanner data on elemental composition.

Preliminary results show negligible variations in fuel composition through time at each site, with broad correspondence between fuel type determined by morphology and isotope composition. Variations are apparent between different charcoal size classes (macroscopic and microscopic) in both abundance and fuel composition at all sites, reflecting differences in local and regional fire signals and highlighting the importance of size differentiation during analysis.

This study is a step towards filling the palaeofire knowledge gap represented by northern Australia and is an important assessment of the application of existing palaeofire techniques to this unique context.

A new method to reconstruct past fire temperatures from charcoal chemistry

William Gosling¹, Henk Cornelissen^{1,2}, Crystal McMichael¹

¹University of Amsterdam, Amsterdam, Netherlands. ²University of Manchester, Manchester, United Kingdom

Abstract

Fire activity plays an important role in natural ecosystem function and as a tool for the human modification of ecosystems. For example ecological studies have shown that exposure to low temperature fire can be required to promote seed germination, while high temperature fires can remove all but the most specialist species. Furthermore, due to the intrinsic dangers of fire to people, management of fire today is a critical part of humans relationship with many ecosystems. In the past fire must also have played a critical role in ecosystem function and the ecosystem-human relationship. However, due to methodological constraints, palaeoecological studies do not typically reconstruct key aspects of past fire activity, such as temperature, focusing instead on the metrication of the past abundance of charcoal. Consequently, studies of palaeo-fire are likely missing information on how fires modified ecosystems in the past.

Here we present a new palaeoecological approach to reconstruct past fire temperatures. We achieve this through the exploration of the relationship between the chemical composition of charcoal and the temperature at which it was combusted. We use Fourier Transformed Infrared Spectroscopy (FTIR) to infer the chemical composition of a reference charcoal data set and compare these data with charcoal fragments picked from a sedimentary sequence dating from ca. 1400-450 years ago. The FTIR spectra of the datasets were statistically analysed to identify and match charcoals with similar chemical composition.

The inferred chemistry (FTIR spectra) of the reference and fossil charcoal were directly comparable, allowing likely fire temperatures to be assigned to the fossil fragments. Our results suggest that the use of FTIR analysis of charcoal can differentiate low (<400°C) and high (>500°C) temperature fires. The new method for reconstructing past fire temperatures presented here will, we hope, allow understanding from modern fire ecology to be tested against longer term palaeoecological data sets.

Evidence of anthropogenic modification of the landscape through biomass burning from an Amazon lake sediment core

Monica Arienzo¹, Yoshi Maezumi², Nathan Chellman¹, Jose Iriarte³

¹Desert Research Institute, Reno, USA. ²University of the West Indies at Mona, Mona, Jamaica. ³University of Exeter, Exeter, United Kingdom

Abstract

Anthropogenic modification of the Amazonian landscape has been one of the most debated issues in recent decades. A published lake sediment record of pollen, macrocharcoal (>125µm) and land use metrics from Lake Carana in the Amazon Tapajos Reserve shows the extent of human modification of the landscape throughout the past 4,500 years (Maezumi et al., 2018, *Nature Plants*). This record shows human land use for the cultivation of multiple annual crops and enrichment of edible plants that intensified with increased human populations. Of particular interest is the ecological impact of the use of fire in the pre-Columbian period. Here, we build upon these findings using a recently developed method for the determination of refractory black carbon (rBC) from lake sediments using a new incandescence-based method (Chellman et al., 2018, *Limnology and Oceanography: Methods*). Sub-micron rBC particles are approximately three orders of magnitude smaller than macrocharcoal fragments and transported through eolian rather than fluvial processes, BC records have thus been interpreted as reflecting regional to global scale carbon emissions from past fires.

The Lake Carana sediments were sampled at 0.5 cm intervals, dried, milled, and analyzed for rBC concentration and particle mass distribution. The rBC flux record demonstrates excellent agreement with the existing macrocharcoal record from Lake Carana. These records show a significant increase in biomass burning 1,250 years before present, associated with an increase in pre-Columbian activity, and a decrease in biomass burning associated with the arrival of Europeans and fire suppression during the rubber boom in the region. The rBC flux record also demonstrates agreement with BC records from South America and Antarctica, suggesting a regional change in biomass burning at these same time intervals. We also show an increase in the rBC particle mass distribution from ~2,500 to ~750 years before present associated with increased human modification of the landscape through biomass burning practices during the pre-Columbian period. rBC particle mass distribution reaches a low associated with fire suppression during the rubber boom and increases in the last two decades. The Lake Carana rBC and macrocharcoal measurements were compared with a neighbouring speleothem record which supports the interpretation that humans were the dominant driver of biomass burning in the eastern Amazon, rather than climate. This is in contrast to previous publications which have proposed climate to be the primary driver of biomass burning in the Southern Hemisphere during the past 2,500 years.

Ice-flow patterns and precise timing of ice sheet retreat across a dissected fjord landscape in western Norway

Jan Mangerud^{1,2}, Anna L.C. Hughes^{1,2,3}, Tone H. Sæle^{1,2}, John Inge Svendsen^{1,2}

¹University of Bergen, Bergen, Norway. ²The Bjerknes Centre for Climate Research, Bergen, Norway. ³University of Manchester, Manchester, United Kingdom

Abstract

We reconstruct patterns of ice flow and retreat of the south-western Scandinavian Ice Sheet across a landscape of dramatic topographic variations, where fjords hundreds of metres deep are oriented parallel, obliquely and at right angles to the dominant paleo-ice-flow direction. We combine field observations of glacial striae ($n = 2900$) with LiDAR/GIS-mapping of 60 ice-marginal delta locations and altitudes to resolve the pattern and timing of retreat. Each ice-marginal delta is dated with decadal precision by reference to a regional shore-line diagram constructed from two relative sea-level curves dated with over 100 radiocarbon dates from isolation basins. This approach allows us to date the pattern of ice margin retreat and timing of deglaciation with unprecedented precision.

Rapid retreat commenced immediately at the Younger Dryas/Holocene boundary at 11,600 cal. years BP. Retreat rates were fast in the deepest fjords (160 m a^{-1}), slower in shallower fjords ($60\text{-}80 \text{ m a}^{-1}$) and even slower on land. The fastest retreat rates, 240 m a^{-1} and 340 m a^{-1} , were experienced in the largest fjords, Hardangerfjorden and Sognefjorden, bordering the study area to the south and north, respectively. Cross-cutting glacial striae along wide fjords indicate the development of calving bays during retreat, which can be mapped up-fjord with decadal resolution. Observations of glacial striae directions confirms the isolation of ice caps/remnants on islands and peninsulas as retreat progressed. The combination of the complex pattern of deep fjords with fast ice-margin retreat, further increased the speed of deglaciation by isolating such ice remnants from the source areas of the main ice sheet. Ice-margin retreat paused, or slowed down, between 11,300-11,100 BP, probably due to cooling and/or increased precipitation during the Preboreal Oscillation. The final section of the ice margin that reached sea level is dated to 10,900 BP, and may be contemporaneous with the well-mapped Eidfjord-Osa moraines near the head of Hardangerfjorden.

During the Last Glacial Maximum, ice flow was towards the west across the entire study area, including across and independent of several-hundred meter deep fjords. During deglaciation the ice flow adjusted to the topography and the dominant flow direction switched towards the south-west

O-1051

Retreat pattern and chronology of the Scandinavian Ice Sheet using high-resolution landform mapping and varved sediments

Rachael Avery^{1,2}, Sarah Greenwood^{1,2}, Barbara Wohlfarth^{1,2}

¹Stockholm University, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm, Sweden

Abstract

The commonly-found annual silt-clay alternations in eastern and southern Sweden have, since the late 1800's, been used to map the retreat of the Scandinavian Ice Sheet by recording the site-to-site onset of proglacial lake sedimentation. The ensuing Swedish Varve Chronology is an unparalleled tool for linking the deglacial history of Sweden with associated palaeo-environmental change at an annual timescale. However, the construction of the chronology, especially for the earlier deglacial picture, has been fraught with problems arising from misidentifications, miscorrelations, and missing varves. The southeastern-most corner of Sweden (eastern Blekinge and southern Småland) is particularly problematic, with few varved records successfully connected to reconstruct local ice retreat, nor connected to existing robust regional chronologies. However, this region also encapsulates the abrupt warming of the Lateglacial Interstadial (~14.7 ka BP) and associated rapid and highly-dynamic ice margin retreat across the marine-terrestrial transition.

Here we revisit varved clay sequences in the Blekinge-Småland area, in conjunction with high-resolution digital terrain analysis of the pattern of ice margin retreat, in order to reconstruct the timing, style, and magnitude of ice sheet response to late-glacial warming. Digitisation and reanalysis of existing unpublished varve thickness records, typically ~30-120 varve years long, alongside acquisition and analysis of new varve sequences both on land and at sea, has enabled us to connect local varve sequences as well as to extend an existing robust chronology eastwards. Detailed mapping of glacial landforms from new terrestrial and bathymetric terrain data informs and supports the varve correlations, and reveals a complex pattern of ice flow and retreat in this area. The distribution and size of the eskers and meltwater channels draining the area indicates an area of high meltwater flux to the ice margin, with ice likely funneled into the Kalmar Strait (between the Swedish mainland and the island of Öland) as grounding line retreat responded to the local bathymetry. We present an ice retreat framework spanning the Blekinge-Småland region and interpret how both the pattern and magnitude of ice margin retreat responded to late-glacial warming.

¹Lund University, Lund, Sweden. ²UiT the Arctic University of Norway, Tromsø, Norway. ³Stockholm University, Stockholm, Sweden. ⁴University of Iceland, Reykjavik, Iceland

Abstract

Northern Fennoscandia is a key area for reconstructing the timing and extent of the Scandinavian ice sheet during the early and middle Weichselian. In this area, sediments and landforms have survived the Last Glacial Maximum and provide records of interstadial environments, glacial dynamics and ice-sheet extent in time and space. With few exceptions, most of these records are, however, fragmented and poorly constrained in time, which lead to large uncertainties and diverging interpretations of the glacial history.

A distinct feature is the so called Veiki moraine landscape which forms a lobate belt in northern Sweden (Fig. 1A, B). The Veiki moraine plateaux are currently interpreted as ice-walled lake plains that have been overridden by at least one ice sheet, and their distribution has been suggested to represent a former margin of the Scandinavian ice sheet. Their time of formation is proposed to be either Early or Middle Weichselian (Marine Isotope Stage 5c or 3).

We have used digital elevation models, derived from LiDAR data, for geomorphological mapping and studied the sediment architecture of the plateaux with ground-penetrating radar profiling (Fig. 1C, D). Sediments and small-scale structures have been documented in natural exposures and in excavated trenches as well as by coring. Luminescence and radiocarbon dating is used to determine the age of the deposits.

There is a range in plateau morphology from high, relatively flat-topped hills to low rim ridges surrounding a depression. The variation in height has a spatial trend, which may reflect original sediment abundance. Many plateaux have double rim ridges and these seem to largely consist of stratified sediments, either sorted or diamict, which were deposited by flowing water or by mass movements. Diamict sediments also seem to dominate the bulk of higher plateaux, while sandy-silty or organic sediments are found in the basins of lower landforms. The first dating results suggest an age of ca 50 ka for the basin infill sediments; more ages are pending.

Here we will present our interpretations of depositional processes and environments of Veiki moraines as well as the implications of the results for the glacial history of Fennoscandia.

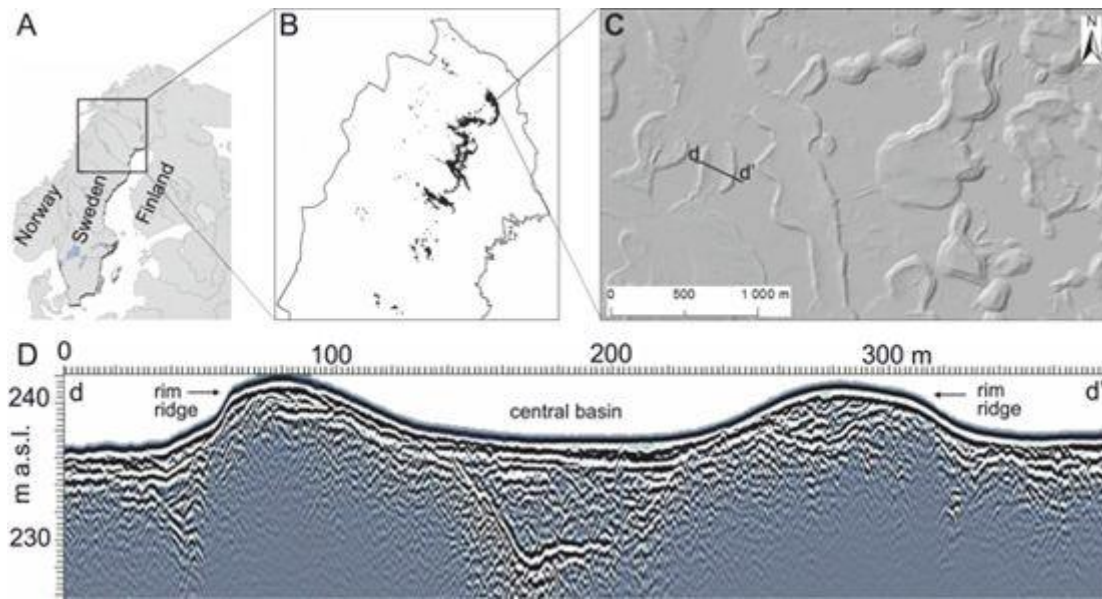

Figure 1. Location of Veiki moraine in northern Sweden (A, B), a hillshade of the Kortejärvi area with several Veiki moraine plateaux (C) and a 100 MHz ground-penetrating radar profile across one of the plateaux (see line d-d' in C for location).

Abstract

The last Scandinavian Ice Sheet (SIS) in northern Europe was one of the major Northern Hemisphere ice-sheets of the last glacial cycle. The southern fringe of the last SIS located to the south of the Baltic Basin reached its last maximum extent during the Late Weichselian, around 24–19 ka, and retreated gradually with episodes of regional and local ice readvances. The timing of the last SIS retreat reflects the Late Weichselian climate fluctuations, as well as the internal dynamics of the ice-sheet controlled largely by activation and deactivation of ice streams. Here, we present new results of erratic boulders dating with in-situ cosmogenic nuclides from the southern sector of the last SIS. This new data set compiled with already published but recalculated ¹⁰Be surface exposure ages, as well as OSL/¹⁴C ages available in the literature, enabled to explore the timing of the last SIS maximum expansion and retreat with respect to the climate fluctuations during the Late Weichselian.

The new 55 ¹⁰Be ages and one ³⁶Cl age come all from erratic located in-situ on glacial landforms in NW Poland, and were compiled with 20 already published ¹⁰Be ages recalculated according to the most recent ¹⁰Be production rate. The full surface exposure age dataset is interpreted as representing the initiation of the ice sheet retreat at the termination of specific glacial phases during the Late Weichselian. The error-weighted mean ages of the ice margin retreat for the Brandenburg, Frankfurt and Pomeranian Phases are calculated at 20.7 ± 0.8 ka, 17.3 ± 0.5 ka and 16.4 ± 0.3 ka respectively. Based on these results and their correlation with independent age constraints (¹⁴C ages of organic deposits and OSL ages of sand deposits intercalated in tills deposited by the last SIS), the age of the maximum ice sheet limits during the Brandenburg, Frankfurt and Pomeranian Phases may be estimated at ~25–21 ka, ~22–18 ka and ~16.5 ka respectively.

The available geochronological data (cosmogenic nuclides, ¹⁴C and OSL ages) together with the morphostratigraphical and lithostratigraphical contexts of the dating sites, were used as inputs in a Bayesian approach to model the chronology of the last deglaciation along the southern front of the SIS. This approach allows to construct a consistent chronology of the last SIS retreat and to model the rate of the ice front recession in northern Poland.

This research was funded by the National Science Centre, Poland - grant no 2014/15/D/ST10/04/113 to K. Tylmann.

Abstract

Andøya and Rendalssølen are situated at two extreme locations with respect to the Last Glacial Maximum extent of the Scandinavian Ice Sheet; at the margin and beneath the ice divide, respectively. Both areas have bedrock surfaces providing ¹⁰Be surface exposure ages older than the timing of the last deglaciation. Samples from such surfaces have been reprocessed for AMS analysis of Al and Be and erosion rates based on Markov Chain Monte Carlo modelling of ²⁶Al and ¹⁰Be will be presented.

Andøya (69°N, 16°E) is the northernmost island of the Vesterålen archipelago in northern Norway. It is located between the 500-m-deep Andfjorden and the shelf. The short (8-15 km) distance to the shelf-break has two major implications with regard to ice-sheet boundary conditions: a proximity to northward flow of ocean currents, as well as to the margin of large continental ice sheets. Andøya is characterised by N-S trending mountain massifs with steep slopes hosting cirques and tarns, separated and surrounded by a gently undulating, mire-covered strandflat. Summits reach above 500 m a.s.l., and plateaus, arêtes and rock pinnacles are common. Exposed bedrock is relatively rare and mainly found in steep slopes and cirque headwalls. The bedrock mainly consists of granite, gneiss and gabbro.

Rendalssølen (61°N, 11°E, 1755 m a.s.l.) is an isolated mountain massif protruding the Femunden mountain plateau (600-1000 m a.s.l.) in southeastern Norway. The region has experienced limited glacial erosion, as indicated by few deep glacial valleys and widespread regolith cover, and this is usually explained as a result of cold-based glaciers and proximity to the ice divide. Openwork blockfields dominate the surface above 1100 m a.s.l. Exposed bedrock is found in steep slopes and cirque headwalls on the western side of the massif, and locally on the summits. The bedrock consists of arkosic sandstones, conglomerates and mudstones.

Abstract

During the Last Glacial Maximum (LGM) western Scotland and northwest Ireland supported coalescing ice centres that were drained respectively by ice streaming across the continental shelf of the Malin Sea between Ireland and Scotland, and westwards from Donegal Bay in Ireland. Geophysical data from the continental shelf, mapped terrestrial glacial landforms and a range of new and legacy radiocarbon and cosmogenic nuclide exposure ages from offshore and onshore locations provide a detailed history of ice sheet retreat in this large sector of the British-Irish Ice Sheet (BIIS). Our new data reveal that the ice margin was located at the shelf edge around 27 ka BP, with ice retreat having started by 26 ka BP, prior to the global LGM. Extensive grounding zone wedges across the Malin Sea shelf and arcuate recessional moraines on the Donegal Bay shelf indicate that net retreat of the ice margin was punctuated by readvances or stillstands, with evidence of a major stillstand on the mid-shelf at ~23–22 ka. Subsequent decoupling of Scottish and Irish-based ice occurred at ~20.6–19.4 ka BP and was accompanied by the cessation of ice streaming across the Malin Shelf. During this time, the ice margin in NW Ireland lay along the northern coastline and crossed the mouth of Donegal Bay, where the prominent ‘Donegal Bay Moraine’ records a major stillstand or possible readvance of the ice sheet during deglaciation between 20 and 18 ka BP. The contemporaneous ice margin off western Scotland lay offshore in the Sea of the Hebrides, and thereafter underwent slow oscillatory retreat, becoming grounded amongst the Inner Hebrides. Quite rapidly after this time and by 17–16 ka BP ice had retreated entirely on land in both western Scotland and NW Ireland, and by ~15.0 ka only residual land-based icefields occupied mountain source areas. Our chronologically-constrained reconstruction suggests that the initial retreat of the marine-terminating western margin of the BIIS was initially driven by local ice loading that increased water depths, promoting ice losses by calving, rather than forcing by rises in ocean and atmospheric temperature. Subsequent timing of episodic retreat is possibly linked to a combination of substrate and topographic characteristics and local sea-level changes rather than by external forcing. The final stages of deglaciation, however, appear to have been driven by changes in global temperature.

Reconstructing the Last Irish Ice Sheet in the Irish Midlands: Mapping Hummocky Topography using LiDAR and Ground-Penetrating Radar (GPR)

Cathy Delaney¹, Kathryn Adamson¹, Lorna Linch², Stephen Davis³, Stephen McCarron⁴

¹Manchester Metropolitan University, Manchester, United Kingdom. ²University of Brighton, Brighton, United Kingdom. ³University College Dublin, Dublin, Ireland. ⁴Maynooth University, Maynooth, Ireland

Abstract

Ice-marginal and sub-marginal landforms that formed during the recession of former ice sheets are widely used to reconstruct ice retreat dynamics, including shifting thermal conditions and marginal oscillations. This information is used to predict the future behaviour of modern ice sheets during recession. The last Irish Ice Sheet is of interest in this context, due to its southerly position and proximity to the North Atlantic. Prominent moraines along the coast and on the continental shelf clearly indicate ice margin positions during retreat. However, there are few well-developed moraines inland. Instead, hummocky topography, interpreted as evidence of ice stagnation, has been used as evidence for former ice-marginal positions. However, hummocky topography may form in a variety of ways and in a number of positions in relation to the ice margin.

In the central Irish Midlands hummocky topography has been previously used to indicate the position of the Drumlin Readvance Moraine (DRM), originally proposed to have formed during a readvance associated with the formation of extensive drumlin fields in the northern half of the island. However, the position and nature of this inland ice margin, and the evidence for ice readvance, remains under debate. Here we use a combination of LiDAR, mapping from high-resolution air photos, ground-penetrating radar (GPR) surveys, and sedimentological analyses to examine hummocky topography in 3D in the central Irish Midlands, in order to establish (i) how the topography formed and (ii) inform ice sheet dynamics during deglaciation.

Results show that extensive areas previously mapped as hummocky topography actually consist of multiple short, ice-marginal, diamicton ridges with streamlined crests, that have been superimposed on the remnants of mega-scale glacial lineations. We interpret these features as evidence for accelerated ice flow and ice readvance. A second type of hummocky topography, consisting of geometric arrangements of mounds, with evidence of normal faulting along the margins of individual mounds indicates supraglacial deposition of sediments within crevasses during ice melting. We conclude that at least one significant readvance of the Irish Ice Sheet associated with accelerated ice flow occurred in the central Irish Midlands, but that this post-dated drumlin formation.

Geoconservation of Quaternary sites and landforms in the Republic of Ireland

Matthew Parkes¹, Robert Meehan², Ronan Hennessy³, Vincent Gallagher⁴, Sarah Gatley⁴

¹Natural History Museum, Dublin, Ireland. ²Independent Consultant, Dublin, Ireland. ³University College Cork, Cork, Ireland. ⁴Geological Survey of Ireland, Dublin, Ireland

Abstract

The Quaternary is one of 16 themes addressing geological heritage in the Republic of Ireland in the Irish Geological Heritage Programme of Geological Survey Ireland (GSI). An original scheme to identify and designate statutory geological and geomorphological Natural Heritage Areas has been superseded for pragmatic and resource reasons. Now, the only effective geoconservation is through the listing of geoheritage sites as County Geological Sites. These are fully defined and documented in county-based audits led by the GSI but funded mainly by the Heritage Council and commissioned by the Heritage Officer in each county. On completion, the County Geological Sites (CGS) are adopted into County Development Plans, acquiring an effective protection against many, but not all developments requiring planning permission. Only raising landowner awareness through the audit process can protect sites from damage through activities such as field clearance, drainage or earthworks. Subsequent outreach activities such as pictorial exhibitions or non-technical books are also employed to promote geoconservation of such sites.

Around three quarters of all Republic of Ireland counties have now been audited and a more complete picture of many hundreds of important Irish Quaternary sites is developing. Quaternary CGS include erosional landforms such as corries and glaciated mountain terrains and depositional forms such as eskers, fans, drumlins, rogen moraine, erratics, kettle holes, pingos along with stratigraphical sites. Many sites have multiple interests, also representing karstic or coastal or lacustrine geology.

The presentation will include an overview of the progress with auditing Quaternary sites, show some highlights and lesser known examples, but also discuss the criteria for selection of sites. Of potential importance to other territories or agencies embarking on Quaternary geoconservation initiatives will be some discussion of the approaches taken to the definition of boundaries and the question of scale of sites. Also examined in the presentation is the issue of listing active quarries and pits within Quaternary sand and gravel deposits.

Conserving Scotland's Quaternary marine geoheritage: the role of Marine Protected Areas

John E Gordon¹, Vanessa Brazier², Ben James³

¹School of Geography & Sustainable Development, University of St Andrews, St Andrews, United Kingdom. ²Scottish Natural Heritage, Perth, United Kingdom. ³Scottish Natural Heritage, Inverness, United Kingdom

Abstract

In comparison with the terrestrial environment, the conservation of marine geoheritage has been largely neglected. However, the application of new underwater survey techniques, using sonar, seismic and multibeam swath bathymetry methods, combined with coring of seabed sediments has revealed a great wealth of information about Scottish Quaternary nearshore and offshore landforms and deposits. The last Scottish Ice Sheet (SIS) and its predecessors were largely marine-based. Their geomorphological and dateable sedimentary records are particularly important for understanding the history and dynamics of marine-based ice sheets and their responses to climate change, ocean circulation and other forcing factors such as sea-level change. The landforms and deposits of the west coast fjords also demonstrate the later stages of deglaciation of the SIS and the subsequent re-expansion of glaciers in the North and West Highlands during the Loch Lomond (Younger Dryas) Stade. In addition to glacial landforms and deposits, the offshore and nearshore zones include submarine mass movements, submerged coastal landforms and dynamic bedforms. Using a methodology comparable to that of Geological Conservation Review, 35 key areas have been identified in Scottish territorial and offshore waters to represent the range of geological and geomorphological features of high scientific importance on the seabed. As well as for their scientific value, there is also growing recognition of the importance of seabed landforms and sediments in providing a platform supporting a diversity of marine habitats and fisheries, while the sediments form significant marine sinks for organic carbon from terrestrial sources. The Marine (Scotland) Act 2010 and the Marine and Coastal Access Act 2009 have enabled the establishment of 33 Nature Conservation Marine Protected Areas (MPAs) within Scottish territorial and offshore waters. Although these are designated primarily for biodiversity, they incorporate many geoheritage features which provided a strong supporting case. In addition, other existing protected area designations that form part of the MPA network include key geoheritage areas. Practical and policy issues present challenges that demand a flexible approach to marine geoconservation involving integration with biodiversity management in existing protected areas, and elsewhere for stand-alone measures to be based on evidence of the sensitivity and vulnerability of the interests present.

Geoconservation comparisons, UK and Portugal: Rivers Thames and Tejo (Tagus)

David Bridgland¹, Pedro Cunha², Peter Allen³, Mark White¹, Silvério Figueiredo⁴, Antonio Martins⁵

¹Durham University, Durham, United Kingdom. ²University of Coimbra, Coimbra, Portugal. ³Essex Field Club, Cheshunt, United Kingdom. ⁴Portuguese Center of Geo-History and Prehistory, Tomar, Portugal. ⁵University of Évora, Évora, Portugal

Abstract

The authors have been undertaking comparison of the scientific records of the two important European rivers, Thames and Tejo, which share lower reaches with important evidence of hominin occupation during the Quaternary. Key differences are that the Thames also has an exemplary palaeontological record (largely lacking in the Tejo) and the Tejo has been more influenced by sea-level fluctuations, on account of the narrow offshore continental shelf. There are advanced geoconservation measures in the UK and Portugal, although differences exist in the approach used in the Thames and Tejo. Thames Quaternary interests are well covered by a network of statutory site designations, with a network of 'Sites of Special Scientific Interest' (SSSI) and, the jewel in the crown, the Swanscombe National Nature Reserve (NNR), where pieces of a single hominin skull were found in 1935, 1936 and 1955. Outreach measures are somewhat limited, however, and have long been problematic, as has casework in relation to development projects, this area being a prime area for infrastructure improvement (to the east of London, close to the river crossing of the orbital motorway). Outreach is to the fore in the Lower Tejo. Two contrasting examples are the 'Núcleo Museológico do Centro Português de Geo-História e Pré-História', a local museum established in an old school at Golegã, a small town in the middle Portuguese sector of the Tejo valley, with a particular relevance to children, and explanatory boards at a low-terrace archaeo-geological site at Foz do Enxarrique, near the border with Spain. In both valleys there is a significant overlap between Earth science and archaeology, with the Palaeolithic record from the Thames representing something of a template for the rest of southern Britain. The museum at Golegã covers both geological and archaeological interests, the former including fossils (dinosaurs and their footprints are prominent) from the Mesozoic strata that form the basement of the Tejo synclinal basin. The site at Foz do Enxarrique was excavated recently to investigate Mousterian and Upper Palaeolithic levels, with vertebrate fossils preserved in some of these low-level Pleistocene sediments.

Kula Unesco Global Geopark and its importance in terms of human history and Earth sciences

Ahmet Serdar Aytac^{1,2}, Tuncer Demir^{3,2}

¹Harran University, Şanlıurfa, Turkey. ²Kula UNESCO Global Geopark, Manisa, Turkey. ³Akdeniz University, Antalya, Turkey

Abstract

Kula Geopark is located within the administrative territories of the Kula and Salihli districts of Manisa Province in the central part of the Gediz graben in the Aegean Region of Turkey. The Kula Geopark is situated in a tectonically active region and also constitutes one of the youngest volcanic fields in Turkey. This geopark is not only an important window for the study of tectonic forces in Western Turkey, but an excellent example, of world-wide comparative significance concerning geomorphology and climatic change. Due to its outstanding significance of tectonism, stratigraphy, paleobiology, paleoclimate, petrography, erosional process, and volcanism, it provides an ideal location for the study of both past and current and ongoing geological/ geomorphological processes, regional tectonic evolution and environmental change. The Geopark records the Earth's history spanning over 200 million years, and provides significant evidence from the paleotectonic and neotectonic periods. The Park offers wide-ranging insights into a vast array of Earth surface processes, both active and in the recent geological past. Therefore it presents an outstanding opportunity to engage with a wide variety of stakeholders in the Earth Sciences. The Kula Geopark contains more than 65 geosites, some of which have international importance in terms of Early Pleistocene climate changes, landscape evolution and Early Pleistocene hominin occupation of western Anatolia.

Kula Geopark, which won its global geopark title in 2013 for the first time, has been the subject of extensive scientific research in the last two decades. As a result of these scientific studies, geosites with different levels of importance were identified in the geopark area. In this presentation we introduce some examples.

Holocene history of the Kungur forest-steppe (pre-Urals, Russia): origin and nature conservation

Lyudmila Shumilovskikh

Georg-August-University of Göttingen, Göttingen, Germany. Tomsk State University, Tomsk, Russian Federation

Abstract

The Kungur forest-steppe is the most northern outpost of the European forest-steppe zone, the ecotone biome between woodlands and open landscapes stretching from the Carpathians to the Ural Mountains. The Kungur forest-steppe is located in the SE Perm region (Russia) within the zone of the pre-Uralian belt of hemiboreal spruce and fir-spruce forests with intermixed broadleaf trees. Due to the co-existence of boreal, temperate and steppe species, this island is characterized by high plant diversity and represents an important biodiversity hot-spot in the boreal zone. Intensive agriculture, pasture, and lumbering are leading to the loss of these unique steppe ecosystems. For sustainable protection management, a background in vegetation history is a necessary requirement. Several driving factors for the origin of the Kungur forest-steppe were proposed by botanists and geographers: geology, the climate of the past, or humans. However, no palaeoecological studies were implemented in order to understand its history. The project aims to understand the phenomenon of the Kungur forest-steppe in terms of its formation and dynamic within the hemiboreal zone of the pre-Urals. For this, peats and lacustrine sediments from Kungur forest-steppe are being studied in comparison to those from the typical hemiboreal forests. Studies on pollen and non-pollen palynomorphs (NPP) provide a basis for the reconstruction of vegetation and environmental history of both regions. While pollen is used for reconstructions of the vegetation history, NPP indicate other important processes for the landscape dynamic such as pasture, erosion intensity or eutrophication. Since almost no pollen studies were carried out in the entire Perm region, in this work I will present the first results of the project with a special emphasis on nature conservation issues.

O-1062

Beyond the bog: the importance and value of small-scale stratigraphic deposits in the landscape as archives for applied palaeoecology.

Helen Shaw

Maynooth University, Maynooth, Ireland

Abstract

A growing desire for both high-nature value farming and rewilding as conservation strategies has highlighted a pressing need to understand long-term dynamic change in natural and semi-natural vegetation systems. Palaeoecology can, and does, contribute much to our understanding of ecological dynamics in these systems. Modern palaeoecology is increasingly focussed on linking with ecosystem models at regional and global scales, and scaling up collated datasets from lake and bog archives. However much information of application to nature conservation requires scaling down. There are still surprising gaps in our knowledge-base: areas where paleoecology is either missing, or at too coarse a temporal or spatial resolution to provide useful data for modern application. In order to develop understandings of local-scale ecological dynamics and their drivers new local-scale palaeoecological histories, from mosaics of small sites, in landscapes of interest are required. Scaling down and collecting new data can also assist in filling in the considerable spatial gaps in the current set of regional-scale palaeoecological models.

Whereas large areas of peat, or lake systems, are increasingly recognised, as carbon stores and for biodiversity value, with ecosystem service valuation driving protection, preservation and conservation of the geoheritage archive within them; in contrast, local-scale palaeoecological archives are seldom considered and are potentially being lost. Much ecologically relevant palaeoecology relies on samples from small peat hollows, ponds etc. within cultural and woodland landscapes. These deposits are often disturbed or drained with little thought for the historical and palaeoenvironmental records that they contain.

This paper will present and explore examples of local-scale palaeoecological research especially in the context of social-ecological systems in traditional agricultural and wooded landscapes. Examples from personal research in Ribblesdale, north Yorkshire, Scotland and the English Lake district will be presented, as well as some review of other studies. Via these examples, the paper aims to highlight the value of a range of non-standard palaeoecological sites within the landscape, and to urge consideration of a wider range of sites as contributing to a valuable palaeoecological geoheritage.

O-1064

Late Pleistocene glacier chronologies and fault slip rates in the Teton Range, USA, revealed by ^{10}Be dating of fault-displaced moraines

Joseph Licciardi¹, Kenneth Pierce^{2,3}, Glenn Thackray⁴, Mark Zellman⁵, Darren Larsen⁶, Avriel Schweinsberg⁷
¹University of New Hampshire, Durham, NH, USA. ²U.S. Geological Survey, Bozeman, MT, USA. ³Northern Rocky Mountain Science Center, Bozeman, MT, USA. ⁴Idaho State University, Pocatello, ID, USA. ⁵BGC Engineering Inc., Golden, CO, USA. ⁶Occidental College, Los Angeles, CA, USA. ⁷University at Buffalo, Buffalo, NY, USA

Abstract

The Teton Range of the western USA is bound by the eastward-dipping Teton normal fault which extends ~70 km along the base of the mountains. An intertwined history of late Pleistocene glaciation and tectonism is evidenced by exquisitely preserved moraine sequences that are offset by prominent scarps along the trace of the Teton fault. Modeling studies suggest that fault slip rates are dynamically linked to glacial episodes in the greater Yellowstone-Teton region, such that faster slip is predicted to be stimulated by intervals of ice unloading during deglaciation. We aim to evaluate this prediction by developing chronologies of Yellowstone-Teton glacier fluctuations and constraining time-integrated offset rates along the Teton fault.

At its late Pleistocene maximum, the greater Yellowstone glacial system consisted of an ice cap on the Yellowstone Plateau that coalesced with glaciers from adjacent high mountains, including the Teton Range. Although the Tetons harbored only a small fraction of the greater Yellowstone ice mass, valley glaciers in this range left behind some of the region's best-preserved moraine sequences and ice-scoured bedrock, thus enabling reconstruction of detailed high-resolution glacier chronologies. Our investigations are focused on obtaining ^{10}Be exposure ages of glacial landforms in drainages along the eastern Teton Range front. Specific dating targets include moraine ridge crests and deglaciated surfaces that are measurably displaced by the Teton fault, which affords an opportunity to determine time-averaged slip rates.

Initial ^{10}Be results show that high lateral moraines in selected Teton drainages date to ~23–21 ka, whereas adjacent distal end moraines date to ~17–15 ka. These ages indicate construction of the high lateral moraines during an earlier phase of the last (Pinedale) glaciation, and suggest the younger end moraines record a subsequent advance and eventual retreat of more deeply scouring valley glaciers that extended further downvalley. Rapid and widespread deglaciation of the greater Yellowstone region occurred at ~15 ka, as defined by ^{10}Be ages of recessional moraines and scoured bedrock in the Teton Range, ^{10}Be ages of end moraines around the periphery of the Yellowstone ice cap, and basal-most radiocarbon ages in postglacial lake sediments in the Tetons. Measured vertical relief of fault scarps that cut across the older high lateral moraines and younger deglaciated surfaces, respectively, indicate faster offset rates as high as ~2.1 mm/yr from 22–15 ka followed by slower postglacial rates of ~0.8 mm/yr since 15 ka. These geomorphic constraints on late Pleistocene and Holocene tectonic activity are complemented by published and newly emerging paleoseismic evidence of Holocene slip rates from trench exposures across the Teton fault. Coordinated efforts involving additional ^{10}Be exposure dating, fault trenching and lake sediment analyses are underway and will elucidate a more comprehensive glaciotectonic history of the Teton Range.

O-1065

Constraining complex history of fluvial deposits using a ^{10}Be complex depth profile, OSL dating and modelling

Nathan Vandermaelen¹, Veerle Vanacker¹, Koen Beerten², Marcus Christl³

¹Earth and Life institute, University of Louvain, Place Louis Pasteur 3, 1348 Louvain-la-Neuve, Belgium. ²Engineered and Geosystems Analysis, Waste and Disposal, Belgian Nuclear Research Centre SCK•CEN, Boeretang 200, 2400 Mol, Belgium. ³Laboratory of Ion Beam Physics, ETH Zürich, Department of Physics, Zürich, Switzerland

Abstract

The Campine Plateau (CP, NE Belgium) is a low-altitude plateau (100-30 m a.s.l.) covered with fluvial sediments and gently dipping towards the north. The area west and east of the plateau is known to be in an erosive regime since the last 0.6 to 1 Ma, the dominant geomorphic process being differential erosion between the surrounding region and the relatively erosion resistant material of the CP. Nonetheless, the post-depositional history of the different lithological units of the CP remain poorly understood, and quantitative data on topographic evolution of these sediments are scarce. The objective of this research is to constrain depositional and post-depositional history, of a fluvial sediment sheet made of fine to coarse gravels (called “Zutendaal gravels”) of the CP over the last 1 Ma. To constrain scenarios explanative for the formation and evolution of the Zutendaal gravels, in-situ cosmogenic radionuclide (CRN) dating is applied using a ^{10}Be depth-profile in the Zutendaal gravels, containing 14 samples covering 7 meters of depth at regular interval. The ^{10}Be concentration of the sediments was measured at the AMS facility of ETH-Zurich.

Subsequently, a modelling approach simulating scenarios of alternating burial/erosion/stable episodes given as parameters, was developed. The model output is the concentration in ^{10}Be over a 10 m depth column at centimeter resolution resulting from the parametrized sequence of episodes. The model encompasses 3 production pathways (spallation, fast muons and negative muons) and dynamically adjusts ^{10}Be concentrations as a function of time-variable denudation and burial, inheritance and total exposure duration.

Realistic model scenarios are firstly constrained with geological evidence, i.e. intra-formational hiatuses encompassing a series of fining-upward sequences in the 7 topmost meters. We also applied independent dating of the upper sandy unit using optically stimulated luminescence (OSL). This allowed model scenarios to be further constrained by both providing minimum absolute age for this youngest sequence and a minimum burial duration for the unit located below.

Model output is then compared with observed data. Diagnostic scenarios for the observed ^{10}Be concentrations and its variability in the Zutendaal gravels were determined from optimization of the Nash-Sutcliffe efficiency index, over a limited range of unconstrained parameter values.

O-1066

Integrating soil characteristics and cosmogenic nuclide dating in the study of active faults: examples from the southwestern Basin and Range

Eric Kirby¹, Eric McDonald², John Gosse³, J Douglas Walker⁴

¹Oregon State University, Corvallis, USA. ²Desert Research Institute, Reno, USA. ³Dalhousie University, Halifax, Canada. ⁴University of Kansas, Lawrence, USA

Abstract

Widespread application of cosmogenic isotope dating of alluvial fan surfaces and deposits reveals intriguing temporal patterns in fault slip over timescales ranging from 10^4 – 10^5 yr. Such behavior may emerge from static and dynamic stress changes during earthquake cycles, geometric and mechanical interactions among fault networks, and/or variations in climatically modulated surface loading. At present, epistemic uncertainties associated with post-depositional modification of alluvial surfaces can severely limit the utility of cosmogenic nuclide (TCN) ages to address the timescales of these processes. Moreover, the difficulty and expense of obtaining ages often limits their application to a single site along a given structure. Soil profile development indices (PDI) can be acquired for a fraction of time and cost of absolute ages, and calibrated soil chronosequences can provide a reliable chronologic framework across a region of similar climate.

We illustrate this approach with an example drawn from recent work along active faults in eastern California. We developed a soil chronosequence that relies on well-preserved and dated surfaces from Panamint Valley and the western Mojave Desert spanning a range in age from $\sim 10^3$ - 10^5 ka. These surfaces have been dated using a combination of ^{14}C (wood and tufa), optically-stimulated luminescence (OSL), and ^{10}Be depth profiles. Morphologic descriptions of soil development were conducted at all sites and combined using a PDI index. We rely on these observations to establish local soil stratigraphy and to evaluate post-depositional modification of surfaces (erosion or deposition) critical for the interpretation of TCN results. Along the Garlock fault, sinistral displacement of a ~ 30 ka fan generated a shutter ridge that blocked drainage along the southern flank of the Slate Range; soils developed within an alluvial fan unit truncated by the shutter ridge are ~ 2 -4 ka, suggesting an exceptionally rapid pulse of slip in the late Holocene that is 2-3 times the long-term average rate (Rittase et al., 2014). In southern Panamint Valley, right-lateral displacement of a debris-flow levee provides a precise estimate of dextral-oblique fault slip along the Panamint Valley fault zone. However, exposure ages of unweathered boulders on debris-flow levees range from 20 – 40 ka. The degree of soil development and local cross-cutting relationships with dated Late Pleistocene lacustrine shorelines indicate that this flow is only ~ 9 -12 ka. The cosmogenic nuclide concentrations in these boulders are interpreted to reflect significant inheritance accumulated in the steep, high-relief catchment. In both examples, the degree of soil development provides critical information that informs and refines the dating of the surface. Our results demonstrate how radiometric dating of geomorphic surfaces can be combined with soil stratigraphic studies to refine our understanding of active fault systems.

Integration of soil-profile development improves age interpretation of TCN depth profiles: An example from Late Pleistocene lake shorelines, southwestern US

Eric McDonald¹, Eric Kirby², John Gosse³, Fred Phillips⁴, Shasta Marrero^{5,4}, Brad Sion¹

¹Desert Research Institute, Reno, USA. ²Oregon State University, Corvallis, USA. ³Dalhousie, Halifax, Canada. ⁴New Mexico Tech, Socorro, USA. ⁵University of Edinburgh, Edinburgh, United Kingdom

Abstract

Interpretations of cosmogenic isotope accumulation in the shallow subsurface are well-known to be sensitive to post-depositional surface modification by erosion and deposition. The influence of these processes is typically the single largest source of uncertainty in age determinations from depth profiles of isotope concentration. Here we show how soil stratigraphy can assess the relative stability of depositional surfaces locally, and can provide relative age-control. We focus on a Late Pleistocene lacustrine shoreline in Panamint Valley, California. The age of this feature has been problematic; previous efforts to date it with a range of techniques generally yield ages that fall between 50 – 100 ka. Such ages are inconsistent with well-dated lacustrine highstands in adjacent valleys, where shorelines are dated to ~180 ka (Death Valley) and ~160 ka (Searles Valley). To assess this discrepancy, we combine TCN (¹⁰Be and ³⁶Cl) dating techniques with soil stratigraphy on both shoreline remnants (gravel beach ridges) and adjacent alluvial fans.

Four soil profiles on preserved remnant surfaces of a gravel beach ridge (~615 m amsl). The soils all consist of a well-developed Av-ABvk-Btkyz-BCKy-CB-Ck vertical horizon sequence with soil depths of ~125-135 cm. Both the vesicular Av-ABvk horizon (6-8 cm thick, prismatic structure) and Btkyz horizon sequences (~65-85 cm thick, 7.5YR-5YR hues, prismatic to blocky structure) are well-developed. All remnant surfaces are level, at the same elevation, have smooth surfaces (no rills, gullies), and are covered with well-developed desert pavement. The lateral distribution of identical soil profiles and surface properties indicate that these soils formed beneath the original depositional surface and have experienced minimal net erosion.

TCN depth profiles yield disparate dates resulting from assumed erosion rates. Best-fit model ages from a ¹⁰Be depth-profile are ~71-106 ka (-10-30 cm total erosion). By comparison, ³⁶Cl depth-profile ages are ~164 ka if model-predicted erosion rates (~100 cm total erosion) are used, and ~84-111 ka if -10-30 cm total erosion is considered. Removal of a potential outlier sample from the model analysis yields best-fit ages of 74-96 and 143 ka (-10-30, and 100 cm erosion, respectively). Expected ages of the beach ridge soils are ~70-80 ka when a well-constrained regional soil chronosequence (14 dated soils ~0.6 to ~176 ka) is considered. Consistent soil stratigraphy and regular surface morphology indicate minimal erosion and do not support model results that imply >30 cm erosion. The presence of the well-developed Av horizon and Btkyz horizon sequence form a systematic vertical soil-horizon sequence supporting this argument. If net-zero erosion is assumed, as indicated by the soil-stratigraphy, the resulting shoreline age is ~88 ka from both TCN chronometers and is reasonably consistent with the independent chronosequence data. These results show that inclusion of soil stratigraphy can greatly enhance age interpretations of TCN depth profile ages.

Glacial chrono-stratigraphy constrained by rock avalanches along the Mendoza river valley, Argentine Central Andes (32° S).

Stella Maris Moreias

IANIGLA - CCT Mendoza, Mendoza, Argentina. Facultad de Ciencias Agrarias, Universidad Nacional de Cuyo, Mendoza, Argentina

Abstract

Huge rock avalanches clustered in the northern extreme of the Cordón del Plata range (32°S) stratigraphically related to Pleistocene glacial drifts and valley fill deposits were chrono-stratigraphically studied. Cosmogenic dating (TCN) on surficial blocks of the rock avalanche deposits and optically stimulated luminescence dating (OSL) of paleo-lakes dammed by these rock avalanches were performed. These dates (17 TCN and 4 OSL) determine Middle-Late Pleistocene ages contrasting with the previously glacial chronology of Mendoza river valley that was established based on relative dating techniques, paleontological context, and tephrochronology. Hence, the previously dated ash layers were geochemically analyzed by ICP spectrometry to clarify if indeed those tephra relate to a single event.

TCN dating technique opens the possibility of dating landslide directly constituting the most useful tool for Quaternary studies for the Arid Central Andes where tephrochronology is limited to relative ages, and thermoluminescence techniques (TL/OSL) are limited to fine sediments. Late-Middle Pleistocene age obtained by TCN for rock avalanches clustered in the Cordón del Plata range is significantly confident and consistent with stratigraphic studies. Besides, new findings throw light on the regional neotectonic as the studied rock avalanches, presumably triggered by $M > 6$ earthquakes, are gathered along the active Carrera Fault System. As well, obtained cosmogenic dates adjust the ages for the first horse (*Hippidion devillei*) remains found in the province of Mendoza, initially assigned to the Middle Pleistocene by stratigraphic relationships.

Clearly, our findings help to redefine the geomorphological evolution of the Mendoza river valley. Especially indicate that the glacial stratigraphy earlier proposed must be reconsidered. In addition, our data suggest that the Carrera Fault system bounding the valleys of the Cordillera del Plata has been more recently active than earlier proposed.

Chlorine degassing of Early Holocene lava domes, central Turkey, estimated by cosmogenic ^{36}Cl and radiocarbon dating

M. Akif Sarıkaya¹, Attila Çiner¹, Erdal Şen², Orkun Ersoy², Marek Zreda³

¹Eurasia Institute of Earth Sciences, Istanbul Technical University, Istanbul, Turkey. ²Geological Engineering Department, Hacettepe University, Ankara, Turkey. ³Hydrology and Atmospheric Sciences Department, University of Arizona, Tucson, AZ, USA

Abstract

We provide a novel approach to estimate the Cl degassing on young lavas and deliver new evidence of geochronology of the volcanism and activity of the Cappadocia Volcanic Province in the central Anatolia during the early Holocene. We applied a combined approach using the cosmogenic ^{36}Cl and radiocarbon dating methods to unravel the Cl degassing partition coefficients and eruption chronologies of three volcanic domes on the slopes of the Mount Erciyes (ancient name *Argaeusor Argaios*), the largest stratovolcano in central Turkey. The famous ancient geographer, Strabo (63 B.C.-23 A.D.) described swampy plains around Mt. Argaios, where local fires break out in pits. Here, we collected 27 cosmogenic samples to date three monogenetic parasitic lava domes on the flanks of the volcano. Our ages indicate an early Holocene eruption activity of lava flows and yielded average age range between 6-10 ka. We also applied radiocarbon dating using two charcoal samples from burned tree branches in a pyroclastic flow related to the lava domes. Charcoals provided an average age of 9.7 ± 0.1 ka cal. B.P. (calibrated with Calib 7.1). We argue that since the radiocarbon age does not agree with the cosmogenic ages, the nucleogenic ^{36}Cl were probably affected by the Cl degassing of the magma. Our study suggests that the radiocarbon age indeed lies between the 0% Cl degassing (6.8 ± 0.5 ka, under nucleogenic ^{36}Cl equilibrium) and the 100% degassing conditions (9.9 ± 0.6 ka, under nucleogenic ^{36}Cl disequilibrium), which implies a partial Cl degassing (93%) during the eruption. Earlier estimates of Cl degassing from melt inclusions, matrix glass, and volcanic vents are range from 17% to 67%. Our value is somewhat higher than earlier estimates and the difference may result from the miscalculated nucleogenic and/or low-energy neutron production of ^{36}Cl , uncertainties arising from the corrections due to hydrogen-rich cover (i.e., snow) of lava surfaces or due to unconsidered geological complications.

Abstract

Glacial erosion can be intensive and it has created some of the most dramatic landscapes on Earth. Estimated glacial erosion rates range over multiple orders of magnitude, with very low erosion evidenced by preservation of landforms under non-erosive ice and high erosion illustrated by deeply carved fjords and by sediment output from present-day glaciers. Most glacial erosion estimates are derived from high-relief mountainous landscapes and their glaciers. Ice sheets that covered North America and northern Eurasia during the Quaternary covered low-relief topography and it is the erosional imprint of these ice sheets on low-relief landscapes that is the focus of our study.

To investigate glacial erosion of low-relief topography under large ice sheets we have measured ^{10}Be and ^{26}Al in 32 bedrock samples from the east coast of Sweden. These samples are derived from a low-relief (0-70 m a.s.l.) crystalline basement region around Forsmark with well-constrained timing and rates of deglaciation and isostatic rebound. Simple exposure ages range from 2 to 71 ka. Taking the shielding by water due to isostatic rebound into account, all samples but one have ^{10}Be and ^{26}Al concentrations higher than commensurate for deglaciation, with most samples being 3.5-10 ka too old. This cosmogenic inheritance due to prior exposure enables us to explore model space for past glacial erosion. Tracking the cosmogenic nuclide production rate over time and depth, we simulate the buildup of ^{10}Be and ^{26}Al under a range of scenarios with varying ice cover durations, subaerial erosion rates, and modes of glacial erosion (constant erosion rate or constant erosion depth for each ice cover period). Under these assumptions and if excluding one sample, the simulations yield Quaternary glacial erosion lower than 0.4 m/ka or 3.3 m per ice cover period. For most of the samples for which we yield a solution for both ^{10}Be and ^{26}Al , glacial erosion was restricted to 0.04-0.09 m/ka or 0.4-1.1 m per ice cover period. For the last glaciation (last 100 ka), this translates into a total erosion of only 1.6-3.5 m. A comparison with previously published ^{10}Be and ^{26}Al data from bedrock samples in low-relief regions of Fennoscandia lends support to limited glacial erosion, with a large number of samples displaying cosmogenic inheritance. Our data and analysis show that the glacial erosion rate of the low-relief landscape under the last Fennoscandian ice sheet may be significantly lower than common glacial erosion rates in alpine regions.

Deciphering ~45.000 years of Arctic Ocean lithostratigraphic variability through multivariate statistical analysis

Stefanie Kaboth-Bahr^{1,2}, Vianney Denis³, Chih-Chieh Su³, Matt O'Regan⁴, Richard Gyllencreutz⁴, Martin Jakobsson⁴, Ludvig Löwemark²

¹Heidelberg University, Institute of Earth Sciences, Heidelberg, Germany. ²National Taiwan University, Department of Geosciences, Taipei, Taiwan. ³National Taiwan University, Institute of Oceanography, Taipei, Taiwan. ⁴Stockholm University, Department of Geological Science, Stockholm, Sweden

Abstract

Our understanding of past climate conditions in the Arctic Ocean has been hampered by poor age control caused in part by low sedimentation rates (< 1cm/kyr), hiatuses during glacial intervals as well as the scarcity and poor preservation of calcareous nanno- and microfossils in the sediments. Although recent advances using variations in single element (e.g. Mn) content or physical sediment properties (e.g. bulk density, grain size, colour) of the recovered sediments have aided Arctic core-to-core correlations, unique depositional events and post-depositional changes can complicate stratigraphic interpretations based on individual or even multiple, physical or chemical parameters. Furthermore, clear correlations between cores using physical and chemical parameters are not always possible to establish. To tackle this issue, we developed an algorithm that combines clustering and multivariate ordination to test the interrelation of multiple input parameters (e.g. an array of individual XRF elemental contents), and subsequently identifies statistically significant stratigraphic units on centimetre to decimetre scales. Our preliminary results show that a distinct sedimentological pattern during the past 45,000 years characterizes cores from the region of the Morris Jesup Rise and the Greenland side of the Lomonosov Ridge. Stratigraphic patterns of the Siberian Side of the Lomonosov Ridge yield distinct differences, thus allowing for novel insights into sedimentary processes shaping the different regions within the Arctic Ocean. We also argue that our approach can compensate for some of the weakness of single element or proxy applications, and hence aid the construction of a robust stratigraphic framework for a wide geographical range of Arctic Ocean sediments.

Towards 250,000 years of paleoenvironmental and paleoclimate evolution recorded in Onepoto Maar Lake, New Zealand.

Benjamin Laeuchli

University of Auckland, School of Environment, Auckland, New Zealand

Abstract

Long, continuous maar lake sediment sequences spanning at least 100 ka are well documented and researched in the Northern Hemisphere mid-latitudes and have enabled climate reconstructions as far back as the Mid-Pleistocene. In contrast, records of similar quality and length are rare in the Southern Hemisphere and tend to be discontinuous. However, Auckland's maar lakes provide long, continuous, high-quality, laminated sediment records that are very suitable to study Southwest Pacific paleoclimate for the last two glacial cycles at resolutions down to a sub-decadal to even annual-scale.

Onepoto paleolake, located within the Auckland Volcanic Field, New Zealand, contains a lacustrine sediment record spanning from ca. 9 ka BP back to its formation (ca. 250 ka). The sediments have been subject to various research projects focusing on the preserved tephra layers or on paleoenvironmental research questions. Yet, until recently no complete sediment record had been retrieved. Therefore, we here present a complete composite lake sediment record at sub-decadal resolution unique in the Southern Hemisphere and established from a recent drilling campaign undertaken in 2018 and well-preserved, core material from extracted 2011. Furthermore, based on continuous, high-resolution micro-XRF data sets, we provide new insights into the sedimentary and environmental evolution of the lake, as well as climatic-forcing recorded in the sediments. These novel results, together with related work currently underway for nearby Orakei Maar, will substantially reduce the existing gap in two glacial cycle paleoclimate data from the Southern Hemisphere mid-latitudes.

New Zealand is ideal for the application of tephrochronology due to the many active volcanic centers in the Taupo Volcanic Zone and the Auckland region. However, in contrast to the well-dated post-46 ka record, the tephra older than 46 ka suffer from poor age control, the dating of which depends on discontinuous sequences. Nevertheless, using sedimentation rates extrapolated from the ca 46 ka Rotoehu tephra to the base of the laminated Onepoto Maar paleolake sequence we expect to be able to produce ages robust enough to relate observed environmental events in the sequence to broader climatic trends and environmental events in the study area and eventually to larger interregional, and perhaps even global trends. Additionally, $^{40}\text{Ar}/^{39}\text{Ar}$ dating on basalt lava from the crater base as well as U-Th measurements will provide further evidence to narrow down absolute ages in the lower part of the paleolake sequence.

O-1073

Using XRF to differentiate between sediments of glacial and periglacial origin in the Vale of York, UK

Della Murton, Simon Crowhurst
University of Cambridge, Cambridge, United Kingdom

Abstract

Glaciolacustrine deposits are important archives of palaeoenvironmental change and suitable for high-resolution analyses by XRF core scanners. In particular, captured elemental data are useful for estimating grain size and determining sediment provenance. As yet, there are limited investigations into sediment provenance that differentiate between glacially-derived inputs resulting from seasonal melting of adjacent ice lobes and periglacially-derived inputs from weathering of the surrounding extra-glacial terrain. To test this approach we compare elemental data—acquired using an Avaatech XRF core scanner—from known glacial and periglacial deposits in eastern England with high-resolution elemental data from the basin-fill sediments in the Vale of York. These sediments comprise alternating units of reddish brown to dark greyish brown laminated to faintly stratified silty clay and dark greyish brown silt interbedded with yellowish brown silty sand. They were deposited during the Devensian (Weichselian) glaciation, when ice lobes of the British–Irish Ice Sheet impounded regional drainage, forming glacial Lake Humber. The adjacent uplands are mantled by discontinuous deposits of gravelly clay, and matrix-rich diamicton interdigitated with sands and gravels. These are interpreted as colluvial deposits, sourced largely by periglacial weathering of the underlying frost-susceptible and predominantly calcareous bedrock. Using principal component analysis, we identify sedimentary texture and carbonate content as the two dominant parameters (principal components) explaining elemental variance in our data. While this can differentiate between the glacial and periglacial end members it is less robust for other aspects of the basin-fill elemental data, where additional sedimentary parameters such as colour reflectance are needed.

The link between precipitation and sedimentation processes in a subtropical mountain lake, north-eastern Taiwan during late Holocene

Tsai-wen Lin¹, Stefanie Kaboth-Bahr², Kweku Afrifa Yamoah³, Chih-Chieh Su⁴, Pei-Ling Wang⁴, Hong-Chun Li¹, Yuan-Pin Chang⁵, Jyh-Jaan Steven Huang⁶, Ludvig Löwemark¹

¹Department of Geosciences, National Taiwan University, Taipei, Taiwan. ²Institute of Earth Sciences, Heidelberg University, Heidelberg, Germany. ³School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom. ⁴Institute of Oceanography, National Taiwan University, Taipei, Taiwan. ⁵Department of Oceanography, National Sun Yat-sen University, Kaohsiung, Taiwan. ⁶Institute of Geology, University of Innsbruck, Innsbruck, Austria

Abstract

Monsoon rainfall in eastern Asia is an essential sub-system of the global monsoonal belt and affects nearly one-quarter of the world's population. Yet our understanding of its variability on different geological time scales is limited. An ideal location to study East Asian monsoonal variability is Taiwan, an island located in western subtropical Pacific, and situated in the purview of the East Asian monsoonal system. Additionally, the island is also exposed to strong typhoon activity during summer/autumn. This provides the unique opportunity to study monsoon and typhoon changes in the western subtropical Pacific during the geological past. However, Holocene paleoclimate records retrieved from various lakes in Taiwan have shown discrepancies in their recorded climate variability. This is aided by the lack of modern sedimentological observations which limit our understanding of the mechanisms controlling lake sedimentation and thus introduces uncertainty in comparisons between lake records. In order to tackle this issue, sediment traps were collected monthly since July 2017 at Cueifong Lake (24°30' N, 121°36' E, 1840 m above sea level) in northeastern Taiwan. The collected data encompasses variations in sediment influx during winter and summer monsoon seasons, as well as sediment related to typhoon events. These results enable us to specify the main factors controlling sediment deposited in the Cueifong Lake and link these to seasonal precipitation variability. Subsequently, our modern findings have been applied to the lake sediment, allowing core records to be used for paleoclimatic reconstructions of a ~1.8 m long sediment core retrieved from the deepest part of the lake covering the last ~3 kyr, based on ²¹⁰Pb and ¹⁴C dating. A multi-proxy approach analysis was applied for the sediment core consisting of X-ray fluorescence (XRF) core scanning, grain-size analysis, geochemical analysis (TOC, TN), and stable carbon isotope (d¹³C) analysis.

Our modern findings indicate that decreases in sediment grainsize occur during high lake level periods, which correspond with winter monsoon season. In the core record, three periods of sediment fining (high Rb/Sr, reduced mean grain-size) can be observed during 1040-1150 yr BP, 1680-1810 yr BP, and 2400-2550 yr BP. These intervals are also accompanied by decreased TOC and thus point towards high lake level periods. Additionally, we find another period of sediment fining between 1900-2010 CE, accompanied by a sharp increase in the inc/coh ratio. This most likely correlates to a logging event around the lake during 1912-1982 CE. Our results not only clearly demonstrate the unique ability of the alpine lakes in Taiwan to act as a truthful recorder of East Asian monsoon variability, but also highlight the need to better link modern observations and paleo-records.

High resolution scanning of South Pacific lake sediment: relative benefits offered by state-of-the-art micro-XRF and SEM systems

Marjorie Fis, Ian Croudace, David Sear, Peter Langdon, Richard Pearce
University of Southampton, Southampton, United Kingdom

Abstract

A methodological evaluation for the efficient investigation of laminated core material collected from the South Pacific islands is presented that is expected to be of broad interest to the core scanning community. Efficient identification of laminae, their number, chemistry and mineralogy provide crucial information in inferring sediment accumulation rates and environmental and climate change. The material investigated was collected as part of NERC grant NE/N006674/1 - **The legacy of cyclone Pam: a unique opportunity to build a long term record of cyclone activity in the western tropical Pacific** (PIs David Sear, Pete Langdon and Ian Croudace). The project is part of a multi-party study involving the PIs, 3 PhD students and collaborating specialists. Analytical data obtained from measurements of a 10 cm section of resin impregnated lake sediment from Lake Te Roto (Atiu Island, Cook Islands) will be discussed. Investigation of the sediment block was made using Itrax, Bruker M4+ micro-XRF and Leo SEM systems. The benefits of using the different approaches are evaluated with the purpose of establishing a preferred approach that would be applied to detailed investigation of all or selected core material collected from two field campaigns. The analytical timeline including an efficiency budget (sample preparation, analysis) as well as the robustness and comparability of analytical outputs (textural, density and elemental variations) will be presented.

Figure: SEM montage of BSE-Ca and S for impregnated Lake Atiu laminated sediment (10 cm). Darker layers have higher mean atomic number. Very bright areas represent Ca and S (hence gypsum) which are inferred to correlate with drying episodes.

Don't count on it – Robust use and interpretation of geochemical records obtained by XRF core scanning

Rik Tjallingii¹, Menno Bloemsmas^{2,3}, Weltje Gert Jan², Achim Brauer¹

¹GFZ German Research Centre for Geosciences, Potsdam, Germany. ²(2) Department of Earth and Environmental Sciences, Leuven, Belgium. ³ASCAR, Velsen-Zuid, Netherlands

Abstract

The use of XRF core scanning data in terms of geochemical element records has become a routine analysis. Most commonly used are element intensity records produced by XRF scanners, despite the known weaknesses these records. The great benefit of XRF cores scanning is that analyses are performed directly at the core surface, which provides continuous element records at sub-millimeter sampling resolution. However, element intensity records are not only affected variations in the chemical composition but also by variations of the sample geometry, attenuation, and matrix effect down core. Aside of matrix effects, these variations are effectively eliminated by normalization of element intensities in terms of element ratios or proportions of a constant number of elements. Unfortunately, matrix effects are non-linear and not effectively compensated by normalization. By estimation of relative matrix effects, log-ratio calibration is the only model providing a solution for non-linear matrix effects.

The log-ratio calibration model demonstrated that log-ratios of XRF intensities are linearly related to log-ratios of geochemical concentrations, and are consistent with statistical analysis of compositional data, unlike net counts or element intensities. Consequently, log-ratios of element intensities provide the most reliable records for statistical analysis of XRF core scanning data in terms of chemical composition. These advantages are combined in the Xelerate software package and facilitate statistical analysis, calibration and visualization of XRF element records and core photographs. This software provides detailed and robust statistical analyses of sediment composition and reduces the influence of elements with a low precision by including analytical uncertainties as derived from replicate scans or quantitative calibration. Here we present several examples that demonstrate the benefit of this method for climatic and environmental interpretations of XRF cores scanning results.

O-1077

An empirical method to predict sediment grain size from XRF core scanner measurements

Dawei Liu¹, Sébastien Bertrand¹, Gert Jan Weltje²

¹Renard Centre of Marine Geology, Ghent University, Ghent, Belgium. ²Department of Earth and Environmental Sciences, KU Leuven, Leuven, Belgium

Abstract

Grain size is one of the most fundamental properties of sediments. It is frequently used in paleoclimate, paleoceanographic and paleoenvironmental research as a proxy for river discharge, current and wind strength, and to identify mass flow deposits. Measuring grain-size is, however, time-consuming and destructive. Given the strong influence of grain size on sediment inorganic geochemistry, single element variations measured by X-ray fluorescence (XRF) core scanning are increasingly used to estimate grain-size variations at high resolution in sediment cores. This approach is however limited to a narrow grain-size range since individual elements only monotonically relate to grain size over a narrow size range. Here, we present a simple, code-free, multi-element technique based on Partial Least Square regression to predict sediment mean grain size from inorganic geochemical data over the range of sizes commonly encountered in sedimentary basins. The method was first tested using river sediment samples separated in eleven grain-size fractions and it was later successfully applied to two sediment cores from the Chilean fjords, with mean grain sizes ranging from 16–31 and 7–180 μm . Our technique only requires measuring grain size on a limited number (around ten) of selected training samples, and it allows to predict mean grain size at XRF core scanner resolution. Provided sediment provenance, weathering, and diagenesis are relatively stable through time, this technique is applicable to any lake or marine sediment core, and we anticipate that it will result in a significant increase in the resolution of sediment proxy records of climate and environmental change.

O-1078

How tides and rivers shape flood-protecting levees and crevasses

Harm Jan Pierik, Jelle Moree, Lonneke Roelofs, Marcio Boechat Albernaz, Steven Weisscher, Tjalling de Haas, Maarten Kleinans
Utrecht University, Utrecht, Netherlands

Abstract

Natural levees and crevasse splays are highly-elevated geomorphological overbank features in dynamic delta and tidal environments. They are important for past and future human occupation and protection against floods. Their dimensions vary owing to differences in sediment supply, flood regime and floodplain properties. Despite their importance for safety around estuaries, their formative controls have so far been mainly analysed for fluvial environments only. We focus on the levees and crevasses of the Old Rhine estuary in the Netherlands to better understand how tidal and fluvial processes form these overbanks deposits. The main Rhine branch debouched into this estuary between 6500 and 1000 cal yr BP. The 50 km long channel belt runs through a vast peatland and formed the natural corridor for the limes in the Roman period. We use existing geological data and new field data to reconstruct levee evolution, which we correlate to reconstructed changing boundary conditions over the late Holocene (fluvial discharge, tides, sediment supply). Numerical and experimental modelling in Delft3D and the Metronome facility respectively were used to test the mechanisms behind levee evolution inferred from the Holocene geological record.

The variation in overbanks in space and time along the Old Rhine shows the influence of tides and tidal backwaters. Orientation, abundance and size of crevasse splays indicates increasing tidal influence towards the estuary mouth. Field data furthermore reveals two distinct phases of overbank deposition from the fluvial to the coastal realm. In the middle of the channel belts' lifespan around 3500-3000 BP, the thickest and siltiest levees formed together with 10 km long narrow crevasses penetrating into the peatland. As the estuary mouth became smaller the tidal influence reduced after ca. 3000 BP these crevasse splays became less active. The importance of tides is confirmed by our model results showing that they trigger relatively large and abundant levee-crevasse complexes. The effects of increased fine sediment supply are observed from ca. 2800 BP onwards. This human-induced effect was caused by land-use changes (i.e. deforestation) in the upstream Rhine catchment. As a result, peat formation stopped and relatively clayey, very wide and thin overbank deposits were formed. Our experimental and numerical modelling demonstrates that, besides these external forcings, floodplain setting (e.g. vegetation density) and autogenic feedbacks between accommodation space (max. water level) and levee growth, are important drivers in levee dimensions and phasing. This study shows how tidal levees are distinctly different from their fluvial counterparts and provides important clues on how vulnerable landscapes can change when human induced changes in sediment load and river discharge occur.

Prehistoric coastal changes of the Mekong delta: Implications for recent erosion

Toru Tamura^{1,2}, Yoshiki Saito^{3,1}, Marcello Gugliotta³, Van Lap Nguyen⁴, Thi Kim Oanh Ta⁴

¹Geological Survey of Japan, AIST, Tsukuba, Japan. ²University of Tokyo, Kashiwa, Japan. ³Shimane University, Matsue, Japan. ⁴Vietnamese Academy of Science and Technology, Ho Chi Minh City, Vietnam

Abstract

The coastline of the Mekong delta is thought to have suffered the decline in the fluvial sediment supply after the enhanced human disturbance, especially the construction of hydropower dams in the upper reach, since the late 20th century. However, coastal erosion observed after 1970's is not fully accounted for by the recent disturbance, and thus may also reflect the longer-term trends in sediment discharge. To compare with the historical observation, we report prehistoric changes of a 320 km stretch of the South China Sea coastline of the Mekong delta over the last 2500 years based on fossilized shoreline records and their OSL and radiocarbon dating. The South China Sea coast of the Mekong delta is divided into two parts: the northeastern part characterized by inter-distributary sandy compartments, and southwestern muddy coast. The coastline is affected by the southwestward longshore drift. The northeastern sandy compartments show minor shifts of depocenter, but their total accretion rate is consistent ranging from 0.7 to 1.2 km²/year before 400 year BP, followed by a modest increase to 2 km²/year in the last 400 years. The accretion rate of the southwestern muddy coast was 2 km²/year before 1400 year BP and increased by several times after 1400 year BP. The Camau Peninsula, which outlines a remarkably prominent delta shoreline towards the sea, was formed entirely in the last 600 years. Accelerated accretion of the southwestern shoreline after 600 year BP is thus inferred, owing to an overwhelming mud supply, while the modest accretion of the northeastern compartments after 400 year BP is caused by sand supply. These separate trends may be linked to the contrast between the northeastern and southwestern shorelines observed over the last 20 years. The overwhelming mud supply is possibly linked to the migration of the large population into the Yunnan in China, the uppermost reach of the Mekong River, in the 14th century and extensive shifting cultivation. The majority of the current erosion is happening in the southwestern coastline, which started even before the hydropower dam construction. This severe erosion thus may reflect longer-term fluctuations in mud supply that was overwhelming over the last 600 years but sharply decreased sometime before 1970's, which are not relevant with the hydropower dam construction.

Rapid shifts in storm climate 3,500-2,200 years ago, detected from the ancient coastal formations – Estonia, NE Baltic Sea.

Hannes Tõnisson¹, Shinya Sugita¹, Are Kont¹, Egert Vandel¹, Tiit Vaasma¹, Kadri Vilumaa¹, Agnes Anderson²

¹Institute of Ecology, Tallinn University, Tallinn, Estonia. ²School of Natural Sciences and Health, Tallinn University, Tallinn, Estonia

Abstract

Beach ridge systems and foredune plains are widespread worldwide and are common features on many types of coasts. Postglacially uplifting seacoasts of Estonia are rich in rhythmic coastal landforms such as ridge-depression sequences and spits. These rhythmic patterns may extend kilometres inland from the current shoreline. It should be noted that the Baltic Sea coast is a tideless environment with water level fluctuations forced by strong storms. The ridge systems in this region are offering a unique opportunity to examine the events over at least the last 6,500 years when the Baltic Sea mean water table has been consistently dropping and a steady shoreline advancement has been punctuated by rare extreme events. We have found that the signs of past storms are clearly reflected in the internal structure and size of the ancient ridges. The current study is focusing on high ridge systems containing extensive seaward-dipping layers formed 3,500–3,000 years ago and the following small, nearly unnoticeable ridges, formed 3,000-2,200 years ago.

In this study, ground-penetrating radar survey, complemented with drilling results and GIS analyses based on LiDAR topography were carried out in the coastal ridge systems. Four study areas with different exposure to the storms and different rates of land uplift were selected. The records of aeolian sand influx into the nearby peat bogs and past climatic records of northern Europe were compared with recent (last 100 years) shore processes. The findings of this study are supported by previously published luminescence dating results.

We have found that higher ridges with extensive seaward-dipping layers, large foredune systems and major spits were formed 3,500-3,000 years ago. Also, an increased sand influx was reported into the bogs in this period. The period was characterised by increased storminess – similar to today's situation. A rapid drop in the heights and nearly no seaward dipping layers characterise the ridges formed during the next 800 years. Sand influx into the bogs also dropped significantly. This suggests a rapid regime shift towards much calmer conditions. It should be noted that the contemporary increase in storminess is related to the shifts in cyclone trajectories. Similar shifts have probably taken place 3,500 years ago. However, it is likely that around 3,000 years ago the shift did not restore the previous state but created a new one. We may assume that during continuous shift of cyclone trajectories northwards, a certain threshold was exceeded and the cyclones were probably redirected along the high Scandinavian mountains to the north leaving our region in more continental climatic conditions. A number of palaeoclimatic records also support this theory. Similar shift cannot be ruled out today.

Recent coastal barrier evolution in the Bras d'Or Lake, Nova Scotia, Canada

Francis Chantel Nixon¹, Chris White², Thomas Lakeman³, Edward King⁴, Gordon Cameron⁴

¹Norwegian University of Science and Technology, Trondheim, Norway. ²Geoscience and Mines Branch, Government of Nova Scotia, Halifax, Canada. ³Geological Survey of Norway, Trondheim, Norway. ⁴Natural Resources Canada, Dartmouth, Canada

Abstract

Barrier beaches enclosing small ponds and lagoons (locally known as 'barachois') form a significant part of the Bras d'Or Lake shoreline in Cape Breton, Nova Scotia, Canada. The Bras d'Or Lake itself, is a large, inland sea, with many of its coarse gravel barriers developed into harbours, roads and recreational areas. Well preserved, submerged (≤ 25 m below msl) early-mid Holocene coastal landforms identified from multibeam acoustic imagery in the Bras d'Or Lake, including spits, tombolos and barrier beaches (Shaw et al. 2006), may represent an indication of things to come, especially given the predicted relative sea-level rise for this region over the next 100 years: the highest in Canada (James et al., 2014). An understanding of the age of the barachois, the paleoenvironmental records archived in their underlying sediments, and the morphodynamics of their barriers (i.e. how quickly they evolve from growth or stable phases to landward-migrating or submerging phases), represents important baseline data with which modern and future coastal dynamics may be compared, and with which vulnerability to future sea-level rise and coastal erosion can be estimated. Interpretations of recently acquired acoustic data collected inside the barachois (shallow seismic, sidescan sonar), as well as sediment core data (XRF, radiocarbon dates, lithology, and organic matter), will be presented.

Applying faunal indices for palaeoenvironmental reconstructions with benthic foraminifera: a case from a Holocene succession of the Po Delta, Italy

Utsha Dasgupta¹, Giulia Barbieri², Stefano Claudio Vaiani², Anupam Ghosh¹

¹Jadavpur University, Kolkata, India. ²University of Bologna, Bologna, Italy

Abstract

In the last decades, the depositional history of the Po River coastal plain has been studied using different environmental proxies. In this work we first ever attempt to interpret the palaeoenvironmental evolution of a shallow marine succession from this area (core 205-S9, collected about 10 km south of the modern Po Delta) using several diversity indices, bivariate analysis and Murray's Ternary Plot. We also tried to find out the potentials and limits of these tools in reconstructing palaeoenvironments.

The analysed shallow marine succession was formed in response to the last phases of sea-level rise (ca. 8 kyr BP) and the Holocene regression resulted from the high-stand coastal progradation. In this part of the core, Murray ternary plot and Bivariate plot of Fisher's alpha index and Shannon-Wiener index show two distinct clusters highlighting high percentage of calcareous porcelaneous forms in the lower part and high percentage of calcareous hyaline taxa in the middle and upper portions. Fischer's α index and species richness values provide evidence for three intervals: the lower is highly diversified while in the middle the value gets decreases and in the upper the value increases but not as high as lower part. Evenness (E) and Dominance (D) indices show that the lower part is characterised by a homogeneous, highly diversified and evenly distributed fauna. In contrast, the middle part shows a strong dominance of few species with low faunal diversity with some variations in the upper part. The ratio of epifaunal and infaunal species defined oxygenated bottom water condition with low organic matter in the lower part, and high organic matter with relatively low oxygen concentration in the upper part.

All these indices clearly discriminate between a lower and a middle-upper portion of the sediment succession. The integration with the distribution of selected species allows to attribute the lower interval to a shallow marine environment with low fluvial influence (transgressive barrier and offshore transition), whereas middle and upper parts record an increase of fluvial influence (prodelta). Therefore, the applied indices can be considered as good proxies for recognition of deltaic conditions and identification of changes in riverine influence within shallow marine deposits. Furthermore, most indices highlight variations in foraminiferal distribution within the prodelta. Combining foraminiferal distribution and indices values, these variations can be attributed to unsteady freshwater influx.

Holocene paleoecology of black mangrove (*Avicennia germinans*) along the northern Gulf of Mexico coast, U.S.A.

Kam-biu Liu¹, Qiang Yao¹, Junghyung Ryu¹, Marcelo C.L. Cohen², Alejandro A. Aragón-Moreno¹, Érika F. Rodrigues², Nina S.N. Lam¹

¹Louisiana State University, Baton Rouge, USA. ²Federal University of Pará, Belém, Brazil

Abstract

The modern distribution of black mangrove shows a disjunct distribution along the northern Gulf of Mexico Coast of the U.S. It has dense populations in southern and central Florida, the Mississippi River delta, and western Texas, but notable gaps exist in the Florida Panhandle, Alabama, Mississippi, western Louisiana, and east-central Texas. It is unknown whether the disjunction is a result of recent long-distance dispersal in response to climatic warming, or range contraction from a former widespread distribution attributable to climatic cooling during the Little Ice Age. We reconstructed the Late Holocene history of *Avicennia* along the northern Gulf Coast by means of palynological and stratigraphic techniques and investigated their modern distribution and environmental controls by means of remote sensing and geomorphological mapping using drones. Multiple sediment cores were taken from a suite of coastal locations from Cedar Keys and Apalachicola Bay in Florida, Port Fourchon and Rockefeller Wildlife Refuge in Louisiana, and the Bolivar Peninsula and Port Aransas in Texas. Pollen data from Port Fourchon, Louisiana, where dense populations of black mangrove occur today, show that *Avicennia* pollen was absent throughout much of the Late Holocene and only started to appear in the uppermost sediments less than 100 years ago. Pollen data from the Rockefeller Wildlife Refuge in western Louisiana, where black mangroves are absent today, suggest that *Avicennia* never colonized this coastal area even during the Medieval Warm Period. Our drone surveys and ground observations of modern coastal vegetation communities in southern Louisiana and eastern Texas show that *Avicennia* populations suffered significant mortality as a result of the freezing events in the winter of 2017/2018, but the overall long-term trend was marked by population expansion and colonization in response to warmer winters over the past few decades. The paleoecological data so far seem to support the hypothesis that the modern disjunct distribution of *Avicennia* along the northern Gulf Coast was a function of long-distance dispersal in response to climate warming during the past century, and black mangrove had not expanded beyond its present distribution limit during the Late Holocene. Spatial modeling and transfer function studies will be conducted to relate modern and fossil pollen data to contemporary environmental parameters to shed light on the environmental factors limiting the distribution of black mangroves along the northern Gulf Coast.

It's in your glass: A history of sea level, storminess and human activity from the Laphroaig peat bog

Malin E. Kylander^{1,2}, Jenny Söderlindh¹, Fredrik Schenk^{1,2}, Richard Gyllencreutz^{1,2}, Johan Rydberg³, Richard Bindler³, Alasdair Skelton^{1,2}

¹Department of Geological Sciences, Stockholm University, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ³Department of Ecology and Environmental Sciences, Umeå University, Umeå, Sweden

Abstract

Severe winter windstorms in northwestern Europe have become an increasingly common occurrence over the last few decades. This increase in storminess is thought to be a result of global warming and, as such, is expected to intensify in the future. The IPCC has however, “low confidence” in these future projections, particularly on regional scales. This is in part due to a lack of continuous data detailing natural changes in storminess, which limits our ability to predict future scenarios. Peat-based storm records can be exploited to fill this gap. To date these records have been from coastal areas located downwind from significant sand sources. The basic premise is that stronger winds during stormier conditions transport larger grains to these peat bogs. The island of Islay on the southwest coast of Scotland provides an excellent location for studying storminess as it meets three key criteria: (i) it is one of the first landmasses to be hit by storms crossing the Atlantic Ocean; (ii) the wet maritime climate favours peat development, and the island therefore is rich in deposits; and (iii) the island has extensive sand dune and tidal flat systems providing an abundance of sand.

For this study a ~4 m long peat sequence was recovered from the Laphroaig peat bog (of whisky fame). This is an ombrotrophic (atmospherically fed) peat deposit located ~600 m downwind from a coastal dune system on Laggan Bay. Conventional peat paleostorm proxies such as ash content and grain size were used to acquire detail about changes in relative wind strengths over time. This was complimented by mineralogical analyses and multi-element XRF data treated using Principal Component Analysis. If we only consider changes in ash contents and Principal Component 1, which is interpreted to represent the input of large grained detrital minerals and therefore storms, no storm signals are found between ~7000 to 3000 cal yr BP. However, the grain size data from this period show several increases in the proportion of larger grain sizes (>150 µm), suggesting stronger winds. Elemental biplots show that the source of the detrital minerals reaching the peat bog transitioned ~3000 cal yr BP. These features can be linked to falling sea levels, consequent changes in sand source (size and location) and the build up of the dune system on Laggan Bay. At Laphroaig we find general agreement with available regional peat based storm records including key events such as the 2.8 event and the Little Ice Age. Broadly speaking, observed periods of storminess co-occur with periods of ice rafting in the North Atlantic, although multiple drivers of varying temporal importance are likely and need to be further investigated. This highlights the need for further such peat paleostorm records.

Abstract

During the last termination of ice age cycle (deglaciation), Heinrich event 1 as well as B/A, Antarctic Cold Reversal (ACR) and Younger Dryas occurred as millennial scale climate changes. On the other hand, millennial scale climate changes such as D-O cycles recorded in ice core and deep sea cores in both hemisphere seem to occur more frequently during the mid-glacial state than during the early or late glacial state. Here we ran several sensitivity experiments and deglaciation simulations using a coupled atmosphere and ocean GCM (MIROC4m AOGCM) developed in Japan and analyzed the stability of AMOC and climate. Many model experiments were run for longer than 10000 years under many different conditions of constant Greenhouse Gas levels, obliquity with/without glacial ice sheet and with and without freshwater flux into North Atlantic region. The results show large self-sustained oscillation of AMOC and high latitude temperature change similar to B/A and D-O cycles, comparable with ice core data and deep-sea data for some cases. We show that the D-O like oscillation and B/A-Y/D type change occur with Glacial ice sheets under limited range of CO₂, obliquity, and freshwater forcing. Implication on the mechanism and the conditions of the millennial scale climate changes for the past time period is discussed.

Abstract

Ocean circulation at high latitudes exerts a strong control on heat transport, biological productivity, and ocean-atmosphere CO₂ exchange. Today, the North Atlantic and North Pacific have contrasting circulation regimes, with vigorous deep-water formation in the North Atlantic, but only limited local ventilation in the North Pacific. This drives distinct patterns of nutrient supply and heat transport in each basin, and represents a first order asymmetry in global biogeochemistry and climate. Here, using a variety of high-resolution sediment core records, we demonstrate that this Atlantic-Pacific circulation asymmetry was repeatedly reversed during rapid climate change events of the last ice age, with invigorated overturning in the North Pacific during intervals of reduced overturning in the North Atlantic. This drove abrupt changes in nutrient and CO₂ supply to the high latitude surface ocean, with reduced overturning associated with high biogenic flux. Using an earth system model, and by analogy to the modern circulation and nutrient regimes of the North Atlantic and Pacific, we show that a “stratified” basin allows nutrients to accumulate, whereas a vigorous local overturning circulation flushes nutrients from high latitudes. Our results thus challenge the paradigm that regional stratification necessarily drives reduced nutrient supply. They also support the idea of a dynamic link between Atlantic and Pacific overturning and suggest an active role for the North Pacific in glacial climate and CO₂ change.

⁴Michigan State University, East Lansing, USA

Abstract

The recent refinement of cosmogenic nuclide dating has revolutionised glacial chronologies and, in turn, our understanding of the manifestation and terrestrial impact of abrupt climate change. With the objective of providing a robust geologic baseline for conceptual and numerical models, we present a new record of cryospheric change, as a proxy for atmospheric temperature, in the northern British Isles. This chronology, constrained with cosmogenic beryllium-10 and calculated using the new Scottish ^{10}Be production rate (Putnam *et al.*, 2018), captures the intricate pattern of deglaciation and periodic readvance of the British ice sheet following the Last Glacial Maximum (Termination 1). Exploiting the highly sensitive, yet intrinsically straightforward, relationship between temperature and glacier mass balance, this and similar emerging glacial records are painting a fascinating picture of 'stadial' climate that contrasts with the traditional view of these severe climatic perturbations. Taken together with existing palaeoclimate data for Termination 1, the glacial record from northern Scotland implies a central role for seasonality in North Atlantic stadial-interstadial climate and, crucially, helps place regional events into a global context.

Abstract

The last deglaciation (20-10 ka BP) represents a rich, and sometimes abrupt, interplay between different components of the Earth System set in motion by gradual orbital variations. The large-scale atmospheric circulation is an important component of these coupled changes, for example via the strength and meridional position of the southern hemisphere (SH) westerly winds. Proxy evidence on past atmospheric circulation changes is typically indirect, for example via tropical hydrology, isotopic composition of meteoric waters, ocean frontal positions, El Niño strength, windblown dust, or ocean upwelling.

Here we present a newly developed ice core gas-phase proxy that directly samples an important component of the large-scale atmospheric circulation: synoptic-scale pressure variability. Krypton-86 excess ($^{86}\text{Kr}_{\text{xs}} = \delta^{86/82}\text{Kr} - \delta^{40/36}\text{Ar}$) reflects the degree of gravitational disequilibrium in the firn layer. Surface pressure variations from passing weather systems drive macroscopic air movement in the firn, causing gravitational disequilibrium and a shift in $^{86}\text{Kr}_{\text{xs}}$ towards negative values. Note that ice cores do not record individual weather systems, but rather the time-average intensity of barometric variability.

We present a 'core-top' calibration of $^{86}\text{Kr}_{\text{xs}}$ using late-Holocene ice core samples from nine locations around Antarctica and Greenland that shows a strong correlation between multi-sample-average $^{86}\text{Kr}_{\text{xs}}$ and site synoptic variability from ERA-interim reanalysis, providing the first validation of this new proxy. We address several caveats in the interpretation.

Next, we present a new $^{86}\text{Kr}_{\text{xs}}$ record from the WAIS Divide ice core in West Antarctica through the last deglaciation. We find a negative excursion in $^{86}\text{Kr}_{\text{xs}}$ during the deglaciation, with peak values during Heinrich Stadial 1 and the Younger Dryas – abrupt cold phases in the North Atlantic associated with warming in Antarctica and the global ocean interior, and rising atmospheric CO₂. We interpret the $^{86}\text{Kr}_{\text{xs}}$ record as an increase in barometric variability in West Antarctica during the last deglaciation. We suggest this may be linked to poleward displacement of the SH westerly winds during this time, which brings storm tracks closer to Antarctica, allowing cyclonic systems to penetrate more deeply into the continent.

The $^{86}\text{Kr}_{\text{xs}}$ record moreover closely resembles Southern Ocean Opal flux records that have been interpreted as markers of wind-driven upwelling, suggesting both may have a common driver, with the SH westerly winds being a candidate. The coincidence of enhanced SO upwelling with periods of atmospheric CO_2 increases is commonly cited as evidence of wind-driven ventilation of respired carbon from the abyssal ocean controlling the deglacial CO_2 rise. Our gas-phase storminess proxy allows direct comparison to ice core CO_2 records with zero age uncertainty. More broadly, our work provides a new forensic tool for investigating past changes to large-scale atmospheric circulation, to which synoptic activity is closely tied.

The impact of abrupt sea ice loss on Greenland water isotopes during the Last Glacial Period

Louise Sime¹, Peter Hopcroft², Rachael Rhodes³

¹British Antarctic Survey, Cambridge, United Kingdom. ²University of Birmingham, Birmingham, United Kingdom.

³University of Cambridge, Cambridge, United Kingdom

Abstract

Greenland ice cores provide excellent evidence of past abrupt climate changes. However, there is no universally accepted theory of how and why these Dansgaard Oeschger (DO) events occur. Several mechanisms have been proposed to explain DO events, including sea ice, ice shelf build-up, ice sheets, atmospheric circulation, and meltwater changes. DO event temperature reconstructions depend on the stable water isotope $\delta^{18}\text{O}$ and nitrogen isotope measurements from Greenland ice cores: interpretation of these measurements holds the key to understanding the nature of DO events. Here, we demonstrate the primary importance of sea ice as a control on Greenland ice core $\delta^{18}\text{O}$: 95% of the variability in $\delta^{18}\text{O}$ in southern Greenland is explained by DO event sea ice changes. Our suite of DO events, simulated using a general circulation model, accurately captures the amplitude of $\delta^{18}\text{O}$ enrichment during the abrupt DO event onsets. Simulated geographical variability is broadly consistent with available ice core evidence. We find an hitherto unknown sensitivity of the $\delta^{18}\text{O}$ paleothermometer to the magnitude of DO event temperature increase: the change in $\delta^{18}\text{O}$ per K temperature increase reduces with DO event amplitude. We show that this effect is controlled by precipitation seasonality.

O-1090

Impact of the Channel Outburst Flood at 455 kyrs before present on North Atlantic climate

David Hodell¹, Gloria Martin-Garcia², Francisco Sierro², Maryline Mleneck-Vautravers¹

¹University of Cambridge, Cambridge, United Kingdom. ²University of Salamanca, Salamanca, Spain

Abstract

Geophysical evidence from the seafloor of the English Channel provides strong evidence for the occurrence of an outburst flood caused by the spillover of a proglacial lake in the southern part of the North Sea that breached the chalk ridge, thereby forming the Strait of Dover (Gupta et al. 2017). Marine sediment cores from the Bay of Biscay indicate that the initial breach occurred at 455 ka (Toucanne et al. 2009) during the Elsterian–Anglian glaciation which is correlated to Marine Isotope Stage (MIS) 12. Here we studied MIS 12 at Site U1385 (Shackleton site) on the Iberian Margin and identified a distinct peak in ice rafted detritus (IRD) at 455 ka, which is accompanied by an increase in the abundance of the polar foraminifer *Neogloboquadrina pachyderma* (sinistral). At the same level in the core, the 455-ka event is marked by a decrease in benthic $\delta^{13}\text{C}$ indicating a reduction in the influence of North Atlantic Deep Water and an increase in remineralized carbon in the deep North Atlantic. The EPICA-Dome C ice core indicates the 455-ka event coincides with a drop in atmospheric methane (a northern hemisphere signal; Louergue et al., 2008) and an increase in Antarctic temperature (Jouzel et al., 2007), which is a typical signature of a bipolar seesaw response to freshwater forcing and reduced overturning circulation in the North Atlantic. These results suggest the Channel Outburst Flood had a significant impact on climate at 455 ka, which will be tested by model simulations forced by a point source of meltwater emanating from the English Channel.

Strong Atlantic overturning circulation under high-latitude freshwater input during marine isotope stage 11: Insight from modelling and nitrogen isotope.

Benoit Thibodeau

The University of Hong Kong, Hong Kong, Hong Kong

Abstract

The marine isotope stage 11 (MIS 11) is often used as a potential analogue for the Holocene because of its similarities regarding orbital and greenhouse gas forcing (e.g., Droxler et al., 2003). However, recent studies portrayed the surface subpolar North Atlantic to be fresher by about 6 salinity units compared to today (Kandiano et al., 2017). This added to the growing body of evidence that the subpolar North Atlantic was characterized by much fresher and cooler surface waters during MIS 11 peak interglacial conditions (MIS 11 *sensu stricto(ss)*) compared to the Holocene (Kandiano et al., 2016; Thibodeau et al., 2017). Interestingly, MIS 11ss is often characterized by a strong AMOC (e.g., Vázquez Riveiros et al., 2013; Dickson et al., 2009), which seems at odds with the notion of major fresh and cold water input at high latitudes (e.g., Rahmstorf et al., 2005). Here, I show that the fresh and cold surface layer in the Nordic Seas created a strong salinity gradient in the polar North Atlantic at the beginning of the interglacial concurrent with strong variation in the surface nutrient utilization. I further demonstrate, with the help of a simple box model, that the weakening of this gradient in the peak interglacial allowed for the onset of deep water formation in the Nordic Seas, which contributed to a global intensification of the AMOC. Finally, I highlight that this thermohaline-driven sharp intensification of the AMOC is concomitant with the observed general enrichment in North Atlantic benthic $\delta^{13}\text{C}$ (Lisiecki, 2010) and could help explain the abnormally long duration of MIS 11 (Dickson et al., 2009), underlining the importance of the North Atlantic freshwater budget in regulating AMOC.

Social resilience to climate instability in mainland Southeast Asia: the influence of socio-political factors

Tegan Hall¹, Rebecca Hamilton², Dan Penny¹, Jo Gillespie¹

¹University of Sydney, Sydney, Australia. ²Australian National University, Canberra, Australia

Abstract

For communities across the Southeast Asian mainland during the last millennium, episodes of societal florescence, decline and mobility are often linked to climate fluctuations (Lieberman and Buckley, 2012). For example, the Khmer kingdom, which dominated the mainland between the 9th and 15th century C.E., experienced an alternating series of severe dry and wet episodes during the 14th and 15th centuries C.E. that broadly coincided with a dramatic reconfiguration of Khmer society and its borders. At this time, Khmer political power waned, territory contracted, and urban populations across the kingdom migrated away from urban complexes toward smaller centres on the kingdom's periphery, presenting an apparent case of mobility and rupture in the face of heightened climate variability (Buckley et al., 2010, Hua et al., 2017).

However, two aspects of this narrative are worthy of further investigation. First, placed in the context of long-term climate records and socio-ecological dynamics the climate variability of the 14th and 15th centuries should not have been catastrophic for mainland communities. Second, recent palaeoenvironmental research indicates that land use attenuation within Angkor (Penny et al., in review) and at two (at least) secondary centres elsewhere in the kingdom (Penny et al., 2014, Hall et al., 2019) was complex and protracted and had begun a century or more before the climate crises of the preceding centuries, while other centres maintained populations throughout these centuries of climate instability (Hall et al., 2018). Therefore, what characteristics of these communities and Khmer society overall accounted for this variability in mobility and rupture at this time? This paper discusses the influence of socio-political factors, particularly increasing power centralisation in the kingdom, on the vulnerability of urban-agrarian populations through this important transition period in Southeast Asia, and discusses the implications for Cambodian communities facing increased climate variability in the contemporary landscape.

What is behind crop change? Agricultural decision-making and water availability during the Neolithic in the NW Mediterranean region

Ferran Antolin¹, Héctor Martínez-Grau¹, Valentina Caracuta², Stefano Bernasconi³, Pablo Martínez⁴, Manuel Edo⁴
¹IPAS, University of Basel, Basel, Switzerland. ²Equipe Dynamique de la biodiversité, anthropo-écologie (DBA), UMR 5554 – CNRS – Université de Montpellier, Institut des Sciences de l'Évolution de Montpellier, Montpellier, France.
³Geologisches Institut, Department of Earth Sciences, ETH Zurich, Zurich, Switzerland. ⁴CIPAG, Universitat de Barcelona, Barcelona, Spain

Abstract

Archaeobotanical research has been so far widely implemented for the study of agricultural practices in the past. The NW Mediterranean region is a particularly interesting area during the Neolithic period because it witnessed the contact between at least two different farming traditions corresponding to the two waves of advance of Neolithic groups from SW Asia: the central-european LBK tradition and the Mediterranean one. Crop changes over the early Neolithic and subsequent periods in this area might be due to several factors, both of cultural and climatic nature. In the framework of the SNSF-funded AgriChange project (2018-2021, PP00P1_170515), we want to use several on-site proxies to approach climatic fluctuations in the past in connection to crop change. For this presentation we want to focus on stable isotope analyses (mainly C, but also N) obtained from charred grains in order to see if crop changes observed in the archaeobotanical record coincide with changes in any of these values, and thus help us to start putting forward better-funded hypotheses regarding agricultural decision-making during the Neolithic period. There is abundant existing research on the use of stable isotopes as proxies for crop spring-water availability (C) and manuring (N). For this presentation we chose one site with an excellent and well-dated stratigraphy: the Cave of Can Sadurní (Barcelona, Spain). It contains deposits dated between 5400 cal BC to 3900 cal BC and abundant plant macroremains. Previous archaeobotanical research showed a first phase with a high importance of glume wheats in the late 6th millennium cal BC, followed by a period with more naked barley and naked wheat during most of the 5th millennium cal BC and a subsequent increase of glume wheats towards the end of this phase. According to soil micromorphology analyses, glume wheats coincide with drier phases, while naked wheat and naked barley expand in wetter periods. This is therefore an ideal case study to attempt an approach using stable isotope values and contribute to the main question of this session regarding the potential role of environmental factors in economic change.

Developed viticulture and winemaking in the mountains of Transcaucasia - an indicator of the Holocene climate warming

Eliso Kvavadze

Georgian National Museum, Tbilisi, Georgia

Abstract

The discovery of new markers for the presence of wine in archaeological vessels according to palynological data, which, in addition to grape pollen, is starch and epidermis of grapes, as well as the remnants of fruitfly *Drosophylla*, helped to clarify the history of wine in Transcaucasia. The first and the earliest traces of viticulture and winemaking were found in the cultural layers and in the vessels of the early agricultural Neolithic settlements in the territory of Georgia. According to the result of radiocarbon dating, these archaeological sites existed 5900-5500 BC. This is the earliest discovery of wine residues in the world. A long palynological study of material from Neolithic settlements, as well as from lake and sea sediments of the Transcaucasia showed that 8,000 years ago the climate became much warmer than at the very beginning of the Holocene. According to palynological and archeobotanical data, the next stage of intensive development of viticulture and wine-making was associated with the Holocene optimum and dates from the turn of IV and III millennia BC. At this time, a new Kuro-Araxes culture appears on the territory of the Transcaucasus, which was a very long culture. The warm climate at this time contributed to the spread of the population in the highlands. Traces of viticulture according to palynological data were found on the settlements and barrows of the high mountains of Transcaucasia up to 2000 m.a.s.l. The important point is the fact that the wine at this time takes a cult purpose as the vessels with wine are placed in the grave of the dead for the afterlife. Wine rhytons are also found on the altar of the temple of the settlement of Aradeti-Orgora, the layers of which date back to 14C as the 31 - 28th centuries BC. Traces of intensive viticulture in the high mountains are noted in the material of the mounds of the period of the Bedeni culture, dated to 14C by 25-22 centuries BC. This period in the South Caucasus is also characterized by a significant warming of the climate. In the first millennium BC, and especially with the warming climate of 6-4 centuries BC, wine-making on the territory of Georgia acquires a special role in human economic activity. For storing wine, a new kind of huge Kvevri ceramic tableware appears. There, they were completely buried in the ground, which contributed to the best preservation of wine. Such a long history of the development of viticulture in the South Caucasus, and especially on the territory of Georgia, has led to a large number of grape varieties (525 varieties).

Neolithic plant economy in the SW Baltic area – a long-term perspective

Wiebke Kirleis¹, Dragana Filipovic¹, Stefanie Klooß²

¹CAU Kiel, Kiel, Germany. ²Archäologisches Landesamt Schleswig-Holstein, Schleswig, Germany

Abstract

Continuous collective effort in retrieving and analysing archaeobotanical material from the Neolithic sites in SW Baltic region has resulted in a large collection of the remains and the data on plant production and use during the Neolithic. Combined with the high-resolution absolute chronology, the qualitative and quantitative archaeobotanical data now offer a comprehensive picture of the introduction and establishment of crop production and plant economy. Further, the results allow tracking of trends and changes in the choice of cultivated crops and gathered plants through time. The arable weed record gives insight into the conditions in which crops grew and helps identify specific agricultural strategies. Changes in the plant assemblages and the subsistence strategies are discussed in the light of environmental and cultural developments.

O-1096

Prehistoric Land Use and Settlement Dynamics in Mining Districts of the Eastern Alps

Klaus Oegg

Department of Botany, University of Innsbruck , Innsbruck, Austria

Abstract

Prehistoric peopling of the Eastern Alps occurred in several waves according to palynological data. The first occurred in the 4th millennium BC and seems to be correlated to hydrological changes in the southern Alpine foreland. In the 3rd and 2nd millennium BC follow further settlement phases. Thereby the possibility of the procurement of raw materials appears to be relevant. The research centre “HiMAT - The History of Mining Activities in the Tyrol and adjacent areas: Impact on Environment and Human Societies” at Innsbruck University deals with these issues in a multidisciplinary approach. A crucial problem in the evaluation of the pollen record is the segregation of agricultural and mining activities. Here we present a multi-proxy approach by pollen, geochemistry and historical data to separate these two components. A calibration data set of pollen and geochemical analyses in a mediaeval and Early Modern mining district reveals the vegetation development in connection with mining, which we validate by historical data on the demography of miners and silver production volumes in the mining district. Thereby a spread of the pioneer trees *Pinus* and *Larix* is detected which might be connected either with selective clearances for the gain of pastureland or with a natural reforestation on scree. A correlation of the pollen values of these pioneer taxa as well as those of Poaceae, settlement and cultural indicators with historical data of silver production volumes as a proxy for former mining activities reveals that a secondary succession on the waste dumps is more likely than the expansion of pastureland. Furthermore, this multi-proxy approach with modifications in geochemical analysis of heavy metals is applied for other prominent mining districts in the Eastern Alps. Moreover, we correlate the vegetation and land use changes in the districts’ surroundings with climate proxies. Settlement/farming activities appear overall climate driven, albeit changes in mining activities seem to be governed by economic regularities too.

Abstract

The Lucone Basin (Italian Alpine foothills) originated as an intermorainic depression in the Last Glacial Maximum. After a phase of high-stand, proglacial lake, it hosted a closed, shallow lake (about 800 m diameter) until artificial drainage in the late Middle Ages. The limnic sedimentation consisted of alternating authigenic carbonates and organic mud, recording several phases of human impact. These started with late Neolithic (Copper Age) clearance by burning the oak-beech deciduous forest surrounding the basin. During the end of the third and the first half of the second millennium BC the littoral lake was inhabited by at least three pile-dwelling villages. Two of them were archaeologically excavated. After the complete abandonment of the lake dwelling, two subsequent phases of human impact are recorded by palaeobotanical evidence of land-use, respectively in the late Iron – Roman Age and the late Middle Age. Overall, the lake record consists of three intermittent phases of human impact, separated by phases of complete recovery of the terrestrial forest ecosystem to the late Neolithic baseline.

We explore this intermittent record of the terrestrial and aquatic ecosystems by changes in pollen, green algae, microcharcoal concentration, macrofossils, dung spores, and correlated P and K nutrients supply in the last 5500 years of the littoral sedimentation. We aim to disentangle the relationships between forest clearance, farming, domestic fire activities and limnic macrophyte and planktonic algae communities, together with the effects on sedimentation. We also aim to analyze the resilience of the seminatural terrestrial ecosystems at a centennial scale after the farming and dwelling activities abandonment.

The first impact phase, i.e. at the end of the third millennium BC, is of special importance as the study site was inhabited by farmers during the first phase of the Early Bronze Age. They built a typical, though small, pile-dwelling village. The human impact on littoral lake sedimentation is recorded in a near-site position by the studied archeological deposits. The forcing over the biochemical carbonate / organic ratio along the sequence near to the dwelling is highly correlated with farming and dwelling, with no lag at a decennial time scale resolution. At the time of the dwelling, the marginal lake acted as a sink for waste disposal of livestock, crops and forest residues, partly committed to domestic charring and partly to non-charred plant waste. Sediment recorded an expanded accumulation of bone and plant ash and plant detritus supplying P and K-rich organics, non-airborne pollen, and charred wood. The aquatic communities were impacted by strong alkalinity. We discuss the outlook for a quantitative interpretation of terrestrial ecosystems from palaeobotanical assemblages recorded in a virtually continuous sediment record near-site to a dwelling. The near-site concept requires further focusing in terms of potential for palaeoecological reconstructions.

Abstract

When looking at landscape-human interaction and the resultant environmental changes, the Late Roman Period (AD 300-500) and Early Middle Ages (AD 500-1000), pose an interesting case study. This time period, sometimes called the Dark Ages or migration period, is a period of large cultural change in NW Europe. New data from the Netherlands show that a shift to a colder climate, forest regeneration, geomorphological changes, and a population decline all occurred simultaneously here. The collapse of the Roman Empire is often seen as the main factor controlling the subsequent population decline and the Dark Age reforestation. However, the timing of all these changes suggests that climate developments had an (in)direct influence on landscape developments and cultural trends. Using a multi-disciplinary approach which combines climatological, palynological, geomorphological, and archaeological data the cause and effect of the changes during this time period is investigated. Hereto, we present the first chironomid-inferred temperature reconstruction from this period for the Netherlands, a unique overview of regional vegetation developments and landscape changes, combined with a detailed population density reconstruction.

In the summer-temperature record from lake Uddelermeer, we identified the presence of a Roman Warm Period and the Dark Age Cold Period. In the Uddelermeer pollen record the Dark Age Cold Period is contemporaneous with a reforestation phase. This Dark Age reforestation phase is additionally recognized in numerous palynological records throughout the Netherlands. The intensity of this reforestation trend varies as a result of landscape setting and varying population densities. Additionally, the Dark Ages in the Netherlands are characterized by large-scale landscape changes, especially in the coastal and river area. Here we see increased flooding and the emergence of new tidal inlets and river systems. These changes were most likely the result of human interference as well as environmental/climatic change. In the river area this increase flooding led to the abandonment of marginal areas which were previously used for habitation as well as agriculture resulting in a reduced human impact. Overall this study highlights the importance of understanding the relation between landscape and humans to explain complex changes in geomorphology, vegetation and population densities.

Abstract

Amplified warming in the Arctic is causing marked shifts in tundra vegetation. Such changes are not only dramatically impacting local ecosystems, but are also contributing to global climate feedbacks through changes in albedo and greenhouse gas concentrations. Past distributions of tundra vegetation, particularly during warm periods in the Quaternary, can help provide a blueprint for how—and how quickly—the Arctic landscape may change. Recent advances in lake sediment analyses are enabling more detailed reconstructions of past plant communities, but each technique is limited by a unique set of biases related to the production, transport, and preservation of the compounds that inform each proxy. Here, we present a comparison and integration of three proxy approaches for understanding landscape changes in a lake catchment: 1) bulk geochemistry, including $\delta^{13}\text{C}$ and C:N ratio for characterizing organic matter sources, 2) leaf wax biomarkers, including the distribution of fatty acid chain lengths to distinguish between terrestrial and aquatic plant sources, and 3) sedimentary ancient DNA (*sedaDNA*) metabarcoding using universal plant primers. By combining proxies of varying levels of specificity, we gain more comprehensive insight into climate- and succession-driven landscape changes, from the dominant organic matter sources to a lake to the presence/absence of particular plant taxa. Our analysis focuses on two lake sediment records from Baffin Island, Arctic Canada, that span the Holocene and capture dynamic vegetation responses to the insolation-driven warmth of the early Holocene. We will also present preliminary data from a third lake sediment record that extends through the warmer-than-present Last Interglacial, investigating the potential for vegetation reconstructions via lacustrine *sedaDNA* on longer timescales than have previously been explored.

Abstract

Metabarcoding of sedimentary ancient DNA (*sedaDNA*) has proven to be a powerful tool for recovering ecological data from sediments. The main advantage of *sedaDNA* over more traditional methods such as pollen or macrofossils is the potential for a higher taxonomic resolution. A second advantage is the identification of taxa that normally do not preserve well in sediments and that are difficult to detect with traditional methods.

Metabarcoding relies on the use of generic primers for the amplification of larger groups of species (e.g. plants or mammals). But due to the generic nature of the primers, they may amplify more than just the target organisms, resulting in a large set of “bycatch” sequences. These sequences are often ignored since they are not the taxa of interest, or because they cannot be identified.

The amount of reference sequence material is ever increasing, via both large-scale sequencing efforts (for example the Barcode of Life Consortium) or smaller sequencing efforts targeting a handful of species. The larger pool of reference material allows us to identify the mostly ignored bycatch sequences generated by metabarcoding and allow for novel ecological interpretations, which can have strong environmental implications.

Here two studies are presented of unexpected bycatch taxa in *sedaDNA*. First the detection of various worm species in mammalian lake sediment metabarcoding data from the Varanger peninsula, northern Norway (10 700-3300 cal. a BP) and the Polar Urals in Russia (24 000-1300 cal. a BP). Second the detection of freshwater (non-diatom) algae in plant metabarcoding data from lake sediments across northern Norway and Svalbard (27 000 cal. a BP-present), which occasionally dominate the datasets, indicating the presence of algal blooms. Both the reason for the unexpected detection and the potential for both groups of taxa as proxies for environmental conditions such as temperature, moisture and nutrient availability are discussed.

Abstract

The survival of boreal trees in ice-free cryptic refugia's at high latitudes during the Last Glacial Maximum has been subjected to a long-standing debate. Norway spruce (*Picea abies* L. Karst) is generally believed to have recolonised Scandinavia from the east after the last glaciation. Spruce appears for the first time in the pollen assemblages in central Sweden around 3000 years before present (yr BP). However, a growing body of macrofossil and genetic evidence suggested that spruce could have survived in ice-free areas around the Norwegian shore and contributed to the recolonisation of Scandinavia from the west. Genetic research has shown that modern spruce populations contain two sequence variants for the maternally inherited mitochondrial mh05 fragment across its Eurasian distribution, of which one is unique to Scandinavia. The Scandinavian variant shows the highest frequency in western Scandinavia and its modern distribution suggesting that the variant was already present before the last glacial period. In previous research, the Scandinavian variant was also detected in lake sediment dating back to 10,300 yr BP at Trøndelag in Central Norway (63°N), and chloroplast DNA from spruce and pine was recovered at Andøya in north-western Norway as early as ~22,000 years ago.

We are using sensitive melting curve qPCR assay and high-throughput sequencing to detect the presence of the Scandinavian variant in several sediment cores covering Scandinavia and north-east & southern Russia. So far, the qPCR melting curve assay detected the Scandinavian variant in peat sediment from northern Finland (~52,000 – 42,000 yr BP), in lake sediments in central Sweden and central Norway (~10,000 – 900 yr BP) and in southern Sweden (~12,000 – 11,000 yr BP), which is far earlier than currently believed. Additional lakes are being processed and samples positive for the Scandinavian variant with the qPCR assay will be subjected to high throughput sequencing to confirm sequence identity. The results of this study will increase our understanding of the glacial survival and colonisation of Norway spruce in Scandinavia after the Last Glacial Maximum.

³University of Potsdam, Institute of Biochemistry and Biology, Potsdam, Germany

Abstract

Although the climatic conditions in Siberia are similar to those in Northern Europe and North America, the latter regions are dominated by evergreen needle-leaf forest in comparison to the deciduous larch (*Larix* Mill.) forests in Siberia. This is even more peculiar as *Larix* is a poor competitor with evergreen needle trees in mixed stands. The basic mechanisms controlling the distributions of these two biomes are still not well understood and future alterations due to climatic changes are uncertain. Previous work has failed to provide insights into long-term biogeographic patterns of *Larix* species, as established methods (pollen analysis, metabarcoding) cannot distinguish ancient *Larix* below genus level. In this study, we want to sequence whole ancient chloroplast genomes of *Larix* from lake sediment samples originating from southern Taymyr peninsula (72.399° N, 102.289° E). We will do this by enriching sedimentary ancient DNA (*seda*DNA) extracts for *Larix* chloroplast DNA using hybridization-capture prior to high-throughput sequencing. In a second step, we will extend the capture target to informative mitochondrial and nuclear SNPs. Preliminary results from shotgun sequencing of *seda*DNA from a sediment core dated back to 7000 years BP show that, although most of the sequences are of bacterial and archaeal origin, *Larix* chloroplast DNA was recovered. The enriched data set will enable us to trace distribution changes of Siberian *Larix* lineages in Northern Siberia through time.

O-1103

Ancient DNA taphonomy and the challenges for palaeoenvironmental reconstruction: an integrated approach for understanding Holocene intertidal deposits at Cardigan Bay

Rosie Everett¹, Roselyn Ware¹, Becky Cribdon¹, Vince Gaffney², Robin Allaby¹

¹University of Warwick, Coventry, United Kingdom. ²University of Bradford, Bradford, United Kingdom

Abstract

With the emergence of ancient sedimentary DNA (sedaDNA) as a novel tool for palaeoenvironmental reconstruction, current research into the proxy has demonstrated the potential for enhancing or complementing standard palaeoecological data.

However, as with all new proxies, there is a need to address the issues of taphonomy, as a means to provide robust interpretations of sedaDNA within the context of the sedimentary archives. At current, key issues such as biological source of sedaDNA and the mechanism of deposition (i.e. local-scale, wind-blown, etc) have been addressed and widely discussed within the discipline. However, the impact of inmaterial source-type and post-depositional taphonomic processes remains a key issue, in particular how sediment composition and subsequent binding properties (i.e. organic or minerogenic clays) may affect preservation on sedaDNA within in-situ palaeoenvironmental deposits.

Using samples taken from an area with rich paleoenvironmental records (therefore providing a reference point for understanding taphonomic processes), this project aims to address some of the questions relating to post-depositional taphonomy, in particular how this will impact on the on the bioinformatic processes of data analysis for addressing the key criteria for assessing sedaDNA authentication (damage assessment, controls, replication). In order to address all forms of potential authentication criteria, datasets were generated from the two key methods of sequencing (metabarcoding and shot gun sequencing) and have been analysed for the potential presence of ancient sedimentary DNA, with a particular focus on ancient plant DNA. In parallel, analysis has not only focussed on key aspects of authentication, such as replication and damage, but also within stratigraphic context and how this may potentially differ across strata based on material type. It is clear that the two variables inform each other, and are two central components for a robust interpretation of sedaDNA within a palaeoenvironmental context.

The complexity of the intertidal context for this research has been challenging, and poses the validity on working in such environments with sedaDNA, as a tool for palaeoenvironmental reconstruction. However, it has also demonstrated important aspects of working with this novel proxy and providing robust interpretations, including the application of robust bioinformatic tools for analysis of such large and complex datasets. Most importantly, it has highlighted the importance of addressing key questions such as authenticity, and the ability to contextualise such interpretations within the context of taphonomic processes, as this is not only a fundamental component of palaeoenvironmental research, but remains central to the integrity of aDNA research.

Abstract

Wetland archaeological sites, including settlements on lake shores and artificial islands, often provide a wealth of well-preserved archaeological material, but are generally difficult and expensive to excavate. An alternative, or complimentary approach, can be the retrieval archaeological data from lake-edge sediments, which can contain a continuous record of the archaeological site, the lake and its surrounding catchment. Here we present data from a study of crannogs (artificial island settlement) and an Iron Age lakeshore village where *sedaDNA* and faecal steroids were analysed from proximal sediment cores. The sites are located in SW Scotland and Northern Ireland, UK and range in date from the Iron Age to the early Medieval period. The *sedaDNA* metabarcoding and steroids provides direct and detailed information about the plants and mammals that lived, died, or were kept on the sites in different periods of site use. This information is compared with traditional proxies that allow us to differentiate between (i) changes that happened regionally in the lake catchment (ii) changes that happened in the lake ecosystem and (iii) changes that occurred very locally at the sites (based on pollen and spores, diatoms, invertebrates, sterols and *sedaDNA*). Unusually strong *sedaDNA* and lipid biomarker results from both plants and animals are believed to result from the creation of a biogeochemical halo around the sites which is preserved due to rapid sedimentation, the presence of clays, and a lack of disturbance. The human activities on the artificial islands caused severe eutrophication of these small lakes, which only partially recovered after the abandonment of the sites. Our *sedaDNA* and steroid results complement data from both archaeological excavation and traditional palaeoenvironmental proxies to provide a more detailed and comprehensive image of the environment in which our ancestors were operating, the changes they had on their ecosystems and the inheritance of this today.

How ancient sediment DNA can improve our understanding of past vegetation and the impacts of climate change

Inger Greve Alsos¹, Peter D Heintzman¹, Tony Gavin Brown^{1,2}, Dilli Prasad Rijal¹, Kelsey Lorberau¹, Youri Lammers¹, Sandra Garcés Pastor¹, Nigel Giles Yoccoz¹, Mary E Edwards^{1,2}, Kari Anne Bråthen¹, Dorothee Ehrich¹, Tina Jørgensen¹, Per Johan Sjögren¹, Ludovic Gielly³

¹University of Tromsø – The Arctic University of Norway, Tromsø, Norway. ²University of Southampton, Southampton, United Kingdom. ³University Grenoble Alpes, Grenoble, France

Abstract

Lake sediment ancient DNA (*seda*DNA) may detect species overlooked by studies of micro- or macrofossils as it may be recorded even in the absence of identifiable plant fragments. The taxonomic resolution obtained depends on the molecular methods used, the local flora, and the representation of species in the DNA reference library, and may be as high as 80-90% of taxa detected. The detection of taxa may vary among lakes, plant families, distance from lake and quantity in the vegetation (figure), and common species growing close to the lake (or within the lake) are best detected. Compared to macrofossils, *seda*DNA generally gives a higher number of species and is superior in displaying species persistence. It may show species diversity similar to pollen records, but it is superior in detecting terrestrial and aquatic herbaceous species. Also, as it is deposited locally, results are not confounded by long-distance transported pollen. False positives due to contamination, PCR or sequencing errors, DNA reference library errors, and/or the erroneous identification of short DNA fragments are still issues but may be overcome by stringent laboratory routines, reference databases of high quality and representation, and optimized bioinformatic filtering. Our lab has analysed, or is in the process of analysing, ~40 long (up to 26 000 year old) and 11 short (0-1000 year old) lake sediment cores from the Alps to Svalbard and Scotland to the Polar Urals. General patterns have emerged from these data. Aquatic vascular plants are exceptionally well represented and do often show marked change through time. The taxa recorded in *seda*DNA often indicate a warmer climate than what has been inferred based on pollen records; this is in concordance with macrofossils. The *seda*DNA further indicates that limits of the past northern treelines have been underestimated based on pollen studies. Some heathland species, such as *Vaccinium* spp. and *Empetrum*, often show a time lag in arrival compared to other species with similar climate requirements. Thus, despite the fact that they have berries and therefore are well adapted to long-distance dispersal by bird, something is constraining their ability to respond to climate changes. In the near future, the combination of many sites, complete reference libraries, and advanced molecular methods will allow for the tracking of individual species through time and space.

Late Pleistocene environments and human occupations of the Thar Desert

J Blinkhorn

Royal Holloway, University of London, Egham, United Kingdom. Max Planck Institute for the Science of Human History, Jena, Germany

Abstract

The Thar Desert, India, is located at a major biogeographic threshold, marking the eastern edge of the Saharo-Arabian desert belt and the western edge of the monsoonal Oriental zone. This threshold is most clearly marked by the change in precipitation and its seasonality associated with influence of the Indian summer monsoon, with ensuing impacts on the ecology of regions on either side of the Thar Desert. Late Pleistocene climatic change appears to have substantially modulated the environments at this key threshold, with evidence for both enhanced humidity and increased aridity at different times through the past, with impacts for the potential for human occupations. It is increasingly apparent that the Saharo-Arabian desert-belt has played a critical role in mediating the eastward expansions of modern humans from Africa, and thus the Thar Desert marks the first major ecological transition that would have been encountered by these dispersing populations. A program of interdisciplinary fieldwork conducted over the past decade has illuminated patterns of human occupation over the Thar Desert and placed this within a chronological and environmental framework. This presentation will review terrestrial archives of environmental change in the Thar Desert and evidence for human occupations through the Late Pleistocene, and place this within wider debates surrounding modern human dispersals.

O-1107

East Asia monsoon variations and the vegetation developments in Southeast and Northwest China during the MIS 5 and MIS 1

Chengyu Weng

Tongji University, Shanghai, China

Abstract

East Asia Monsoon (EAM) origins in western Pacific Ocean, and influences a large region from Southeast China to Northeast China, but goes weaker and weaker northwards. However, the strength of the monsoon varied between glacial and interglacial time. This study is based on the comparison between the pollen records from two marine records from northern South China Sea (SCS) and one record from Lop Nor Lake. The goal is to compare the vegetation developments and the influences of East Asia Monsoon in the two end regions of the monsoon influence, Southeast and Northwest China, during two typical interglacial periods, the MIS 5 and MIS 1.

The records from the SCS show that with the rise of temperature, the vegetation in South China experienced a good succession toward more tropical types. The tropical components started to increase at the beginning of each interglacial (MIS 5 and MIS 1), and then reached the maximum, but dropped near the end of the warm period. This phenomenon is more represented by the rise and fall of some montane components. The sea surface temperature indicates that temperature may be more crucial in the succession.

The vegetation in Northwest China is more sensitive to the moisture, and thus was more controlled by the shifting of the end-line of the EAM. MIS 5 and MIS 1 are two periods that the vegetation was better developed and more mesic, especially during the early-mid Holocene. Based on the vegetation history, we tend to believe that East Asia Monsoon had reached at least eastern part of the desert region in Northwest China during some time of these two periods, but then retreated.

O-1108

Indian Ocean monsoon behavior during the 4.2 kyr event from Madagascan stalagmites

Nick Scroxton^{1,2}, Stephen J. Burns¹, David McGee², Laurie R. Godfrey¹, Lovasoa Ranivoharimanana³, Peterson Faina³
¹University of Massachusetts Amherst, Amherst, USA. ²Massachusetts Institute of Technology, Cambridge, USA.
³Université d'Antananarivo, Antananarivo, Madagascar

Abstract

The climatic and societal impacts of the 4.2 kyr event are centered on the Mediterranean and Middle East. Yet the event is stratigraphically defined by a stalagmite record from Mawmluh Cave in eastern India, which is subject to a different, more tropical, climate regime. The behavior of the tropical rain belt at this time has important consequences for understanding the climate system's response to abrupt Holocene forcing, and to the civilizations surrounding the Indian Ocean at the time. To enhance our understanding of Indian Ocean climate at the 4.2 kyr event we present a high-resolution, precisely dated, stalagmite stable isotope record from Anjohikely Cave in northwest Madagascar.

The new record covers 5.1–1.9 kyr BP at sub-decadal resolution, providing an important southern hemisphere perspective on tropical hydroclimate during the middle to late Holocene generally, and the 4.2 kyr event specifically. We show a two-phase response of the Madagascan monsoon to the 4.2 kyr event: 1) a shorter dry event from 4.2 to 4.0 kyr BP, but one where the magnitude and duration was not unusual; 2) a longer multi-centennial scale drying until 3.5 kyr BP. We also compare our southwestern tropical Indian Ocean with five other high-resolution stalagmite records from around the Indian Ocean basin. Our analysis highlights controls on Indian ocean tropical hydroclimate to both meridional and zonal processes. The results provide new insight into regional coherence and synchronicity of the climate response to the 4.2kyr event.

O-1109

Reconstruction of Holocene (MIS I) paleomonsoons: lake sediments

Hema Achyuthan

Institute for Ocean Management, Anna University, Chennai, India

Abstract

Reconstructions of the Asian paleomonsoonal shifts for the late Quaternary-Holocene period demands a deep understanding of the application of multiproxy data for climate modelling and predicting future monsoon trends. Freshwater bodies such as lakes and ponds are major sinks and depocentres for carbon and detritus and the lake sediments preserve signatures of geochemical and biological variations derived principally from the surrounding rocks and soils owing to precipitation and erosion. In this presentation, multi and interdisciplinary proxy data collected from four lake sediment cores, South India (Pookode, Kukkal, Berijam, and Vellayani) is presented. These lakes receive dominantly the southwest monsoon. Climate proxies, including sediment texture, total organic carbon (TOC), total nitrogen (TN), C/N, pollen and geochemical composition indicate a steady progression to wetter and drier conditions, with two stepwise changes at about 8100, and between 3200 and 1800 yr BP. The change at 8200 solar insolation event - 8100 yr BP appears to correspond to a brief (100–150 years) dry spell recorded elsewhere in India. Most of the lake records show a decline in SWM since the middle Holocene period with intermittent intense wetter conditions since 6240 yr BP to present. This allowed the lake margins to shrink and expand. Some lakes hold the signatures of abrupt and extreme events such as the 4200-extreme aridity, 3800, 2000 and 600 yr BP dry and warm conditions. The change at 3200–1800 yr BP consisted of a rapid weakening of the SWM, and can be correlated with the initiation of the 'Roman Warm Period'. The C/N ratio of the sediments range from 14.02 to 8.31, indicating that the organic matter originated from a mixture of lacustrine algae, vascular and terrestrial plants. Chemical weathering indices (Chemical Index of Alteration (CIA), Chemical Index of Weathering (CIW), and Plagioclase Index of Alteration (PIA)) are consistent with extreme silicate weathering. Pollen data also show a development from savanna vegetation prior to ~8000 yr BP, followed by grassland with palms, the appearance of ferns just prior to 3200 yr BP and the establishment of the tropical humid forest between 3200 and about 1800 yr BP. Decline in the intensity of monsoon led to weakened river dynamics, that played a critical role in the collapse of several river valley civilizations, which relied on monsoon rains to fuel their agricultural surpluses.

O-1110

Monsoonal variations at the northeastern Tibetan Plateau during the Holocene – the aeolian record

Georg Stauch

Department of Geography, RWTH Aachen University, Aachen, Germany

Abstract

Despite being one of the most important atmospheric systems on earth, intensity, timing, and extent of the Asian Summer Monsoon (ASM) is still poorly understood. The northeastern Tibetan Plateau (TP) is located at the present day northern limit of the ASM and was identified as one of the key areas to study the evolution of the ASM. Previous studies in the area mainly focused on lake sediments and resulted in considerable divergent interpretations. These differences are partly related to problems with the chronology as they are influenced by the hard water effect.

For this study, aeolian sediments were used to reconstruct the Holocene development of the ASM on the northeastern TP. They can be easily dated by optical stimulated luminescence (OSL), which captures the last exposure to light. In the case of aeolian sediments, these last exposure occurred during the last transport of the particles. Aeolian sediments are widespread on the semi-arid north-eastern TP. However, many sections in the area are discontinuous. Therefore, a large number of sections has to be analyzed. During the last decades, the number of dated sections from the northeastern TP has been increasing rapidly and now nearly 500 ages are available. Two different trends can be observed in the dataset. At first, there is a time-transgressive onset of the ASM on the northeastern TP. An increase in precipitation occurred at the eastern margin as early as the late glacial, while the central part of the northeastern TP experienced an increase in the early Holocene. However, further to the west, a short-term influence of the ASM occurred in the mid-Holocene only. During this time, maximum precipitation occurred in the eastern regions. The late Holocene is characterized by dry climate conditions with high aeolian activity. The weakening of the ASM occurred more or less simultaneously in the area. Nevertheless, the several decadal to millennial scale climate variations are preserved in the aeolian record from the late Holocene. In the last 2000 yrs, aeolian activity increased during reduced northern hemisphere temperatures. This was accompanied by an increasing strength of the northern hemisphere mid-latitude westerlies. Furthermore, phases of enhanced aeolian activity occurred parallel to the so-called Holocene Bond events in the North Atlantic. However, other high resolution records from the North Atlantic indicate no clear match on the multi-decadal to multi-centennial timescale. The study emphasizes that long and short term trends in the ASM can be reconstructed from non-continuous aeolian sediments in a semi-arid environment, provided a sufficient number of ages is available.

O-1111

East Asian Monsoon History and paleoceanography of the Japan Sea over the last 460,000 Years

Abstract

The Japan Sea is directly influenced by the Asian monsoon, a system that transports moisture and heat across southeast Asia during the boreal summer, and is a major driver of the Earth's ocean-atmospheric circulation. Foraminiferal and facies analyses of a 460-kyr record from Integrated Ocean Drilling Program Expedition 346 Site U1427 in the Japan Sea reveal a record of nutrient flux and oxygenation that varied due to sea level and East Asian monsoon intensity (Fig. 1). The East Asian summer monsoon (EASM) was most intense during marine isotope stage (MIS) 5e, MIS 7e, MIS 9e, and MIS 11c when the Tsushima Warm Current flowed into an unrestricted well-mixed normal salinity Japan Sea, whereas East Asian winter monsoon (EAWM) conditions dominated MIS 2, MIS 4, MIS 6, and MIS 8 when sea level minima restricted the Japan Sea resulting in low-salinity and oxygen conditions in the absence of Tsushima flow. Reduced oxygen stratified, low-salinity, and higher productivity oceanic conditions characterize Terminations TV, TIII, TII, and TI when East China Sea coastal waters breached the Tsushima Strait. Chinese loess, cave, and Lake Biwa (Japan) and U1427 proxy records suggest EASM intensification during low to high insolation transitions, whereas the strongest EAWM prevailed during lowest insolation periods or high to low insolation transitions. Ice sheet/CO₂ forcing leads to the strongest EAWM events in glaciials and enhanced EASM in interglaciials. Mismatches between proxy patterns suggest that latitudinal and land/sea thermal contrasts played a role in East Asian monsoon variability, suggesting that a complex interplay between ice sheet dynamics, insolation, and thermal gradients controls monsoonal intensity.

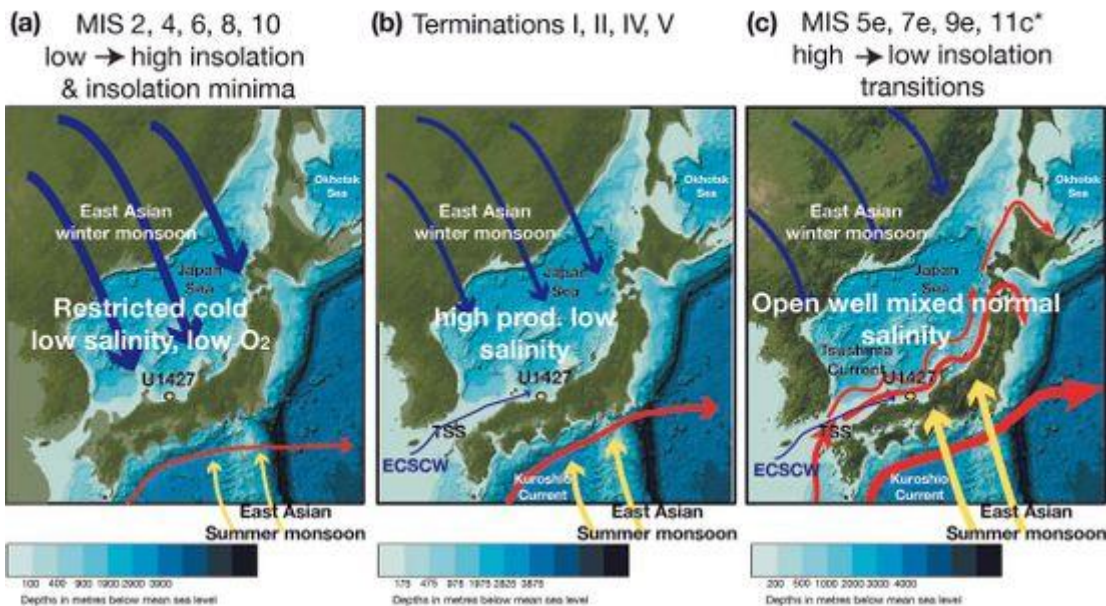

Fig. 1. Variations in

oceanography and the position and intensity of the East Asian monsoon during (a) low to high insolation transitions and insolation minima, (b) terminations, and (c) high to low insolation transitions. *MIS 11c coincides with an insolation maxima during an eccentricity low. The thicker blue arrows signify enhanced EAWM and thicker yellow arrows a stronger EASM. The thin blue line (ECSCW) is the path of fresh water from the China Sea during terminations and interglacial maxima. The base map is from General Bathymetric Chart of the Oceans (www.gebco.net) where modern bathymetry represents interglacial maxima. This is recalibrated to ~100 m below present for glacial phases and ~25 m below present during the terminations. Prod. = productivity; ECSCW = East China Sea Coastal Water; EAWM = East Asian winter monsoon; MIS = marine isotope stage.

Palaeoclimate anomalies since MIS 4 to MIS 1 inferred from Loess Palaeosol Sequences (LPS), Kashmir Valley, Western Himalaya

Rayees Ahmad Shah, Hema Achyuthan
Institute for Ocean Management, Anna University, Chennai, India

Abstract

Understanding climate processes demand reconstruction of environmental and climate history (Krauß et al. 2018). Studies reported during the last few decades have deemed loess sediments as one of the important records for the Quaternary palaeoclimate and paleoenvironmental reconstructions. This study is focused on reconstruction of signatures of the late Quaternary palaeoclimate anomaly recorded in loess sediments of the Kashmir Valley. The loess palaeosol sequences (LPS) exposed around Ganderbal, Kashmir Valley, reveals six polycyclic palaeosols formations of varying thickness, a loess (C) horizon and partially pedogenised loess forming Cambisols. The chronology of the loess section is constrained by five OSL dates and four AMS ^{14}C dates. The loess palaeosol sequence (LPS) represents sedimentation records from 68 ka to 7 ka (MIS 4 to MIS 1). Field observations, sediment textural data, stable isotope ($\delta^{13}\text{C}$), geochemical data, organic elements and supported by AMS ^{14}C and OSL ages have revealed five major climate events since 68 ka. The palaeosols from 8 m to 6.4 m depth represents ameliorated moderate climatic condition since 68 ka to 44 ka (duration 24 ka) supporting deciduous plants or open conifer forest vegetation. Unaltered loess layer from 6.4 m to 6.0 m depth (C horizon) dated to 44 ka to 43 ka reveal influx of fine sand (36%), with very low TOC content, weak weathering, and enriched values of $\delta^{13}\text{C}$ (-23 ‰) indicating dry and cold climate conditions with high wind velocity. Sediment deposition corresponding to 43 ka to 35 ka age yields high TOC content and supported by more depleted $\delta^{13}\text{C}$ values and moderate to strong weathering reflect warmer and wetter conditions leading palaeosols formation. The sediment deposition corresponding to 35 ka to 13 ka, exhibit very weak weathering and accumulation of CaCO_3 , indicating cold and dry conditions representing the LGM forming calciorthids and cambisols represented by Bt/Bck and Bwk horizons. These horizons supported C_3 grasses and shrub coppice vegetation. Loess deposition terminated around 15 to 13 ka and subsequently deposited reworked loess and fluvial sediments that aggraded over the glacial melt water deposits of pebbles and gravels. This signifies the retreat of the nearby glaciers that continued to occur until around the late Pleistocene–Holocene transition. The upper two-meter sediment deposition, age dated from 12 ka to 6.9 ka represents a mixture of reworked aeolian and fluvial sediments that are pedogenised and more depleted values of $\delta^{13}\text{C}$ reflecting an overall warm climate conditions since 12 ka to 6.9 ka.

Key words: Loess palaeosol sequence, climate anomaly, OSL dating, stable isotopes.

Tephrochronology as a Tool for Volcanologists

Katharine Cashman, Alison Rust, Jennifer Saxby, Hannah Buckland
University of Bristol, Bristol, United Kingdom

Abstract

Tephrochronology is a stratigraphic method that is widely used in palaeoenvironmental and archaeological research; its value in synchronising stratigraphic records comes from the ability to identify individual eruptions using often trace amounts of small glass and crystal fragments (volcanic ash). These distal and ultra distal ash deposits are also valuable for addressing questions related to physical volcanology, although they not often incorporated into volcanological studies. Here we review some ways in which tephrochronological data can be used to enhance volcanological research. First and foremost, characterization of distal and ultradistal tephras can substantially improve understanding of eruptive processes, including eruption magnitude, frequency and fragmentation conditions. For example, a major challenge in determining eruption magnitude (volume or mass erupted) is estimating the mass contribution of far-travelled ash, which may comprise a significant proportion of the overall volume. Additionally, determining eruption frequency requires good stratigraphic and age control. This is often best established using sediment cores from lakes, bogs or marine environments, where the legacies of individual eruptions are not disturbed by either post-placement modification or erosion by subsequent eruptive products. Alternatively magma fragmentation is a signature of explosive eruptions. Fragmentation may be primary or secondary, and may occur early or late in the vesiculation process; each leaves its mark in the physical characteristics (size, shape, bubble textures) of tephra particles. Other applications of tephrochronologic data to volcano studies relate to the chemical analysis of constituent glass and mineral phases, which can be used not only to “fingerprint” the deposit, but also to assess source variability (e.g., tapping of zoned magma reservoirs) and pre-eruption conditions (e.g., Fe-Ti oxide constraints on magma temperature and oxygen fugacity), and even to determine which part of the eruption sequence produced widely dispersed ash deposits. Finally, physical characterisation of distal and ultradistal ash deposits can be used to (1) construct more accurate models of ash transport, models that are key to air traffic safety, (2) determine lag times between ash and aerosol deposition in polar ice cores, which is important for climate models, and (3) constrain elements of post-eruption modification of distal tephra deposits by gravity, water and wind, thereby placing constraints on the nature and extent (both spatial and temporal) of post-eruptive ash hazards. In summary, the distal and ultradistal tephra records used in tephrochronology represent an archive of eruptive activity that has been under-utilized by the volcanology community, in part because of the tephrochronology focus on the chemical, rather than physical, attributes of far-travelled ash particles.

⁸Institut für Geographie, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany. ⁹Department für Geo- & Umweltwissenschaften and GeoBio-Center, Ludwig-Maximilians-Universität München, Munich, Germany

Abstract

Here, we revisit the Laguna Potrok Aike (51.97053°S, 70.37551°W) sedimentary sequence which was cored as part of the Potrok Aike Maar Lake Sediment Archive Drilling Project (PASADO; ICDP expedition number: 5022), and sits in the back-arc of the Austral Volcanic Zone (AVZ) of the Southern Andes, Argentina. The record is 106.09 m-cd (metres-composite depth) long and extends back to ~80 ka, providing a detailed record of long-term explosive volcanism in the region. The lake sequence additionally represents one of the only synglacial/glacial records from the region, and as such provides an excellent opportunity to analyse the relationship between ice-unloading and volcanic activity in continental arc settings.

We identified 94 tephra layers in the Laguna Potrok Aike sedimentary sequence, and analysed the textural, mineralogical and major elemental (glass) chemical properties of each layer using microscopy, and wavelength dispersive electron microprobe techniques. To enable robust tephra correlations, a reference tephra (glass) compositional database of expected deposits was created by combining newly acquired and existing data of proximal deposits from: Hudson (H₁, H₂), Aguilera (A₁), Reclus (R₁, R₂₋₃), and Lautaro (historical) volcanoes, and Mt Burney (MB₁, MB₂, MB_x, MB₁₉₁₀). One new correlation was produced to the widespread H₁ eruption from Hudson volcano, dated to 8.6-9.0 cal ka BP; the MB₁ and R₁ deposits, from Mt Burney and Reclus volcano, are now better geochemically characterised, and have depositional ages of 10.0-10.4 and 14.1-14.5 cal ka BP, respectively.

The depositional mechanism of tephra layers was established: 25 were primary, 1 was unknown, 3 were possibly reworked and 65 were reworked. Reworked layers had the characteristics of primary fallout at a macroscopic level, but displayed characteristic features of reworking at a microscopic level. Such features included: heterogeneous compositions, rounded minerals and minerals with minimal glass-coating, increased abundance of organic material, and a low glass-shard abundance. The identification of a high proportion of reworked material throughout this sedimentary sequence indicates that emplacement via primary fallout should not be assumed, and that special care should be taken when analysing visible and invisible (crypto-) tephra layers to decipher their emplacement mechanisms. Using event-frequency, and chemical composition data of the 25 primary tephra layers in the sequence, we finally investigate the relationship between ice-unloading and volcanism and determine that, while there is a marked decline in eruptive activity between 43.4 and 62.9 cal ka BP, no firm relationship between glacial cycles and volcanic activity can be identified in this record.

Zircon U-Pb dates for Gold Run tephra confirm the antiquity of ancient permafrost and the world's oldest recovered genome

Serhiy Buryak, Alberto Reyes, Duane Froese, Britta Jensen
University of Alberta, Edmonton, Canada

Abstract

Gold Run tephra is a prominent Middle Pleistocene chronostratigraphic marker in the Klondike region of northwest Canada, at the eastern edge of unglaciated Beringia. The tephra is broadly dated to the early Middle Pleistocene by glass fission-track ages (0.69 ± 0.05 Ma; 1σ) and the normal polarity of the surrounding fine-grained sediments overlying reversely-magnetized gravels. Gold Run tephra has emerged as a critical marker horizon because of its stratigraphic association with ancient relict permafrost and important paleontological specimens. We report new zircon laser-ablation U-Pb dates for Gold Run tephra that confirm and refine the age of this key marker horizon. Of 25 dated grains, ten yielded a tentative isochron age of 0.70 ± 0.04 Ma (2σ), with a mean $^{206}\text{Pb}/^{238}\text{U}$ age on the youngest coherent grouping ($n=9$) of 0.76 ± 0.09 Ma. Forthcoming analyses will allow us to refine the latter age using a ^{230}Th correction, with additional support from forthcoming zircon U-Pb dating of the overlying Flat Creek tephra. These new U-Pb dates confirm the antiquity and remarkable resilience of relict early Middle Pleistocene permafrost in west-central Yukon, where Gold Run tephra overlies relict ice wedges at multiple sites in the Klondike region. The refined age of Gold Run tephra also confirms the early Middle Pleistocene age for an *Equus* fossil, recovered from relict permafrost, that yielded the world's oldest full genome sequence. The direct age constraint from Gold Run tephra also highlights the underestimation of the molecular clock age for the fossil, and more broadly the challenges and uncertainty of using these age estimates in ancient DNA studies of specimens that lack independent geochronology. Our results underscore the potential for U-Pb dating of the numerous Plio-Pleistocene tephra beds in unglaciated Yukon and Alaska, with applications as diverse as paleogenomics, paleontology, and studies of ancient permafrost.

Reconstructing missing terrestrial eruption records without tephra-fall layers: high-resolution chronology of lacustrine volcanic density flow deposits, Lake Inawashiro-ko, Fukushima, Japan

Kyoko Kataoka¹, Yoshitaka Nagahashi²

¹Niigata University, Niigata, Japan. ²Fukushima University, Fukushima, Japan

Abstract

Volcanic eruptions in geological records are often incomplete. Attempts to reconstruct eruption records from the terrestrial stratigraphy alone are sometimes hampered by limited exposure, low preservation potential of tephra layers due to erosion and reworking, and lack of precise dating owing to discontinuous strata. In order to understand the eruption history, a comprehensive approach through the analysis of volcanic deposits in fluvial, lacustrine and marine sequences is necessary. A lake system adjacent to active volcanoes can record various volcanic events such as explosive eruptions and subaqueous density flows being extensions of subaerial lahars. A lacustrine depositional sequence can constrain high time-resolution of such events because of constant, continuous, and high rates of background sedimentation.

The studied sediment core was obtained from off Lake Inawashiro-ko, Fukushima, Japan at the central and the deepest part of the lake (90 m water depth). The lake is the largest freshwater volcanic dam-lake in Japan and has active Adatara and Bandai volcanoes in its catchment. A 29-m-long core has 19 tephra-fall layers mostly sourced from remote volcanoes other than Adatara and Bandai and 71 flow event deposits in background hemipelagic clayey sediments. The age-depth model, based on the widespread tephra layers and ¹⁴C dating, well constrains the ages and recurrence intervals for individual events during the past 50,000 years.

Sedimentary facies, petrography, grain size, micro-XRF and XRD analyses, and chemistry of glass shards indicate the origin of the flow event deposits as follows. 1) Gray event deposits (Gm/Gs) are usually millimeters to centimeters thick and are composed of clayey silt (Gm) and very fine sand to silt with a subunit of clayey silt (Gs). The deposits contain sulfide/sulfate minerals and have high sulfur content which point to a source from hydrothermally altered material ejected by phreatic eruptions at Adatara volcano as subaerial eruption-associated lahars entered into the lake. 2) Brown event deposits (Bm/Bs) are centimeters thick and thicker than those of Gm/Gs deposits. The deposits consist of clayey silt to silt (Bm) or very fine sand (Bs) and contain fresh glass shards derived from Bandai volcano. It is normally graded with a sharp erosive base and suggests more proximal origin. The characteristics show that the brown deposits were emplaced by density flows triggered by subaerial magmatic hydrothermal eruptions at Bandai and partial flank collapse.

The high-resolution chronology of gray and brown event deposits records subaerial volcanic activity at Adatara and Bandai and increases the known explosive eruption frequency at Bandai adding new 24 magmatic hydrothermal eruptions, and at Adatara by 3-fold number of phreatic eruptions. The results in the present study are critically important to evaluate volcanic risks including frequent eruptions and far-reaching lahars for the heavily populated downstream towns.

Fingerprinting basaltic tephras erupted from mid-Holocene Mounts Gambier and Schank: first analyses of glass and minerals of proximal Australian tephras

David J. Lowe¹, Malcolm J. Sheard², Jock Churchman³

¹School of Science (Earth Sciences), University of Waikato, Private Bag 3105, Hamilton, New Zealand. ²Geologist (retired), 6 Everest Ave, Morphettville, Adelaide, Australia. ³School of Agriculture, Food and Wine, University of Adelaide, Adelaide, Australia

Abstract

Intraplate volcanoes of southeast South Australia (Mount Gambier sub-province) form the western extension to the Newer Volcanic Province of western Victoria. They comprise two groups: a northern Pleistocene group (not considered further) and a southern Holocene group consisting of the isolated Mount Gambier (MTG) and Mount Schank (MTS) complexes, the youngest volcanoes in Australia. MTG and MTS comprise complex maar and cone structures built over eruptive fissures. Strongly influenced by abundant groundwater, they are dominated by pyroclastic (tephra) deposits including scoria, lapilli, and ash, with minor lavas. The two complexes, ~10 km apart, erupted ~5000 years ago and the resultant tephras contain both “exotic” (non-volcanic) crystalline material, derived from underlying Tertiary limestone and calcareous dunes, and juvenile (new) basaltic material. Although petrological and volcanological research has been undertaken on MTG especially in recent years, usually on whole-rock lava or pyroclastic (scoria) samples, analyses of volcanic glass and crystals per se from tephras have not been reported. Ash fractions at MTG are dominated by considerable limestone and quartz, chert, and siliceous sponge spicules (~80%), together with volcanic crystals (forsteritic olivine, labradorite, clinopyroxene (mainly diopside), and Fe-Ti oxides) and comparatively low contents of glass (<20%), much of which is altered. Ash fractions at MTS contain much less exotic material (quartz and sponge spicules) and have higher glass contents (~50%), most unaltered, along with volcanic crystals as at MTG. There is little difference between glass from MTG and MTS with regard to electron microprobe-determined major oxides: mean SiO₂ at MTG is 49.62 ± 0.55 wt % (n = 21) and at MTS is 49.72 ± 0.86 wt % (n = 18) (normalised), with most shards classified as phonotephrites in the total alkali-silica diagram. Al₂O₃ in glass in tephras from both volcanoes is high (16-17 wt%). “Extra” SiO₂ occurs at MTG because of the more abundant xenolithic silica polymorphs. Soils on MTG and MTS tephra deposits are formed under an annual rainfall of c. 700 mm in a xeric moisture regime with long dry summers, and are near neutral or alkaline. They include the only Andisols of Australia, namely Xerands, which are uncommon globally (~3.5%). Clay fractions in soils at MTG (on basaltic tephra with low glass and abundant exotic materials) are dominated by layer silicate minerals, including kaolinite, illite, interstratifications of kaolinite and smectite, and some discrete smectite. In contrast, at MTS (on basaltic tephra with common glass and relatively few exotic materials), the clay fractions are less variable and are dominated by allophane and ferrihydrite. Notably, there is no halloysite formed in any soils at either MTG or MTS. Soils on tephras at MTG are classified in *Soil Taxonomy* as Vitrixerands, Haploxerands, and Calcixerolls; at MTS they are Haploxerands and Melanoxerands.

Unravelling the eruptive history of volcanoes in North Sumatra, Indonesia using tephrostratigraphy

Marcus Phua^{1,2}, Caroline Bouvet de Maisonneuve^{1,2}, Steffen Eisele^{1,2}, Hamdi Rifai³, Rina Zuraida⁴, Satish Singh⁵
¹Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore, Singapore. ²Asian School of the Environment, Nanyang Technological University, Singapore, Singapore, Singapore. ³Universitas Negari Padang, Padang, Indonesia. ⁴Marine Geological Institute, Bundung, Indonesia. ⁵Institut de Physique du Globe de Paris, Paris, France

Abstract

The vast Indonesian archipelago spans more than 5000 km and is host to over 126 recently and historically active volcanoes. Of particular interest is Sumatra in western Indonesia, which accounts for at least 30 of these active or potentially active volcanoes across the archipelago. These volcanoes lie in close proximity to major cities in Indonesia such as Medan (estimated at 2.5 million inhabitants), Palembang (1.6 million) and Padang (1.0 million), but also not too distant from highly populated countries like Malaysia (31.7 million) and Singapore (5.6 million). And yet in spite of the inherent risk, the eruptive history of these volcanoes is poorly known, as only a handful have been studied and regularly monitored. To rectify this, tephrostratigraphy is used as a tool to unravel the history and behaviour of past Sumatran eruptions: their frequency, magnitude and spatial footprint. Tephra/cryptotephra sequences preserved in marine and peatland environments are the focal points of the study. A 17.76 m sediment core MD16-3522 was collected from the north-east Indian Ocean (3.522°N; 92.946°E; 4417 m) in July 2016 during the MD204/MIRAGE I expedition on board R/V Marion Dufresne. Between 0 and 12.20 m below seafloor, three visible centimetre- to decimetre-thick tephra layers were identified in the sediment core: i) MD16-3522-158-161 cm (VTL1); ii) MD16-3522-685-688 cm (VTL2); and iii) MD16-3522-1217-1219 cm (VTL3). ⁴⁰Ar/³⁹Ar age constraints and major and trace element compositions of glass shards extracted from the three discrete tephra layers provide hints towards their volcanic source. VTL1 is genetically related to the Young Toba Tuff eruption, whilst VTL2 and VTL3 are determined to be geochemically distinct from Middle Toba Tuff and Oldest Toba Tuff layers. Other potential source volcanoes were considered, but due to the dearth of geochemical and age data available for Sumatran volcanoes, no correlations were made for VTL2 and VTL3. In addition, magnetic susceptibility, a* (a measure of sediment redness) anomalies, positive Zr peaks acquired with a Multi-Sensor Core Logger (MSCL) and glass shard separations by dense liquids indicate the presence of up to seven cryptotephra horizons in the upper two metres of the core. Continued work on core MD16-3522 is expected to yield an expanded record of eruptions in the Quaternary, presumably with a volcanic source provenance centred on (North) Sumatra. Whilst ongoing research in the region is extended beyond the MD16-3522 core to other offshore deep-sea cores previously collected by the SO189-2 research expedition on board R/V Sonne in 2006 and to various peatlands in North Sumatra.

Quaternary environmental reconstruction from remobilised tephra deposits

Andrew Dugmore¹, Anthony Newton¹, Polly Thompson¹, Richard Streeter², Nick Cutler³

¹University of Edinburgh, Edinburgh, United Kingdom. ²University of St Andrews, St Andrews, United Kingdom.

³Newcastle University, Newcastle, United Kingdom

Abstract

In Quaternary science, tephra layers are primarily used for chronological control, but on occasion, this application is complicated because the tephra deposits may be remobilised either as particles or as entire layers. We explore the ways in which tephra deposits may be remobilised in part, or as whole layers with a series of case studies of late Quaternary Icelandic tephra in both proximal and distal deposits. Partial layer remobilisation in the form of the particle movements may take place over a range of scales from a few millimetres to many kilometres, and involve materials ranging in size from cryptotephra to cobble-grade pieces of pumice. This type of particle mobilisation can provide data on a range of processes from small-scale sediment movements within individual profiles, to the large-scale circulation patterns of wind and water across the North Atlantic. Tephra layers may be also distorted by the movement of the sediment that encloses them, and in this circumstance, the tephra deposit still form a coherent layer, but with a changed morphology. In these cases, it is possible to assess the consequences of range of Quaternary environmental changes from the movement of glacier ice to cryoturbation, and begin to understand the processes that drove them. For example, thufur (frost hummock) formation may occur episodically through time, and because of different types of sediment movement. Tephra layers help us to understand both when episodes of hummock formation took place, and what sort of sediment movements were involved. When taking a narrow view of the utilisation of tephra in Quaternary science as solely chronostratigraphic marker horizons, post depositional movements of grains or layers can be seen as a problem, but this remobilisation also provides opportunities to learn more about both the processes and legacies of past Earth surface processes, and movements wind and water.

Disentangling the effect of thermal and microbial degradation on the distribution pattern of paleosol derived *n*-alkanes: Implications for paleo-fire reconstruction

Vijayananda Sarangi¹, Sayak Basu^{1,2}, Prasanta Sanyal¹, Anoop Ambili²

¹Indian Institute of Science Education and Research Kolkata, Kolkata, India. ²Indian Institute of Science Education and Research Mohali, Mohali, India

Abstract

Biomass burning is an important component of major biomes as it acts as an ecological forcing factor in controlling the vegetation composition as well as biomass production. Thus long-term paleo-fire records are required to understand the extent to which future fire regimes will affect ecosystem health and the global carbon balance. Unfortunately, paleo-fire proxies such as charcoal analysis, dendrochronology, geochemical analysis of sediments and archaeological relicts are often fragmented and difficult to interpret owing to their poor preservation in the natural archives. To resolve the uncertainties associated with the existing paleo-fire proxies, biomarker-based investigations provide a new avenue for gaining insight into the paleo-fire events due to their relatively stable chemical property and low susceptibility to degradation. In this context, core sediments were collected from the Banni grassland located at close proximity to the archaeological site of Dholavira (Harappa Civilization), Northwest Gujarat, India. The samples showed a predominance of short-chain *n*-alkane (C₁₄-C₂₀) which constituted ca. 50 % to 75 % of the total *n*-alkane concentration. In addition, the samples displayed a prominent even-over-odd preference (EOP) in short-chain *n*-alkane. Higher concentration of short-chain *n*-alkane with EOP is often attributed to microbial or thermal degradation of the organic matter. During thermal degradation, short-chain *n*-alkanes are produced at the expense of long-chain *n*-alkanes while sources of short- and long-chain *n*-alkanes differ during microbial degradation. In order to disentangle the effect of thermal and microbial degradation on the distribution pattern of *n*-alkanes, available record from the microbially degraded sediments of the Ennamangalam Lake, Southern India, have been compared with the sediments collected from the Banni grassland. Here, two novel *n*-alkane indices have been developed to disentangle the influence of these degradation processes. Positive and significant correlation ($R^2 = 0.9$, $p < 0.05$, $n=19$) between C₁₈ (dominant in short-chain) and C₂₉ (dominant in long-chain) homologues indicate that the sediments in Banni region have suffered thermal degradation. On the contrary, microbially degraded sediments from the Ennamangalam lake exhibited statistically insignificant correlation ($R^2 = 0.2$, $p < 0.05$, $n=19$) between C₁₈ and C₂₉ homologues. To extricate the influence of microbial and thermal degradation, ratio between the relative concentration of C₁₈ and C₁₉ homologues (P_{Factor}) have been used. For thermally degraded samples, the P_{Factor} values (11 to 62) are much higher compared to that of the microbial degraded samples (1 to 10). Thus, the observed difference in the P_{Factor} values and inter-homologue correlation can be used to disentangle the effect of thermal and microbial degradation on *n*-alkane assemblage. Moreover, the present study suggests that the *n*-alkane assemblage in sediments can be used as a molecular marker to reconstruct paleo-fire events.

Anthropogenic fires in agroforestry landscapes of India: Lessons from the “burnt” past for future ecological management in the tropics

Charuta Kulkarni¹, Shonil Bhagwat^{1,2}, Walter Finsinger³, Sandra Nogue^{4,2}, Pallavi Anand⁵, Kathy Willis²

¹Department of Geography and OpenSpace Research Centre, The Open University, Milton Keynes, United Kingdom.

²Long-Term Ecology Laboratory, Department of Zoology, University of Oxford, Oxford, United Kingdom. ³ISEM, Univ Montpellier, CNRS, EPHE, IRD, Montpellier, France. ⁴Geography and Environment, University of Southampton, Southampton, United Kingdom. ⁵School of Environment, Earth and Ecosystem Sciences, The Open University, Milton Keynes, United Kingdom

Abstract

The effective management of human-dominated tropical forest landscapes is crucial in the wake of global climate change affecting biodiversity, ecosystem functions, and the livelihoods of billions. Among a wide range of practices, agroforestry remains one of the most promising land management strategies in the tropics, promoting intentional maintenance of trees on farmland for productive agriculture, thereby supporting the livelihoods of millions and providing avenues for climate change mitigation. Acknowledging its diverse benefits, the Government of India launched the National Agroforestry Policy (NAP) in 2014, world’s first nationwide policy with the central idea of doubling the agroforestry area concurrent with the expansion of national forest cover. As the world’s most populous country, yet its fastest growing economy, moving towards “Green India” would be a serious game-changer for this tropical country with positive environmental implications on a global scale. The effective implementation of this economically important policy falls on the shoulders of Indian Forest Departments (IFDs), who administer a strict policy of preventing fires in and around forests. Fire, however, is an integral part of forest ecosystem functioning; its strict prevention leads to accumulation of biomass, causing more severe fires. A growing body of present-day and palaeo-fire studies showing links between biomass and fire is leading nations to revisit their landscape management strategies with some (e.g. Australia, South Africa, United States) adopting prescribed burning. We argue that in the light of the NAP, understanding the role of historical fire regimes is imperative to the management of age-old, human-dominated Indian agroforestry landscapes where people have traditionally used fires in shifting cultivation. The disagreements in fire practices often instigate serious conflicts between local communities and IFDs, hampering implementation and the desired impact of the NAP and its associated benefits. In this context, we bring a new, high-resolution palaeo-fire record from Western Ghats agroforestry landscape spanning past few millennia. Utilising macroscopic and microscopic charcoal analyses, palaeoecology-driven innovative statistical modelling approaches (e.g. pollen-based REVEALS modelling, rarefaction, and multivariate ordination), and palaeoclimate databases, we present time-resolved transformations of Indian agroforestry landscapes in relation with past fires and monsoonal variability across the Common Era and beyond. Quantitative reconstructions of past landcover and land use at a time-resolution of 20-50 years allow us to: 1) deepen the fundamental knowledge of these long-term social-ecological systems; 2) render state-of-the-art understanding of the efficacy of fires in forest management in a seriously data-poor region; and 3) deliver region-specific, tangible implications for the effective implementation of NAP and its wider applications to other parts of the tropics. Our work is part of project “[EARNEST](#)” that has received funding from the European Union’s Horizon 2020 research and innovation programme under the grant agreement no. 795557.

Fire regimes in consumer-driven C₄ grassy biomes derived from sedimentary charcoal

Abraham Dabengwa

University of Cape Town, Cape Town, South Africa

Abstract

Consumption of grass biomass by fire is an important earth system process contributing to terrestrial nutrient cycling. In assessing long-term controls of fire, Whitlock et al. (2010) propose a framework of overlapping triangles ranging from flammability, fire events, to fire regimes at increasing spatial and temporal scales. However, this system is unsuitable in some C₄ tropical grassy biomes because large herbivores also consume grasses; grass mosaics have multiple stable states; and grass biomass is coupled to climate. Although fire events/ activity increase with the proportion of flammable C₄ tallgrasses, herbivory and wetness of fuels suppress it. As a result, there is confounding in long-term spatial relationships between flammability and fire regimes derived from sedimentary charcoal fire proxy. This idea is explored at persistent wetland margin grasslands using charcoal records from a lowland savanna and two montane grasslands of South Africa where C₄ tallgrasses, herbivory, and aridity decrease with elevation. At all sites, fire activity indicated by charcoal amounts increased along local C₄-C₃ grass biomass gradients, peaking at intermediate values before tapering. There was low variability in charcoal amounts at low and high grass biomass, and in sites with low or high herbivory. Consequently, a single triangle was used to represent multiple regimes along a biomass/ gradient with flammability increasing toward the apex while fire events populated regime partitions. The new triangle provides a template for investigating regime shifts and multiple stable states in grassy biomes with competing consumers. Interestingly, the new framework suggests the extension of the spatial constituent of fire regimes increases uncertainty in pooled fire reconstructions from biome boundaries while indicating the value of consumers-related plant traits.

Biomass burning during the Last Glacial-Interglacial Transition (c. 17-8 ka cal. BP) in the British Isles; spatiotemporal patterning and controls

Margarita Tsakiridou¹, Mark Hardiman¹, Michael Grant², Paul Lincoln³, Laura Cunningham¹, Zoë Hazell⁴

¹University of Portsmouth, Portsmouth, United Kingdom. ²University of Southampton, Southampton, United Kingdom. ³Royal Holloway, University of London, Egham, United Kingdom. ⁴Historic England, Portsmouth, United Kingdom

Abstract

Charcoal records are now widely used to reconstruct and investigate what controls wildfire activity on centennial to millennial timescales. The topic, however, has been largely overlooked in the British Isles, with most evidence of biomass burning being attributed to anthropogenic ignition on the basis that the region does not support natural burning regimes.

Here we present the first synthesis of published charcoal data for the British Isles from records that span the Last Glacial Interglacial Transition (LGIT; c. 17-8 ka cal. BP). In total, 238 sites were identified which allows detailed spatiotemporal trends to be identified. The compiled data were transformed into presence-absence, assigned to the major climatic intervals of the LGIT (GS-2.1a, c. 17-14.65 ka cal. BP; GI-1, c. 14.65-12.85 ka cal. BP; GS-1 12.85-11.25; Early Holocene, c. 11.65-8.28 ka cal. BP) and then assessed in relation to broad patterns in climate, vegetation, and anthropogenic activity.

Results demonstrate the widespread occurrence of charcoal in sediments that span the LGIT in the British Isles. Investigation into the charcoal curves has revealed several interesting patterns: 1) high charcoal values during GS-2.1a that cease with the onset of the GI-1 at c. 14.65 ka cal. BP, 2) spikey or distinct peaks in charcoal records spanning GI-1, as well as enhanced landscape burning during the latter stages of the GI-1 (~14-13 ka cal. BP), 3) high charcoal values during GS-1, and finally 4) multiple charcoal peaks in the Early Holocene with a coincident peak apparent in multiple sites throughout the British Isles at ~9.3 ka cal. BP, the timing of which has been ascertained via new Bayesian age-depth modelling.

No causal links between presence of charcoal and vegetation types can be identified, however contemporaneous burning through different floral mosaics suggests that vegetation was not the principle variable driving fire regimes. The absence of associated archeology in GS-2.1a and GS-1 (as well as the distribution of archaeological sites during GI-1) strongly suggests that humans were not the primary driver of fire regimes during the Lateglacial (i.e. GS-2.1a, GI-1, and GS-1) either. The distinct peak in charcoal identified here during the Early Holocene at c. 9.3 ka cal. BP is explored via correlation to both climatic and archeological datasets, using the 'dates as data' approach to estimate past human population intensity. Although humans on the landscape preclude any strong hypothesis to be made, the synchronicity and spatial extent this peak is evident probably points to a climatic control for the Early Holocene as well.

The findings here fit with other evidence for climatically controlled burning in Northern Europe and suggest that notions that temperate oceanic climate-landscapes such as the British Isles do not naturally burn is incorrect.

Holocene fire and forest histories in relation to climate change and agriculture development in southeastern China

Ting Ma, Zhuo Zheng
Sun Yat-Sen University, Guangzhou, China

Abstract

Four cores (GY1, LTY, SZY, GT-2) taken from lowland to mountain sites in southeastern subtropical China were studied. Charcoal and pollen analyses were conducted to examine the regional Holocene fire history and discuss its possible relationship with both climatic changes and anthropogenic activities. Our results show extremely low charcoal influxes between 9.5 and 3.5 cal ka BP, revealing low fire frequency. Meanwhile, high proportions of arboreal pollen demonstrated expansion of subtropical evergreen broadleaf forest. This phase is consistent with heavy precipitation during the early-mid Holocene. After 3.5 cal ka BP., the abrupt increases in fire frequency revealed by core GY1 and LTY were closely related to gradual drying towards the late Holocene, possibly due to the Asian Summer Monsoon weakening and activation of the El Niño Southern Oscillation. Our pollen records also reveal this drying trend after the mid-Holocene, demonstrating a regional retreat of subtropical evergreen forests and local development of *Glyptostrobus*-dominated wetland community around the LTY and GY1 sites. However, the intensified fires after 3.5 cal ka BP probably resulted mainly from increasing human activities during the Shang-Zhou Bronze age. Pollen results show severe damage of forest by fires, indicated by notable decrease of arboreal pollen and increase of *Dicranopteris* and herbs. After 2.0 ka, obvious growth of Poaceae, *Dicranopteris* and *Pinus* recorded in the GY1 and LTY cores demonstrate agriculture development in low- altitude plains and hills, coinciding with the first human population boom and big progress in agricultural technology during the Warring States to Western Han Dynasty period. Signs of profound human impacts and extensive agriculture in South China appeared after 1.0 cal ka BP, which is revealed by frequent local fires and intensified anthropogenic impact around the mountains sites (SZY and GT-2). Generally, our results reveal a gradual expansion of anthropogenic activities into elevated areas.

Abstract

The influence of different drivers on changes in North American and European boreal forests biomass burning during the Holocene was investigated based on the following hypotheses: land use was important only in the southernmost regions, while elsewhere climate was the main driver modulated by changes in fuel type. Biomass burning was reconstructed by means of 88 sedimentary charcoal records divided into six different site clusters. A statistical approach was used to explore the relative contribution of (1) pollen-based mean July/summer temperature and mean annual precipitation reconstructions, (2) an independent model-based scenario of past land use, and (3) pollen-based reconstructions of plant functional types on biomass burning. Our hypotheses were tested with: (1) a west-east northern boreal sector with changing climatic conditions and a homogeneous vegetation, and (2) a north-south European boreal sector characterized by gradual variation in both climate and vegetation composition. The processes driving fire dynamics in boreal forests varied from one region to another during the Holocene. However, general trends in boreal biomass burning were primarily controlled by changes in climate (mean annual precipitation in Alaska, northern Quebec and northern Fennoscandia, and mean July/summer temperature in central Canada and central Fennoscandia) and, secondarily, by fuel composition (BB positively correlated with the presence of boreal needleleaf evergreen trees in Alaska and in central and southern Fennoscandia). Land use played only a marginal role. A modification towards less flammable tree species (by promoting deciduous stands over fire-prone conifers) could contribute to reduce circumboreal wildfire risk in future warmer periods.

Conceptual study design based on boreal forest regions that contain sedimentary charcoal time series. Hypotheses linking biomass burning and different drivers are displayed in red.

Time, space and causality in past wildfire regimes: a paired-lake study from central Anatolia

C Neil Roberts^{1,2}, Stephanie Arcusa³, Warren J Eastwood⁴, Rebecca Turner¹, Marta Perez⁵

¹University of Plymouth, Plymouth, United Kingdom. ²Oxford University, Oxford, United Kingdom. ³Northern Arizona University, Flagstaff AZ, USA. ⁴University of Birmingham, Birmingham, United Kingdom. ⁵Royal Holloway University of London, London, United Kingdom

Abstract

It has long been known that causal mechanisms in environmental systems are scale-dependent (Schumm and Lichty 1965, *Am. J. Sci.*, 263, 110-19). For wildfires, independent variables such as fuel load can become dependent variables over multi-millennial time-scales. Testing such scalar mechanisms in palaeo-fire research is possible if we can coax Quaternary history to conduct experiments for us (c.f. Deevey 1969, *BioScience* 19, 40-43). Here we compare charcoal records from two maar lakes 25 km apart in Cappadocia, Turkey, since 13.8 ka. For micro-charcoals, laboratory methods involved density separation of contiguous core samples and optical counting. Core dating is based on U-Th and varve counting, with vegetation history from pollen analysis. $\delta^{18}\text{O}$ analysis of authigenic carbonates confirms that the two lakes experienced very similar hydro-climatic histories (Dean et al. 2015; *Quat. Sci. Rev.* 124, 162–174; Roberts et al., 2016; *J. Quat. Sci.* 31, 348–62).

The sedimentary sequence from Eski Acigöl spans the last ~20 ka but is poorly resolved for the last 2 ka, while that from Nar covers the last 13.8 ka, but with a probable mid-Holocene hiatus. The two records therefore overlap in time for the Late Glacial to early Holocene climatic transition, the early-mid Holocene (until 6.5 ka BP) and for part of the Late Holocene (~4.5 to 2 ka BP). There were different fire regimes and forcings for each of these three time periods. At Eski Acigöl, there is a clear correlation between $\delta^{18}\text{O}$ -inferred hydro-climate and micro-charcoal influx throughout the record (Turner et al., 2008; *Glob. Planet. Change* 63, 317-324), with wildfires being fuel-limited and consequently increasing during wetter times with greater biomass. A similar relationship operated at Nar, but only during the Last Glacial-Interglacial Transition (LGIT). At both sites, burning was sharply reduced during the cold, dry "Younger Dryas" stadial associated with low-biomass *Artemisia*-chenopod steppe, and increased during grass-dominated periods of warmer, wetter climate. After ~10 ka BP the charcoal record at Nar lake does not exhibit the same close relationship with $\delta^{18}\text{O}$ -inferred hydro-climate seen at Eski Acigöl. This implies that a more complex set of mechanisms controlled micro-charcoal flux at Nar during most of the Holocene, including human-induced catchment disturbance as early as 9.1 ka BP, associated with Neolithic obsidian mining near the lake. Pollen data from Nar lake (England et al., 2008, *Holocene* 18, 1229-45) indicate that by the last 2-3 ka, anthropogenic land cover change became main pacemaker for burning regimes.

We conclude that when forcings, such as LGIT climate change, were of large magnitude and multi-centennial duration then palaeo-fire regimes were spatially coherent and homogeneous. When forcings were smaller, shorter-lived or multi-causal (e.g. mid-Holocene), then a more heterogeneous pattern of wildfires would have been registered in sedimentary charcoal records.

The role of proglacial lakes in the decline of the terrestrial-terminating Irish Sea glacier

Richard Chiverrell¹, Geoff Thomas¹, Matthew Burke¹, Alicia Medialdea², Rachel Smedley¹, Mark Bateman³, Geoff Duller⁴, Geraint Jenkins⁴, James Scourse⁵, Chris Clark³

¹University of Liverpool, Liverpool, United Kingdom. ²University of Cologne, Cologne, Germany. ³Sheffield University, Sheffield, United Kingdom. ⁴University of Aberystwyth, Aberystwyth, United Kingdom. ⁵Exeter University, Exeter, United Kingdom

Abstract

Proglacial lakes and the subglacial topography were significant regulators of glacial dynamics during the advance and decline of an extensive former ice lobe that invaded the lowlands of northwest England and English Midlands. The eastern sector of the Irish Sea Ice Stream, at the last glacial maximum, extended onto land and then south into the English Midlands as an extensive grounded terrestrial ice lobe. These lowlands received flows from Irish Sea ice and valley glaciers exiting from Wales. New mapping of the sediment landform assemblages of Cheshire, Shropshire, Staffordshire and the Welsh borderlands has recorded the advance to maximum limits and the progressive unzipping of the different ice masses during later retreat. The sediment-landform assemblages reveal the repeated development and then abandonment of ice contact land-systems with numerous styles of proglacial lakes, sandur and moraines with glacial retreat. Major quarries in the region reveal the sedimentology of these environments and provided access to deposits for Optically Stimulated Luminescence (OSL) dating. This new chronology exploits parallel approaches of single grain and small aliquot OSL measurements of quartz, and cobble-based OSL of feldspars in outwash gravels. The new chronology constrains ice marginal retreat to the period after ~25 ka, with ice eventually vacating the region by ~22-21 ka.

Fig 1. Ice marginal retreat sequence in lowland NW England.

Active oscillation of the ice margin during retreat produced the more extensive moraine ridges, with complex terrains of ridges and kettle-basins developing in zones characterised by stagnation of the ice margin. The most substantial deglacial landform in the retreat sequence is the Oswestry-Whitchurch-Congleton moraine formed as the ice margins passed northwards of substantial bedrock highs. Lakes were an endemic component of this deglacial landsystem, and took a myriad of forms including glacial over-deepenings, both moraine and bed-rock confined ice contact lakes and ice melt-out hollows (kettle basins). Late during this deglaciation ice masses sourced from Wales took advantage of the accommodation space vacated by the Irish Sea glacier and advanced crossing-cutting and overprinting the Irish Sea Glacier retreat signature leaving a series of lobate moraine ridges exiting Wales. Retreat northwards and down-wasting of ice meant that individual ice sources increasingly regulated the ice flow dynamics producing the lobate moraine systems in the developing Dee, Weaver basins and the Manchester embayment. Pinned between the mid-Cheshire bedrock high and retreating ice margins separate proglacial lake basins developed, and extensive deltas developed at Wrexham and Delamere. Ultimately, ice marginal retreat led to the evacuation of the basins by 22-21 ka and the escape of lake waters west into a deglaciated western Irish Sea basin.

Large-scale deformation structures characterize glaciolacustrine kame sediments—a new kame-investigation approach

Małgorzata Pisarska-Jamrozy¹, Barbara Woronko², Łukasz Bujak³, Albertas Bitinas⁴, Szymon Belzyt¹, Mateusz Mleczak⁵

¹Adam Mickiewicz University, Institute of Geology, B. Krygowskiego 12, Poznan, Poland. ²Warsaw University, Faculty of Geology, Żwirki i Wigury 93, Warsaw, Poland. ³Warsaw University of Technology, Faculty of Geodesy and Cartography, Plac Politechniki 1, Warsaw, Poland. ⁴Nature Research Centre, Akademijos 2, Vilnius, Lithuania. ⁵Adam Mickiewicz University, Institute of Geology, B. Krygowskiego, Poznan, Poland

Abstract

Fine- and coarse-grained kames are commonplace forms in glacial landscapes. Here six fine-grained kames located in eastern Poland and southern Lithuania are analysed in detail. These kames were formed during MIS6 and MIS2. They consist of a distinctive suite of sediment grain sizes, being in constitution an admixture of clay, a full range of silt fractions, and fine-grained sand. Based on this granulometric composition all are classified as glaciolacustrine kames, and were formed in ice-walled depressions, subsequently infilled by ice-sheet meltwater.

A characteristic feature of all of the analysed kames is their extraordinarily rich scale of soft-sediment deformation structures (SSDS), which were observed across their entire lateral and vertical extent. Among the SSDS were: small- as well as large-scale load casts (≤ 120 cm); variably-sized pseudonodules; silty/sandy injection structures—*i.e.*, mud volcanoes; flame structures; and dish structures. Typically the large-scale load casts and pseudonodules contain a few generations of smaller SSDS. The largest of these load casts can enclose two, three, four or even five generations of smaller deformations. This complexity appears to be a result of multiple-stages of kame-sediment deformation, an artefact of a significant volume of water having been present during the sedimentation process.

It should be apparent from the very fine-grained sedimentary record that a very specific water regime presents during kame formation played an essential role in SSDS formation—specifically having occurred during general deglaciation. These are depositional conditions that are quite different than those that would have existed during the formation of sandy/gravelly glaci-fluvial kames. SSDS formation depended on sediment fluidization, and on slight differences in their grain-size distribution. Additionally, that sedimentation must have taken place prior to a final consolidation and before the melting of the depressions' ice-walls, within which the kame sediments were accumulated. This is evidenced by faults observed in the marginal zones of the kames, which post-cut the SSDS. These fine-grained kames were most likely formed during the initial stages of deglaciation, occurring in isolated depressions within the ice with bottoms located above the sediment-rich subglacial zones.

The aim of our presentation is to propose that SSDS are distinctive indicators that fine-grained glaciolacustrine kame development occurred under specific and limited conditions of deposition and deformation. This work can also help in the identification of kame sedimentological environments during older glaciations in the absence of additional morphological context.

Architecture and structural evolution of the Late Weichselian Jasmund Glacitectonic Complex (Rügen Island, NE Germany)

Anna Gehrmann¹, Martin Meschede¹, Heiko Hüneke¹, Karsten Obst², Stig A. Schack Pedersen³, Chris Harding⁴

¹University of Greifswald, Greifswald, Germany. ²Geological Survey, LUNG M-V, Güstrow, Germany. ³Geological Survey of Denmark and Greenland, Copenhagen, Denmark. ⁴Iowa State University, Ames, USA

Abstract

Glacitectonic deformation in the Late Weichselian (MIS 2) caused the tectonic framework of large-scale folds and displaced thrust sheets of Maastrichtian (Upper Cretaceous) chalk and Pleistocene glacial deposits in the southwestern Baltic Sea area, which are well exposed in Denmark and northern Germany.

A wide spectrum of methods has been compiled to unravel the structural evolution of the 100 km² large Jasmund Glacitectonic Complex. DEM analyses suggest a division into two structural sub-complexes – a northern part with morphological ridges striking NW–SE and a southern part with SW–NE trending ridges. Geological cross sections from the eastern coast (southern sub-complex) were constructed and restored using the software Move™ and the complementary module 2D Kinematic Modelling™.

The final structural model of the southern sub-complex shows a small-scale fold and thrust belt. It includes three different orders of architectural surfaces sensu Pedersen (2014): erosional surfaces and detachment faults (1st order), thrust faults (2nd order), and hanging-wall anticlines as well as footwall synclines (3rd order). Thrust faults inclined towards south indicate a local glacier push from the S/SE.

The glacitectonic structures have a surface expression in form of sub-parallel ridges and elongated valleys in between. Geomorphological mapping and detailed landform analyses together with the structural investigations provide an insight into the chronology of sub-complex formation. The northern part of the glacitectonic complex is suggested to have been formed first by an ice advance from NE, considering the partly truncated northerly ridges and their superimposition due to the slightly younger formation of the southern sub-complex. The crenulated easternmost ridges suggest a third glacier push from E/ENE. Our new genetic model of the Jasmund Glacitectonic Complex contradicts numerous models published earlier, but it is self-consistent and integrates all structural parts.

Figure 1. Principal 3D view of the Jasmund Glacitectonic Complex. a) Interpreted cross section of the southern structural sub-complex below the digital elevation model (DEM5), which shows the main parts of the northern and southern ridge domain. **b)** Map of the Jasmund Peninsula in the SW Baltic Sea with the DEM clip (blue) and the section trace (red line), which are shown in (a). The model is two times exaggerated. The section trace is located further towards the inland than the shown cross section, which is originally from the cliff.

Karpinsky Russian Geological Research Institute (FGUP-“VSEGEI”), St.Petersburg, Russian Federation. ⁵Sweco, Bergen, Norway. ⁶Stockholm University, Stockholm, Sweden. ⁷Columbia University, New York, USA

Abstract

We here present our current understanding of the glacial, environmental and climate history in the Polar Ural Mountains and adjacent lowland of the Russian Arctic. Our reconstruction of the past environment is based on a multitude of data that have been obtained from geomorphological mapping, stratigraphic examination of exposed strata, geo-archaeological investigations of Paleolithic sites and coring of lake basins. The northern rim of the continent appears to have been inundated by the Barents-Kara Ice Sheet twice during some early stages of the last Ice Age, which according to our dating results happened during Marine Isotope Stage (MIS) 5b (~90 ka) and MIS 4 (75-60 ka) respectively. These ice advances blocked the northbound drainage on the continent and led to the formation of large ice-dammed lakes that flooded the lowland areas to the south of the ice sheet. The ice-dammed lakes, which presumably drained catastrophically into the Ocean towards the end of the major glaciations, caused a dramatic cooling of the summer climate across a wide region. At least during the latter glaciation a complex of large glaciers formed within the Polar Ural Mountains and these glaciers coalesced with the Barents-Kara Ice Sheet that were flowing southwards along both flanks of the mountain chain. The large ice sheets that existed at these times appears to have melted completely away during MIS 5a (~85-80 ka) and MIS 3 (60-30 ka). During MIS 3 the northern landscapes hosted a rich and varied mega fauna, and was at least periodically colonized by humans. A new generation of glaciers started to form during a late stage of MIS 3 reaching their maximum extent during MIS 2. However, both the shelf-centered ice sheet and local glaciers in the mountains were then smaller than during the foregoing glaciation, and the major mountain valleys have remained ice-free over the last 50-60 ka. Results from a lake coring campaign indicate that the mountain glaciers during MIS 2 reached their maximum dimension just prior to 24 ka, a few thousand years before the glacial maximum of the ice sheet further to the north. The glaciers started to melt soon after the LGM, and they appears to have been gone by 14 ka. During the Early Holocene, the main valleys in the Polar Urals and the northern rim of the adjacent lowland were forested reflecting a significant warmer climate than today. The present small glaciers that exist in the mountains formed during a late phase of the Holocene and had their maximum extent were attained early in the 20.th century. Presently, almost all glaciers in the Polar Urals have melted away in response to the ongoing global warming.

Rethinking deglaciation of the interior Cordilleran Ice Sheet, southern British Columbia

Jonathan Cripps, Tracy Brennand, Andrew Perkins
Simon Fraser University, Burnaby, Canada

Abstract

Conceptual models of deglaciation of the last Cordilleran Ice Sheet (CIS) in central British Columbia (BC) have historically been limited to reconnaissance-scale investigations. These early studies proposed that the Interior Plateau region of BC deglaciated by regional stagnation, with widespread downwasting and complex frontal recession of valley-confined ice tongues. This conceptual model emerged from interpretations of glacial lakes and meltwater channels identified by early research conducted over the Thompson Plateau, and has been extended to explain the lack of large recessional moraines in central BC. The stagnation model has since been widely applied to the whole interior region of the former CIS. More testing is required in order to assess this model as an analogue for current and future ice sheet decay.

Several recent studies have challenged the stagnation model. This presentation will synthesise detailed investigations of several sub-regions across the southern Interior Plateau, utilising a range of methods including exposure sedimentology, shallow geophysics, mapping from new aerial photography and c. 10 m resolution digital elevation models (DEMs). Common terrestrial and lacustrine (de Geer) glaciotectonised moraines and grounding line deposits identified on the northern Thompson and southern Fraser plateaus indicate active ice front recession to the northwest. This is supported by new constructions of palaeo ice-dammed lakes that expanded and lowered to the west and northwest as ice recession opened progressively lower outlets. Reconstructed glacioisostatic tilts of lake planes are among the highest in the world, at up to 2.3 m/km up to the north-northwest; tilts decline to the northwest, recording either rapid crustal relaxation during deglaciation, or thicker ice on the central Fraser Plateau.

These recent investigations encourage a reappraisal of conceptual models of CIS deglaciation in BC's Southern Interior; available evidence is now consistent with systematic, active recession of the CIS over the Thompson and southern Fraser Plateaus broadly to the northwest.

(How) can large lateral moraines be used as sedimentary archives of Quaternary glaciations? A systematic process-assessment from the European Alps

Sven Lukas¹, Monika Rabanser¹, Harry McMahon², Andreas Graf³

¹Department of Geology, University of Lund, Lund, Sweden. ²Department of Geography, Queen Mary University of London, London, United Kingdom. ³Institute of Geological Sciences, University of Bern, Bern, Switzerland

Abstract

Large lateral and latero-frontal moraines are prominent landforms in mountain environments globally. They have long been regarded as providing key constraints on the extent and timing of Quaternary glaciations, thus adding a crucial layer of evidence to the sedimentary and geomorphological archives left by mountain glaciations in general. Since the introduction of the precursors to the glaciated valley landsystem (e.g. Boulton and Eyles, 1979), large lateral moraines and other ice-marginal landforms in mountain environments have largely been seen as the product of 'passive' supraglacial transport (i.e. resulting from the stacking of supraglacially-released, largely angular debris). However, much of aforementioned conceptual model is without a solid evidence base, at least as far as reported evidence is concerned. This is a significant shortcoming, because – while elegant and plausible conceptually – the model and its facies inferences have clear implications for the retrograde interpretation of glacial dynamics from Quaternary lateral moraines and moraine successions. Therefore, the current perception that large lateral moraines record merely the passive release of glacially-conveyed debris perhaps unduly limits their use as a geological archive of former glacier fluctuations and glacier dynamics.

We here summarise, for the first time, systematic geomorphological and sedimentological process observations and lithofacies analyses from six different glaciated valleys in the European Alps to test the predictions of the original glaciated valley landsystem that are still seen as current today (cf. Benn and Evans, 2010). The outcome of these studies points to a complex continuum between different endmembers that are controlled by very different boundary conditions (*inter alia* different degrees of debris cover on the glaciers, transport pathways through the glaciers, depositional mechanisms, lithological and climatic influences). These are found to have pronounced and characteristic effects on the final lateral moraine products. Based on this multi-factorial analysis, we conclude that lateral moraines are far more complex and enable a far more nuanced interpretation of the depositional palaeo-environment than hitherto appreciated (in the conceptual model of the glaciated valley landsystem). We argue that our initial template should be considered as a first step towards quantitatively assessing how complex landforms such as large lateral moraines may be utilised in the reconstruction of Quaternary glaciations, notably glacier dynamics. Our template could be further enhanced by including systematic studies from other mountain ranges where other controls (such as a stronger tectonic influence, greater range of bedrock lithologies etc.) prevail. This, we predict, would lead to a more holistic understanding of the effects and significance of mountain glaciers on the evolution of their entire catchments.

Glaciers extent and climate in the Maritime Alps during the Younger Dryas

Matteo Spagnolo¹, Adriano Ribolini²

¹University of Aberdeen, Aberdeen, United Kingdom. ²University of Pisa, Pisa, Italy

Abstract

Our planet experienced multiple cooling episodes since the last glacial maximum. One of these, the Younger Dryas (YD), is of particular relevance because it is the most recent period (12.9 and 11.7 ka ago) during which a cooling of the order of some degrees affected a large portion of the Earth. The YD affected the Earth and its inhabitants on multiple fronts. In particular, it caused the widespread (re)advancement of glaciers and the deposition of, usually well preserved, frontal moraines. These glacial deposits are the essential ingredient for the reconstruction of former glaciers, which can then be used to extract a palaeo Equilibrium Line Altitude (ELA), which bears crucial information about the palaeoclimate. Up until recent, this kind of reconstructions has been rather time consuming and usually limited to a few glaciers/moraines. However, recent GIS advances allow for faster (and therefore larger scale) palaeoglacier reconstructions. Such large scale reconstructions could be incredibly useful not only to better understand the glaciological response to past climate changes, but also to interpret human, floral and faunal migration and interaction patterns and dynamics (including extinctions). Here, we present a moraine (Figure 1) in the (European) Maritime Alps newly dated to the YD with cosmogenic isotopes (¹⁰Be). We reconstruct the extent of the glacier that deposited such moraine and extract its ELA. The same is applied to another moraine, already dated to the YD, and located some 40 km ESE. The two ELAs are then combined to define an average, regional ELA for the Maritime Alps and this is, in turn, used to reconstruct all YD glaciers (65) that likely covered this large (615 km²) sector of the Alps. A map of the reconstructed glaciers is presented (Figure 2) along with morphological evidence demonstrating the validity of the reconstruction. Finally, the regional ELA is used to extract local palaeoprecipitations and to discuss the YD climate across the Alps.

Pollen, people and peat: A mixed-methods approach to uncovering the prospects for Malaysia's tropical peatlands

Lydia Cole¹, Shonil Bhagwat², Kathy Willis³

¹University of St Andrews, St Andrews, United Kingdom. ²The Open University, Milton Keynes, United Kingdom.

³University of Oxford, Oxford, United Kingdom

Abstract

The peatland ecosystems of Southeast Asia are undergoing rapid change. Pervasive deforestation and drainage, primarily with the end-goal of large-scale land conversion to oil palm plantations, is disrupting their ability to sequester atmospheric carbon in peat deposits, in addition to causing significant negative consequences for the persistence of biodiversity, for the intensification of fire, and for multiple other processes that provide ecosystem functions of local to global significance. Conserving these peatlands in their intact state has been described as a “low hanging fruit in tackling climate change”. Yet land-use conversion continues in the peat-rich nations of Southeast Asia, where local stakeholders’ priorities are antagonistic to the calls of the international conservation community.

The goal of this project was to explore past vegetation change in these coastal peatlands and set it in the context of their current condition and potential future trajectory. Palaeoecological data were derived from cores collected from three degraded peatlands along the coast of Sarawak, in Malaysian Borneo. Changes in fossil pollen and charcoal were analysed in each core to reconstruct vegetation change and fire over the late Holocene. To understand more of the human history of interaction with the peatlands of this region, a comprehensive literature review and social surveys were performed. Semi-structured interviews were conducted with smallholder farmers, oil palm plantation managers and key informants involved in the management of Sarawak’s coastal peatlands. Enquiry focused on historical and contemporary use, management challenges and future visions for the peatlands.

In combination, the diverse datasets analysed in this study generated a cohesive narrative of peat swamp forest development, and subsequent degradation over the last several hundred years, with the reduction in forest pollen coinciding with the movement of people to the coastal swamps. Contemporary interactions with the peatlands reflected the limited understanding of the globally-significant ecosystem services provided by an intact peat swamp forest, and highlighted their immediate value as a resource to local stakeholders.

This project provides an interdisciplinary piece exploring the complex dimensions of tropical peatland management in Southeast Asia and insights for developing future conservation programs for this carbon-rich ecosystem. Authors are interested to obtain feedback on this study, as a mixed-methods contribution to *conservation* science, and to gather opinion on whether and how such work can contribute to developing effective policy.

Towards an ecocritical palaeoecology

Suzi Richer^{1,2}, Benjamin Gearey³

¹University of York, York, United Kingdom. ²Richer Environmental, Cumbria, United Kingdom. ³University College Cork, Cork, Ireland

Abstract

“Ecocriticism explores the ways in which we imagine and portray the relationship between humans and the environment in all areas of cultural production, from Wordsworth ...to Google Earth.” (Garrard 2012, frontispiece)

In this paper we aim to sketch the outlines of an ‘ecocritical palaeoecology’. Ecocritical studies focus on the relationship between the cultural origins of and responses to, current global ecological and environmental problems and crises. In its reading of texts, ecocriticism takes an earth-centred approach to literary studies. In this paper we consider the potential role of palaeoecology within ecocritical thought and in particular how an ecocritical approach effects the practice of palaeoecology itself. Specifically, how are specific ideas and representations of ‘past ecosystems’ and their relationship to human and non-human actors, created and sustained through palaeoecological work and study? What is the relationship of palaeoecology with the politics of debates such as ecosystem degradation and ‘past human impact on the environment’? Heise (2006) has drawn attention to the lack of a comprehensive model for linking contemporary perspectives and developments in ecology to ecocritical work and thought. Thus, one of our aims may be regarded as part of a broader project to form active disciplinary connections between (palaeo) ecology, ecocriticism and the Environmental Humanities.

Conservation palaeoecology as a participatory science

Althea Davies

University of St Andrews, St Andrews, United Kingdom

Abstract

The prospect of environmental change beyond recent human experience is providing a powerful stimulus to evaluate conservation strategy and the science that underpins it. Although palaeoecologists have written about the importance of long-term data for anticipating and managing environmental change for many years, integrating this evidence into management continues to be a high priority for the palaeoecological community because our sources remain peripheral to conservation and ecology. Social science approaches are being used in conservation and environmental management to understand and bridge gaps between research, practice and policy, but very few palaeoecologists have followed this example to look more critically at how we interact with other communities.

This talk combines social science and palaeoecology to review what palaeoecologists can learn from conservation and environmental management about effective integration and communication. I present a case study on Atlantic woodland management that implements some of these guidelines via a participatory approach to conservation palaeoecology. The study used interviews with local stakeholders to identify key conservation habitats and questions with long-term relevance in the study area of NW Scotland. Stakeholders included the national conservation agency, land owners and managers, local ecologists and community interest groups. After conducting palaeoecological (pollen, charcoal, fungal spore) analyses in areas identified by interviewees, the results were communicated in presentations and evaluated through follow-up interviews with some stakeholders. This iterative approach demonstrates that palaeoecology and stakeholder experience play complementary roles. Long-term ecology can address uncertainties and test assumptions about key ecosystem processes that influence woodland composition and regeneration, while ecological and local experience provide the level of detail and practical knowledge required to translate these into locally-adapted and adaptive management strategies. The study also revealed some of the challenges involved in developing and sustaining dialogue with stakeholders whose management priorities may focus on immediate, short-term concerns, like grazing pressures from wild deer, which create tension locally, dominate management decisions and exclude longer-term issues. More studies that outline the scientific and social efforts, successes and difficulties of applying palaeoecology to management are needed to help the palaeoecological community reflect critically on how we work towards real-world impact.

The last 2000 years of the southern Balkans through the Lake Dojran (Greece, F.Y.R.O.M.) sediment archive and historical sources

Alessia Masi^{1,2}, Laura Sadori¹, Lucrezia Masci¹, Alexander Francke³, Bernd Wagner⁴, Adam Izdebski²

¹Sapienza University, Rome, Italy. ²Max Planck Institute for the Science of Human History, Jena, Germany. ³University of Wollongong, Wollongong, Australia. ⁴University of Cologne, Cologne, Germany

Abstract

Societal and environmental processes influence and adapt each other. The complexity of past societies and the multiple possible environmental conditions bring a surprisingly varied interaction strategy. Going into detail, the interpretation of this relationship and its complex interaction require both high-resolution multidisciplinary studies and the deep understanding of the socio-economic history. This innovative approach is the base of an independent research group recently created at the Max Planck Institute for the Science of Human History in Jena that aims at developing a new methodology that will integrate traditional methods of historical research with those of the natural sciences, in particular palaeoecology and palaeoclimatology.

Lake Dojran (Greece and FYROM) provides a valuable record of the Holocene environmental change reconstructed using not only pollen and NPPs (1) but also other proxies (geochemistry and biomarkers). Here we focus on the last 2000 years of palaeoenvironmental data and in particular on the new 30-years-resolution pollen analysis to offer an insight into our approach within the historical region of Macedonia. The very high arboreal pollen percentage that characterized the mid-Holocene at Dojran strongly reduced since the first century BC (ca. 2000 yr BP). At the same time Macedonia become a Roman province and was integrated into the Roman market economy. The arboreal reduction affected mainly pine and fir, the most important timber for Romans shipbuilding. The whole Roman period (almost 600 years) shows high impact with abundance of cultivated and synanthropic taxa. The undergoing transition to drier conditions, that affects the last centuries of the Holocene, did not prevent the recovery of arboreal vegetation at the end of the Roman period. Many of the most important historical events, like the Plague of Justinian, the collapse of the Roman order in the Balkans and the coming of the Slavs (2) seems do not impact the pollen assemblage, on the contrary a hiatus in cereal cultivation is probably related to the Black Death. Soon after, in the 16th and 17th century (ca. 500-250 yr BP), the cereal pollen achieves highest values. This can be correlated to the role that Ottoman Macedonia played for the provision of the Ottoman armies and the city of Constantinople, as well as in the international grain trade in the Mediterranean.

Mid-Holocene vegetal landscape evolution in the center of Rome

Laura Sadori¹, Laura Motta², Andrea Brock³, Marco Giardini¹, Fabrizio Marra⁴, Caterina Pepe¹

¹Sapienza university, Roma, Italy. ²University of Michigan, Ann Arbor, USA. ³University of St Andrews, St Andrews, United Kingdom. ⁴INGV, Roma, Italy

Abstract

This work is part of a multi-disciplinary investigation of Rome's Tiber River valley aimed to provide new data on the Holocene landscape evolution. The pre-urban landscape was reconstructed using a combination of deep-trench excavation, coring survey, environmental sampling and paleomagnetic analysis (Marra et al., 2018). Two cores (FB38 and FB40) out of eleven have been selected for pollen analysis on the basis of sediment features in the area known as the Forum Boarium, between the Capitoline Hill and the Palatine Hill, in the heart of the ancient city. Very little is indeed known of the natural history of Rome.

Continuous recover of the sediment was provided using a 3 m long corer with inner diameter of 97 mm. The chronology of the eleven cores was established through 28 AMS radiocarbon dates, 7 of which obtained from FB38 and FB40, in particular 2 of them were performed on pollen concentrated residues. Pollen samples often showed a low to medium pollen content, resulting in time consuming microscopic analyses. The portion of the two cores selected for palynology are probably in chronological order, with one older than the other and partially overlapping.

FB38, the older core, drilled in a wetland, shows the presence of an alder carr dating back at ca. 7000 years BP and probably lasting for few hundred years. The alders are accompanied by mesophilous, montane (oaks, hornbeams, elm, beech), evergreen elements (oaks and ericaceous) and water plants. The alder formation was probably altered by the Tiber river floods carrying floating pine pollen grains from upland regions, as it happened in the Tiber delta (Pepe et al., 2016). The increasing NPP (Non Pollen Palynomorphs) *Glomus* and *Pseudoschizaea* are the evidence of an erosion process which parallels the increase in pine. The pollen record is closed on the top by sterile in pollen sediments of the Archaic period. FB40, the younger core, shows more problems related to pollen presence/conservation, with enhanced amounts of *Pseudoschizaea*, high values of pine and evidence of land use in the top samples, the last of which dated at ca. 5600 years BP and covered by anthropic sediments of the Iron age. The two cores indicate a change from a wetland to an open landscape, probably seasonally dry and wet.

⁶Universidad del Pais Vasco, Bilbao, Spain

Abstract

Geological sequences have been used as the main basis for musical pieces both as inspiration for musicians and as raw materials (geochemical data, stratigraphic logs, cycles and frequencies) for compositions produced by computer programs. Telling our stories of Quaternary changes with music presents an opportunity to reach a wider audience and to integrate art and science. Here we present an example of how to compose music from Quaternary lake sequences and illustrate in a new way the main changes in the Pyrenean landscapes since deglaciation. The creation of this music was undertaken within the framework of the REPLIM project, an INTERREG- POCTEFA – project aimed to create a network of climate change observatories on lakes and wetlands in the Pyrenees. Based on the sediment sequence from Marboré Lake (42°41'44.27"N, 0° 2'24.07"E, 2612 m a.s.l), we have selected lithological, compositional and pollen data (Leunda et al, 2017; Oliva et al., 2018) to represent the main changes in the lake and the region during the last 15000 years. To transform the geological data into musical notes, we have used a similar approach than in previous experiences (Simon et al, 2015) but in this case, notes were assigned to compositional range intervals and the tempos were defined using sediment accumulation rates. Different melodies and instruments were assigned at each data set: TOC and Br/Ti as lake bioproductivity, selected pollen data for vegetation dynamics in the valleys, Si/Ti as sediment influx and Pb/Ti as anthropogenic impact. An electronic version of the Marbore Symphony was created by computer software based on the raw data. The music group O´Carolan (<http://www.ocarolanfolk.com>) transformed the electronic version into a six minutes long acoustic version. The Symphony premiered in the town of Bielsa on December 14th, 2018. The Marboré music project has served to increase citizenship awareness about climate change in the Pyrenees and provided a new tool to better communicate past and future changes in the landscapes.

2A Earth Core: The Hominin Project: an art and science collaboration

Julian Ruddock¹, Henry Lamb²

¹University of Wales Trinity St David, Coleg Ceredigion, Aberystwyth, United Kingdom. ²Department of Geography and Earth Sciences (DGES) Aberystwyth University, Aberystwyth, United Kingdom

Abstract

The exhibition, *2A Earth Core The Hominin Project* at Aberystwyth Arts Centre in 2017, marked the culmination of an art-science project focused on climate change. The collaboration brought together an artist undertaking a practice-based PhD at Aberystwyth University and the Hominin Sites and Paleolakes Drilling Project (HSPDP), an international scientific collaboration researching the relationship between climate and human evolution. This presentation relates the experiences of the collaborative enterprise from the perspectives of the artist and a lead scientist in the research cluster, thereby providing insight from both disciplinary fields. This leads to an examination of the creative strategies that were used in translating the data, images and ideas from the science into exhibition content.

The theoretical background to the project lies in the contrasting opinions that have emerged in recent decades regarding the value of collaboration between the arts and the sciences. Some commentators argue that the fundamental differences between art and science make interdisciplinary practice untenable, while others suggest that many potential benefits are achievable through dialogue and mutual work in areas of shared interest. Here, we examine this potential and offer some newly identified approaches to collaboration within the art-science and climate change discourse.

As background, the presentation includes information on the initial stages of the collaboration. In 2014 the artist traveled with the HSPDP team to the dried lake basin of Chew Bahir, southern Ethiopia, regarded as a significant region for early hominin evolution; the experience of the landscape seen from an artistic perspective is discussed. As observer, the artist was able to gain insight into the field research, which involved drilling nearly 300 m of sediment cores, later shown to record climate change of the last 600,000 years.

The collaborative relationship enabled a number of works to be developed, bringing together the knowledge and insight of both the artist and the science team. The exhibition contained two principal works: *2A (2017)* is a film in which hundreds of high-resolution images of the sediment cores were sequenced into a 24-hour film. *2B (2017)* is an installation made of mud from the bottom of the drill hole which, when re-hydrated and then allowed to dry, created an experimental version of the ancient playa lake surface.

The presentation concludes with a commentary on collaboration across art and science, and on the rationale for the curation of the exhibition as a hybrid space, an innovative combination of material that included art, documentary interviews with science researchers and science artifacts. In offering fresh approaches to collaboration, the presentation argues for the crucial role that art can play in enabling audiences to encounter larger narratives of humanity's relationship with a changing climate

10Be dating of Holocene moraines in the Himalayan-Tibetan orogen: noise versus signal

Sourav Saha^{1,2}, Lewis A. Owen³, Marc Caffee⁴

¹University of California, Los Angeles, Los Angeles, USA. ²Northern Kentucky University, New Port, USA. ³University of Cincinnati, Cincinnati, USA. ⁴Purdue University, West Lafayette, USA

Abstract

Cosmogenic ¹⁰Be dating has been used to date young moraines in the eight glaciated valleys of the northwestern and Central Himalaya. Following the north-south (Low to high) precipitation gradient the study areas include: Stok, Lato, Karzok, and Parkachik valleys in the Zaskar range; Hamtah and Kulti valleys in the Lahul Himalaya; Bhagirathi valley in the Garhwal Himalaya; and Lhotse Nup valley in the Khumbu Himal. Also, four hundred and sixty published ¹⁰Be ages are compiled to reconstruct regional stages in the 73 glaciated valleys spread throughout the Himalaya, Tibet, Pamir, and Tian Shan. Whenever possible, additional dating methods, for example, radiocarbon, are used to date moraines independently. We also measured the contribution of prior exposures (i.e., inheritance) to cosmic rays by targeting independent, historically dated moraines. To further detect climate signals from the geological spread, regional Holocene glacier chronostratigraphies throughout the orogen are developed by grouping glaciated regions with comparable climatic characteristics. Three major climatic groups (or five climatic regions) are defined across the orogen using Cluster Analysis (CA) and Principal Component Analysis (PCA). Local glacial stages in each climatic group are then compiled and analyzed for regional stage reconstruction using a combination of the radial plotter, probability density function, and Student's t-test. Extents of Holocene glacier advances are also reconstructed using detailed geomorphic mapping and estimating equilibrium-line altitudes (ELAs). Glacier sensitivities are assessed using modern glacier hypsometries, climate sensitivity (c), and lag time (τ). The net changes in temperature (ΔT) between periods of reconstructed regional glacier advances are also reconstructed using glacial length change (dt), c , τ , and a linear inverse glacier flow model in 66 glaciated valleys across the different climatic regions throughout the orogen. Our results show a high degree of uncertainty of cosmogenic dating of moraines boulders of less than 2 ka old. However, the issue of high-degree of ¹⁰Be age scattering due to prior exposure is more pronounced in cold-based less erosive (<0.01 mm/a) high-altitude glaciated settings relative to erosive (≥ 2 ka) temperate glaciated catchments. Our regional analysis also indicates variable glacier responses throughout the Holocene, especially in the mid-latitude westerlies dominated northwestern regions, in the arid-semiarid northeastern region, and the southern monsoonal wet-warm regions. Overall, the Himalayan-Tibetan orogen may experience at least one late glacial (~15.3–11.8 ka) and five Himalayan-Tibetan Holocene glacial stages (HTHS) at ~11.5–9.5, ~8.8–7.7, ~7.0–3.2, ~2.3–1.0, and <1 ka.

Abstract

Recent studies of High Mountain Asian glaciers using satellite images revealed large regional mass balance variability over the last two decades mainly attributed to distinct climate conditions. This complex pattern makes it difficult to quantify the impacts of anthropogenic forcings on this trend. Two major issues for such quantification are related to a limited knowledge of i) long term glacier changes, ii) the natural forcings effects on glacier evolution. Mera debris-free Glacier (27.7°N, 86.9°E, 5.1 km²) is one of the rare monitored glaciers in Himalaya (Dudh Koshi basin, Everest region, central Himalaya) making possible a full understanding of processes driving glacier mass change. Moreover the numerous and well preserved moraines downstream offer a unique opportunity to document Mera mass balance changes in the past. In 2014 and 2017 twenty boulders were sampled on the four largest moraines close to the front position and dated using cosmogenic method. ¹⁰Be ages span the Holocene. Two fresh moraines close to the current front position were formed during the last millennium while the two lowest ones were formed during the late and early Holocene respectively. Such pattern reveals a glacier history similar to glacier in central Himalaya and in regions, such as the European Alps, out of monsoon climate conditions. We then analyzed possible climate conditions responsible for such changes by applying a glaciological model calibrated on current glaciological observations. Based on this analysis we explored the possible influence of external and internal climate drivers on such chronology.

Investigating asynchronous retreat of glaciers in the Khumbu region, Nepal.

Josephine Hornsey¹, Ann Rowan¹, Stephen Livingstone¹, Duncan Quincey², Derek Fabel³, David Rippin⁴, Martin Kirkbride⁵

¹University of Sheffield, Sheffield, United Kingdom. ²University of Leeds, Leeds, United Kingdom. ³Scottish Universities Environmental Research Centre (SUERC), East Kilbride, United Kingdom. ⁴University of York, York, United Kingdom. ⁵University of Dundee, Dundee, United Kingdom

Abstract

Himalayan glaciers comprise the most extensive body of ice outside of the Polar Regions, with their meltwaters sourcing some of the largest river systems in Central Asia (Bolch, et al., 2012). They have experienced negative mass balance since their last known maximum during the regional Little Ice Age (Rowan, 2017). Despite glaciers being an important indicator for regional climate change, the inaccessibility of Himalayan glaciers has resulted in a relative dearth of data to describe their state, both current and past. In particular, assessments of past change between modelled and measured data differ due to insufficient observations and process understanding (Hock, et al., 2017), making the prediction of glacier evolution uncertain. Investigating glacier response to past climate change through examining relict landforms offers additional validation for their long-term behaviour, advancing our understanding on what may control their response to future climate change so that predictions of meltwater input into local water resources can be more robustly assessed.

Here, we present a glacial geomorphological map of the Khumbu region, Nepal, which facilitates much greater insight into the Holocene glacial history of the Khumbu Glacier and its tributaries. The mapping was completed using SPOT7 Imagery, the NASA High Mountain Asia Digital Elevation dataset, and fieldwork. Field mapping was supported by Schmidt Hammer measurements taken from *in situ* boulders on moraine crests. We mapped Holocene moraine systems surrounding the Khumbu Glacier and two of its tributaries: the Changri Nup and Lobuche Glaciers. The Khumbu and Lobuche Glaciers are both characterised by large proximal lateral and terminal moraines surrounded by smaller, superimposed moraines. The Schmidt Hammer values collected from boulders reveal similar exposure between these two glaciers. Changri Nup Glacier has fewer moraines, with no evidence of reworking, and lower Schmidt Hammer values. There are also smaller glaciers with a series nested moraines indicative of a stepped retreat. By combining the results of the mapping and Schmidt Hammer with analysis of glacier hypsometry, we explore controls governing the pace and style of glacier retreat.

Quantifying post-Little Ice Age mass change in the Himalaya

Ethan Lee¹, Duncan Quincey¹, Jonathan Carrivick¹, Simon Cook²

¹University of Leeds, Leeds, United Kingdom. ²University of Dundee, Dundee, United Kingdom

Abstract

Himalayan glaciers store the greatest volume of ice beyond the Polar ice sheets, but their response to Holocene climate change is not very well documented in the literature. Recent work has focussed on modern glacier dynamics and on reconstructing Last Glacial Maximum extents, while glacier extent during the Little Ice Age (LIA) is relatively poorly understood. The limited research undertaken so far on LIA Himalayan glacier extent has demonstrated asynchronous retreat due to local topographic controls, and suggests that the LIA glacial advancement in this region peaked around 1500 AD with widespread retreat since 1850 AD. Here, we present an inventory of LIA extents across the entire Himalayan region, and provide a first-order estimate of the mass loss since the LIA. We take the Randolph Glacier Inventory (RGI) version 6.0 to represent present day glacial extents and use these data overlaid on recently released High Mountain Asia (HMA) 8m Digital Elevation Models (DEM) and remotely sensed images to digitise interpreted LIA glacial extents. By interpolating an estimated LIA glacier surface we can then quantify areal and volumetric changes between the two epochs. In a final step, the results of their volumetric change are used to quantify the contribution of Himalayan glaciers to sea-level rise (SLR) since the LIA, and to characterise the regional variability in mass loss across the range, taking into consideration possible topographic and climatological controls.

Geochemical provenance of a supraglacial debris cover in relation to changing tributary discharges of a Himalayan compound glacier

Martin Kirkbride¹, Sophie Sherriff¹, Ann Rowan², David Egholm³, Duncan Quincey⁴, Evan Miles⁴

¹University of Dundee, Dundee, United Kingdom. ²University of Sheffield, Sheffield, United Kingdom. ³Aarhus University, Aarhus, Denmark. ⁴University of Leeds, Leeds, United Kingdom

Abstract

The century-scale mass balance of glaciers in the monsoonal Himalaya is related to the northward penetration of the summer monsoon. We test the hypothesis that large glaciers straddling climatic gradients comprise tributary catchments whose mass balances are asynchronous, by studying spatial variation in the geochemical composition of the Khumbu Glacier debris cover. This non-surgingly glacier comprises multiple compound sources forming a debris-covered tongue terminating 11 km south of the Himalayan Divide. 21 samples of supraglacial sediment <2000 μm from six source tributaries achieve an unambiguous statistical differentiation using 11 major elements, reflecting geological differences between catchments. In contrast the <250 μm fraction shows poor source area differentiation. The coarser fraction allows the provenance of debris covering the glacier tongue to be interpreted using the FR2000 unmixing model, which partitions a 'mixed' debris sample according to the proportion of debris from each source tributary. 24 debris cover samples were collected from transects in the upper, middle and lower part of the glacier tongue. In the upper tongue, debris from the western Changri Valley tributary increases downstream at the expense of debris from the Western Cwm (Himalayan Divide) and eastern (Nuptse) sources. In the lower tongue there is a marked increase towards the terminus in debris from the Western Cwm/Divide sources. We compare these patterns with a model of supraglacial debris age, derived from an updated version of the iSOSIA ice flow model applied to the Khumbu Glacier by Rowan et al. (2015). The model tracks debris as discrete particles within the ice from their points of entrainment. At the whole-glacier scale, supraglacial debris derived from the Changri valley has taken >900 years to reach the terminus; in contrast, debris from the Western Cwm has had a transport time of <700 years. Proxy evidence indicates a weakening of the summer monsoon in the early Little Ice Age c. 600 years ago, therefore the Khumbu Glacier debris cover retains an archive of debris sourced throughout the LIA monsoon transition. This may explain the reduction over time of debris from the Himalayan Divide and the increase in debris from lateral tributaries: monsoon precipitation was less able to penetrate to the higher catchments of Khumbu glacier, favouring a relative mass balance increase in eastern and western tributaries. Negative twentieth-century balances across the glacier have caused tributaries to separate and Divide sources to dominate, though stagnation of the tongue is now causing debris to accumulate kilometres upstream of the terminus. The general conclusion is that the climatic response of large compound valley glaciers is complex due to spatial variation in both forcing and response times between tributaries.

O-1146

Holocene Glacial Fluctuations in the Himalaya: Results and Limitations

Milap Sharma

Jawaharlal Nehru University , New Delhi, India

Abstract

The climate of Indian sub-continent is the product of the Himalaya. The huge expanse from the East to West, and South to North, not just works as a water-tower but also conditions the sub-continental climate in a variety of ways. The varied topographic configurations that exist has undergone varied and complex climate-landscape interactions over the geological past. Many phases of glacials and inter-glacial episodes are engraved in the landforms that dominate the present day landscape. Many details of the previous glacial and related processes have been obliterated in the dynamic environment. Although relationships and chronologies have been established between glacials and the ISM and the Mediterranean Westerlies, yet little is understood of the relative role of the Polar Streams and the N-Easterlies in impacting the weather and the glacial expansions within such a huge expanse.

Available chronologies define the general trends in Holocene glacier oscillations that the largest advance during early Holocene in the monsoon influenced Himalayan region. This advance is represented by impressive suites of sharp-crested moraines, dated by the numerous researchers, to between ~11.5 and 8.0 ka. The mid-Holocene moraines have been dated in several regions, with the most extensive in the semi-arid Western part. Five glacial advances have been identified (semi-arid western Himalayan-Tibetan stages for the Holocene in the semi-arid western end of the Himalayan-Tibetan orogen. On the other hand, Murari et al (2014) have reported eleven monsoonal Himalayan-Tibetan stages during the Holocene for the monsoon-influenced regions. Correlation of stages also suggest that there are strong correlations with periods of enhanced monsoonal influence in the Himalaya and Tibet. In recent study, Saha et al. (2018) also recognized seven Himalayan Holocene regional glacial stages for the northwestern end of the Himalayan-Tibetan orogeny i.e. There are immaculately preserved mid and late Holocene relict landforms in the Chenab, Beas and Ravi Basins of the Western Himalaya, constrained within 8.1 ka to 1.0 ka. However, the drumlin field indicate a gradual waning between 6.0 ka and 4.0 ka, and accelerated retreat until ~1.0 ka. The ^{14}C ages further suggest that the period between ~ 12th to 18th Century AD was relatively warmer than today, allowing settled agriculture and related activities in the glacier forefields. There is no denying that a gradual retreat of glaciers began in the 17th Century AD that increased many folds after the mid 19th Century. However, a robust relationships needs to be built of the upland-foreland basins with reference to waxing and waning of glaciers of the Himalaya and the adjoining mountains to understand relative roles of different climatic pattern that control the sub-continent.

Abstract

Reconstructions of ice growth and decay over the last 100-kyr glacial cycle on the South Island New Zealand provide important temperature and moisture proxies at a latitude where terrestrial records are otherwise limited. The maritime climatic setting of the glaciers also allows inference on past Southern Ocean conditions. As such, there has been significant focus on reconstructing ice-margin dynamics of glaciers draining the Southern Alps. Luminescence chronologies provide a much-needed perspective to clarify inferences from extensive CRN chronologies. Much insight has been gained from detailed chronologies based on CRN-dating boulders from moraine sequences. These reconstructions have been key to address important questions regarding temporal and spatial variations in glacial growth and decay across New Zealand and relationships with hemispheric and inter-hemispheric climate events and drivers. However geomorphic and CRN-derived glacial reconstructions are limited by the preservation of glacial moraines and landforms or scoured bedrock and can miss buried stratigraphy and evidence for less extensive ice advances. Here we present complimentary, luminescence-dated stratigraphic evidence for ice dynamics in the Rangitata and Wanaka/Hawea valleys of central South Island. While largely consistent with geomorphic reconstructions, age control from stratigraphic sequences and lithofacies analyses provide more detail on older advances and the styles of ice advance. We discuss chrono-stratigraphic results of glacial advances in the study catchments in context of regional glacial records, and link glacier mass balance inferences to changing climatic conditions during MIS 4-3.

Glacial chronology of the Bale Mountains, Southern Ethiopia

Alexander Raphael Groos¹, Naki Akçar², Georg Miehe³, Serdar Yesilyurt², Christof Vockenhuber⁴, Heinz Veit¹

¹Institute of Geography, University of Bern, Bern, Switzerland. ²Institute of Geological Sciences, University of Bern, Bern, Switzerland. ³Department of Geography, University of Marburg, Marburg, Germany. ⁴Laboratory of Ion Beam Physics, Zürich, Switzerland

Abstract

The Bale Mountains in the Southern Ethiopian Highlands represent Africa's largest alpine environment. Ice caps and valley glaciers are absent nowadays, but glacial landscape features and periglacial phenomena indicate different phases of extensive glacial and periglacial activity in the region during the Pleistocene. Recent archaeological findings from the area provide evidence for the oldest high-elevation site of human activity worldwide. To reconstruct the climate and environment of these Middle Stone Age hunter-gatherers at that time, the extent and timing of different Quaternary glaciations in the Bale Mountains was determined based on comprehensive glacial geomorphological mapping and ³⁶Cl surface exposure dating of 75 moraine boulders from the western, northern and eastern valleys as well as from the central Sanetti Plateau. The established glacial chronology reveals that the local Last Glacial Maximum (LGM) occurred during MIS 3 and therefore prior to the global LGM. Back then, glaciers covered up to 265 km² of the mountain range and were a potential fresh water source for early hunter-gatherers. Intensively weathered boulders and moraines outside the local LGM ice extent probably originate from MIS 4 and 6 glaciations. However, the large spread of surface exposure ages from the oldest features prevents a precise determination. Exposure ages of the youngest moraines in the valleys suggest that the glaciers almost reached the extent of the local LGM ice extent again during MIS 2 (at ~17-18 ka). Deglaciation in the region started at the end of the Late Pleistocene (at ~14-15 ka).

Climatic and environmental history of northern Chiloé during MIS 3

Gabriel Gómez-Szmulewicz¹, Ana María Abarzúa², Juan Luis García³, Carolina Villagrán⁴

¹Magister en Paleontología, Instituto de Ciencias de la Tierra, Universidad Austral de Chile, Valdivia, Chile. ²Instituto de Ciencias de la Tierra, Universidad Austral de Chile, Valdivia, Chile. ³Instituto de Geografía, Facultad de Historia, Geografía y Ciencia Política, Pontificia Universidad Católica de Chile, Santiago, Chile. ⁴Laboratorio de Palinología, Facultad de Ciencias, Universidad de Chile, Santiago, Chile

Abstract

Southern South America has remarkable morphosedimentary features for the development of Quaternary paleoclimate and paleoenvironmental studies. The finding of several sites with fossil wood of conifers in the Chiloé Archipelago is of great relevance because of the few non-infinite radiocarbon dates available, that give to these deposits an age range between 43 – 49 kyr BP (MIS 3). In the context of the last glaciation, the development of primary forests appears as evidence of warmer interstadial conditions. This study seeks to determine the environmental and climatic conditions that prevailed in northern Chiloé during MIS 3. A period in which Northern Hemisphere records have shown relatively warmer conditions, while the chronology of glacial advances in southern Patagonia indicate a local LGM. We present the stratigraphic analysis of five sites on the eastern and northern coast of Chiloé, along with a chronostratigraphic correlation and geomorphological description.

To carry out this study, we performed first a photointerpretation of northernmost Chiloé. Following, we visited and described the sites, four of which are on the eastern side of the local LGM boundary, while the other is located on the western margin (fig 1). Finally, we made the drawing and interpretations of stratigraphic columns, together with geomorphological mapping. The chronostratigraphic correlation was based on ¹⁴C date of wood contained in peat layers and OSL dates of sand lenses contained in till or fluvio-glacial material.

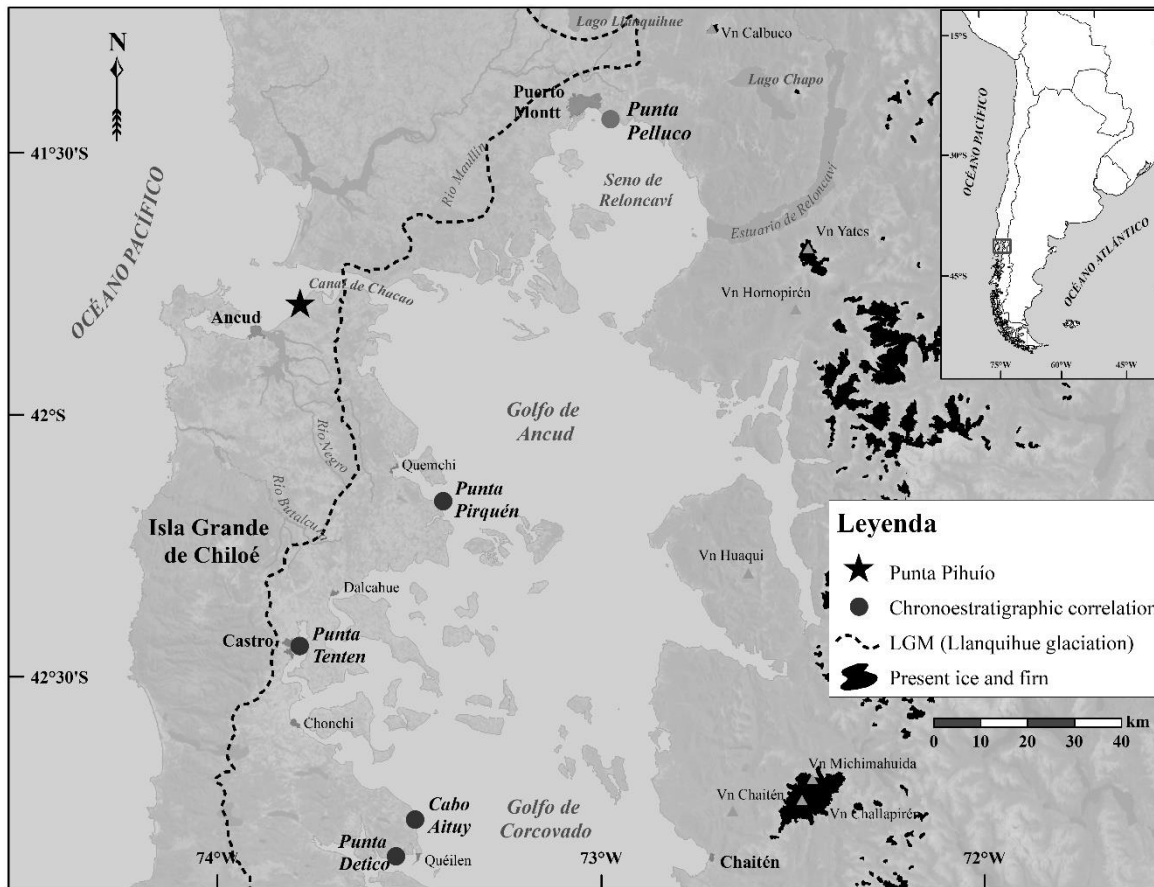

Figure 1. Map of

the study area, showing the sites of stratigraphic descriptions and correlations

The stratigraphic evidence shows in general at least two peats layer with trunks that correspond to a forest paleosol. Underlying the basal peat is possible to observe a till, whereas fluvioglacial material overlies the upper one. These deposits provide evidence to support the ice advance before and after the interstadial MIS 3. Additionally, among the peat strata we observed laminated silts with ripple marks, grey and brown silts, sand lenses and intercalations of peats without trunks and grey silt. These features indicate environmental fluctuations between phases of vegetation development and shallow flooded events linked to the advances and retreats of the glacial front.

The geomorphology shows a line of discontinuous moraine crests and ice contact margins that mark the limit of the local LGM (MIS 2). Punta Pihuío corresponds to an active marine cliff that appears in the western edge of a great fluvioglacial plain that extends from the limit of the LGM until bahía Ancud. Two large channels of glacial drainage dissect the fluvioglacial plain, which have at least one terrace directly related to deglaciation processes.

Our stratigraphic and geomorphological results provide evidence to better understanding the climatic and environmental features during MIS 3 as a prelude for LGM (MIS 2) in northern Chiloé.

Acknowledgments: Fondecyt #1161110

Abstract

The growing application of different dating methods has brought to light two issues: (i) the most extensive glacier advance recorded in multiple mountain environments slightly pre-dates the global Last Glacial Maximum and lies within the Marine Isotope Stage 3 or MIS 3; and (ii) the numerous cases of timing differences between observed glacial advances might be caused by limitations related to the dating techniques without having paleoclimate significance. In this regard, the frequent use of a single technique to date numerically a given glacial sequence makes it difficult to address to what extent age differences can be an artifact related to biased numerical age results or a paleoclimate signature. Here we focus on the study of Pleistocene glacial advances in the central Cantabrian Mountains of the Iberian Peninsula, where numerous chronologies based on radiocarbon and Optically Stimulated Luminescence suggest a pre-LGM advance of glaciers to their maximum front positions (Serrano et al., 2017 and references therein). A preliminary study developed in the Porma valley (central Cantabrian Mountains) based on the ¹⁰Be surface exposure dating of 75 boulders from moraines, erratics and rock glaciers points to a complex exposure history of glacial advances and retreats spanning the Last Glacial Cycle, where the age of the local glacial maximum advance was older than MIS 5d (Stage I: ~110 ka) (Rodríguez-Rodríguez et al., 2016). Here we present a new set of 43 numerical ages based on three dating techniques —¹⁰Be surface exposure dating; radiocarbon; and OSL— that complement the chronology of Pleistocene glacial advances in the Porma valley. Results complement previous chronologies in the area, supporting an important glacial advance during MIS 3 (Stage IIa: ~56 ka) that culminated with the LGM advance (Stage IIb: ~33–24 ka) of MIS 2 in response to increased rainfall and solar insolation minima. Glacier fronts reached elevations as low as 1130 m a.s.l. possibly without overriding evidence related to the previous Pleistocene glacial maximum extent. Glacier recession in the Cantabrian Mountains started at 21–20 ka ago, after the global LGM. We suggest that the recession was initiated by increased insolation followed by hyper-cool and dry conditions during Heinrich Stadial 1 in response to meltwater discharges in the North Atlantic.

Climate and palaeoenvironmental changes in Southern and Central Poland in Interpleniglacial (MIS 3)

Lucyna Wachecka-Kotkowska¹, Leszek Starkel², Danuta J. Michczyńska³, Adam Michczyński³, Piotr Gębica⁴, Dariusz Krzyszkowski⁵, Dariusz Wieczorek⁶, Małgorzata Ludwikowska-Kędzia⁷, Józef Superson⁸, Danuta Dzeduszyńska¹
¹University of Lodz, Department of Geomorphology and Palaeogeography, Łódź, Poland. ²Polish Academy of Sciences, Stanisław Leszczycki Institute of Geography and Spatial Organization, Kraków, Poland. ³Silesian University of Technology, Institute of Physics - CSE, Division of Radioisotopes - GADAM Centre, Gliwice, Poland. ⁴University of Rzeszów, Institute of Archaeology, Rzeszów, Poland. ⁵University of Wrocław, Institute of Geography and Regional Development, Wrocław, Poland. ⁶Polish Geological Institute - National Research Institute, Kielce, Poland. ⁷Jan Kochanowski University in Kielce, Institute of Geography, Kielce, Poland. ⁸Maria Curie Skłodowska University in Lublin, Department of Geomorphology, Lublin, Poland

Abstract

Interpleniglacial deposits (MIS 3) separate two glacial periods (MIS 4 and MIS 2). In the European Lowlands MIS 3 mostly represents alluvia. Until recently, in Western and Central Europe, from 2 to 5 clear warmings with forest flora or tundra-forest (Oerel, Moershoofd, Glinde, Hengelo and Denekamp) were separated. There were also found horizons with periglacial structures that formed during cooling periods. Also erosive breaks have been documented (2-3 series inserted).

The development of the isotope curve of oxygen in the NGRIP ice core (Rasmussen et al. 2014) indicated the existence of more warmings and coolings in MIS 3, ca. 10-12, in addition quite quickly following each other. A large convergence with the NGRIP curve has been demonstrated by studies on changes in fluvial environment conditions in southern Poland - Oświęcim Basin, Sandomierz Basin and Carpathians (Gębica et al. 2015; Starkel et al. 2015, 2017).

At present, the studies have been extended to the areas of Central Poland Lowlands and Uplands in Southern Poland. Radiocarbon and luminescence data originating mainly from river sediments were used for analyzes. Radiocarbon data were calibrated (OxCal - Bronk Ramsey 2009; IntCal13 - Reimer et al. 2013). The probability density functions of radiocarbon dates sets supplemented with palynological information and luminescence dates distributions are presented against the background of the NGRIP curve.

In the analyzed areas, the lack of radiocarbon data from the time corresponding to LGM is marked. This confirms the harshness of climatic conditions on the closer and further foreland of the ice sheet. There was also a record of a sharp transition towards periglacial and continental conditions ca. 33-30 ka BP (end of MIS 3). This is synchronous with the beginning of the expansion of the Scandinavian ice sheet. Part of the research areas is also expressed by the accumulation of loess on river terraces. In small valleys, or closed minor depressions, only 2-3 "climatic" phases were found, which may be related to local morpho- and topographic conditions. In larger valleys in Southern and Central Poland there is a greater number of climatic changes. The issue of the speed of changes in the plant cover in the wake of episodes of warming or cooling remains open - there are no sites with long palynological records from the research area.

Abstract

Megafans on the southern side of the Alps are known to respond to climatically-driven fluctuations of the sedimentary input from the Alpine range, especially in relation to major environmental changes related to Quaternary glaciations (Fontana et al., 2014). Aggradation/incision trends of these alluvial systems mirror the development and downwasting of valley glaciers, thus providing reliable proxy information on upland areas, which may be often scant, disjointed and difficult to date (Rossato and Mozzi, 2016; Rossato et al., 2018).

In our investigation, we could integrate OSL and radiocarbon dating in the juxtaposed megafans of the Brenta and Piave rivers, through morpho-stratigraphic correlation and sediment provenance analysis. The catchments of these rivers include the highest portion of the Dolomites mountains, with main peaks exceeding 3000 m asl and extensive plateaus above 2500 m asl. We correlated the piedmont megafan sector of the Montebelluna Piave megafan (MPM) with the terminal moraines of the LGM Piave glacier ('Quero amphitheater') and the lower Alpine valley sector.

Results show that the proximal sector of the MPM and related Piave valley alluvial fill were continuously aggrading in the 37–27 ka BP time-frame, well before the outermost positioning of the LGM glacier fronts at around 26 ka cal BP. This was accompanied by increased sediment production and fan aggradation in the unglaciated Prealpine tributary catchments, similarly to what observed in alluvial fans located to the east in the Friulian piedmont plain (Monegato et al., 2010). MPM alluvial succession shows no significant variation in lithofacies characteristics and assemblage, nor the presence of major unconformities, at the transition between MIS 3 and 2. Only sand petrography highlights a change in the drainage system just before 27 ka cal BP: a major tributary of the Piave River, the Cismon River, moved towards the Brenta catchment, probably due to the constant growth of the Piave glacier at the junction between these two systems.

We conclude that valley glaciers in the upper Piave and Cismon catchments probably started to develop in the late MIS 3. Such environmental change could be related to the climatic deterioration recognized in the pollen sequence of nearby Fimon Lake around 38.7 ± 0.5 ka (Pini et al., 2010) and correlated with Heinrich Event 4.

Abstract

Ravine slopes at the recently discovered Nesselstalgraben site (47°39.4'N, 13°02.8'E, 555-595 m a.s.l.) in south-eastern Germany provide a unique last glacial sediment record for the Northern Calcareous Alps. The top of the investigated profile is overlain by fluvio-glacial gravels and tills of the Last Glacial Maximum (LGM), while the base is formed by a diamict. The fine-grained section with lacustrine-palustrine deposits in between was dated with 29 radiocarbon analyses on wood, monocotyledon and bryophyte remains. The resulting age model provides extrapolated ages of less than 29.6 ka cal BP for the fluvio-glacial gravels and till overlaying the fine-grained deposits, and more than 59.0 ka cal BP for the diamict below. Thus the lacustrine-palustrine layers cover the entire Marine Isotope Stage (MIS) 3. The MIS 3 deposits have a highly variable lithology consisting of laminated or non-stratified carbonate silts, thin sand or gravel layers, organic-rich silts, and compressed peat. In 2016, 40 overlapping sections were sampled from the outcrops covering the entire MIS 3. These sections were scanned with an X-ray-fluorescence (XRF) core scanner at 2 mm resolution and compiled to a continuous 21 m long sediment profile based on marker layers and XRF data. Thereafter, sediment cores were subsampled at 2 cm intervals. Samples were used for pollen, element contents (C, N, S), isotope geochemistry, and grain-size analyses. Multivariate analyses of XRF data clearly separate Ca from Al, Fe, K, Mn, Si, and Ti. Carbonate contents, represented by Ca and total inorganic carbon, reach maxima in repeatedly occurring carbonate silt layers. The detrital origin of these layers is confirmed by scanning electron microscopy and energy-dispersive X-ray spectroscopy. They consist of rock flour that accumulated due to intense physical weathering of Mesozoic catchment carbonates. The high-frequency proxy variations from the Nesselstalgraben site resemble Greenland interstadial-stadial variability. We hypothesize that the carbonate silts were deposited during cold stadial periods or immediately thereafter. In contrast, organic matter and elements more resistant to chemical weathering accumulated during warmer interstadial climate conditions. Arboreal pollen also peak during several Greenland interstadials, while stadials are dominated by Poaceae pollen. Maxima of arboreal and non-arboreal pollen are, however, not always in total accordance with peaks of elements such as Ca and Si, respectively. Delays and peak shifts between geochemical and pollen records are discussed in terms of differential response times of depositional and biological systems to rapid climatic changes and in terms of the duration and intensity of the interstadials.

Beyond examples: how can knowledge be used to understand social vulnerability and the future of climate change

Isabel Rivera-Collazo

University of California San Diego, La Jolla, USA. Scripps Institution of Oceanography, UCSD, La Jolla, USA. Center for Applied Tropical Ecology and Conservation, University of Puerto Rico, Rio Piedras, Puerto Rico

Abstract

Facing climate change, Science is reaching into all its ingenuity in the search for solutions. One of the most wicked problems we are facing is the impact that climate change will have over human societies, and how can we understand it and prepare for it. Tropical zones – home to over 40% of the world’s population – are particularly at risk as they bear the burden of severe changes in atmospheric circulation, including record-breaking hurricanes; shifts in ecosystems and biotic species distribution; and drowning of small islands due to sea level rise. Upon facing dire prospects, archaeologists have clamored that, given their deep-time perspective, our discipline can make significant contributions to the understanding of both social vulnerability and the process of climate change. This keynote contribution presents an example of how that can be done. Using historical socioecodynamics, the presentation identifies lessons from the past to explore the social vulnerability of maritime or coastal communities on a tropical island – Puerto Rico –, and moves one step further by using that knowledge for on-the-ground engagement towards community resilience to future change. Focusing on the role of traditional ecological knowledge, the presentation considers what is known of the impact of climate change at the end of the Pleistocene and the beginning of the Holocene; the process of decision-making to short- and long-term catastrophic events in pre-Hispanic communities on the island; and the historic evidence of adaptation to change in the early 20th Century. The knowledge recovered from these three examples is currently being applied to tackle social vulnerability and community response to expected climate impacts to a Puerto Rican coastal community. While it is insightful to identify and study individual snapshots of information correlating particular climate events with the social response to them, this application demonstrates how a long-term, deep-time perspective can move knowledge one step further, towards application. Societies have lived with the dynamic nature of coastal environments for millennia. Science can learn from the past, not only to identify isolated events, but also to recover lost knowledge and tie discourses of climate change impacts to local and personal narratives, making it useful for impacted communities in the present and their preparedness for the future.

O-1156

Harmonizing marine and terrestrial palaeoclimate archives to reconstruct hurricane activity in the Caribbean

Michael Burn, Suzanne Palmer
The University of the West Indies, Kingston, Jamaica

Abstract

Atlantic hurricanes are a threat to the Small Island Developing States of the Caribbean primarily because of their potentially devastating impacts on homes and infrastructure, agricultural productivity and food security. However, tropical cyclones also contribute significantly to annual rainfall across the region by replenishing water reserves and buffering national economies from the threat of drought. This 'double-edged sword' that characterises the positive and negative impacts of hurricanes, was also experienced by both pre-Colonial and Colonial inhabitants of the region and is likely to have influenced settlement decisions and patterns. Given that the impact of 21st Century anthropogenic climate change on tropical cyclones is poorly understood, it is first necessary to establish a baseline of natural variability for the Caribbean Region. To this end, we present a novel statistical approach to the reconstruction of hurricane activity in Jamaica for the last 1000 years. We link land and sea by adopting cross-correlation techniques to harmonize the chronologies of a coral-based sea-surface temperature record from the Western Caribbean and a mangrove-lagoon sediment record of lake-level change from Jamaica. Subsequent comparisons between the Jamaican lake-level record, Caribbean-wide SST reconstructions, and instrumental records of hurricane activity since 1850 CE, reveal statistically significant relationships between these variables for the period 1773-2008 CE. Given these relationships, we developed a sediment-based extended hurricane activity index (EHA), which has been extended back to the beginning of the last millennium. The record suggests that hurricane activity exhibited an increased amplitude of variability on interdecadal and multidecadal timescales during periods of low natural radiative forcing compared with a more subdued variability during the warmer mean climate states of the last millennium. Comparison of the EHA index with previously-published Colonial records of storm counts and tropical cyclone-induced Spanish shipwrecks for the period 1495 – 1825 CE, suggest that periods of enhanced hurricane activity exerted significant pressure on the Spanish Colonial fleet. A gradual increase in Atlantic hurricane activity during the industrial period (ca. 1870-present) is probably a response to a combination of natural and human-induced forcing factors. Based on the EHA index, it is clear that contemporary hurricane activity has not yet exceeded its longer-term natural variability when compared with the last 1000 years.

Holocene relative sea level and vegetation changes: implications for human occupation of the north coast of Isla Navarino, southernmost Patagonia.

Eileen Tisdall¹, James Blakie¹, Claudia Mansilla², Robert McCulloch³, Flavia Morello⁴, Ricardo de Pol-Holz², Manuel San Román⁴, Jimena Torres⁴

¹University of Stirling, Stirling, United Kingdom. ²Centro de Investigaciones Gaia Antártica (CIGA), Universidad de Magallanes, Punta Arenas, Chile. ³Centro de Investigación en Ecosistemas de la Patagonia, Coyhaique, Chile. ⁴Instituto de la Patagonia, Universidad de Magallanes, Punta Arenas, Chile

Abstract

Human interactions with the coastal environment of southern Patagonia are strongly evidenced by extensive shell-midden deposits. However, evidence for sites of early Holocene occupation have yet to be found and our understanding of the nature and timing of coastal environmental change is limited. We present a new Late glacial-Holocene palaeoenvironmental record from the north-eastern coast of Isla Navarino (54°55'S, 67°2'W) on the Canal Beagle, southernmost Patagonia. The record was sampled from a mire near Caleta Eugenia located within the evergreen southern beech (*Nothofagus*) forest, pollen and spore analysis suggest a high degree of variability in the woodland cover along the coast driven by changes in effective moisture. AMS radiocarbon dating supplemented by the application of tephrochronology including the geochemical fingerprinting of three cryptotephra layers provides robust age constraint. The Cta Eugenia record commences at c.15.9 ka. The sequence of vegetation changes between c. 15.9 and 8.1 ka reflect changes in temperature and humidity after the early expansion of the southern beech forest, probably reflecting the site's proximity to southern beech refugia located in the south-western area of Tierra del Fuego. We argue that the periods of increased moisture and aridity at Cta Eugenia closely reflect the extent to which the southern westerly winds (SWWs) shifted polewards during the early to mid-Holocene before migrating towards their present latitudinal focus during the late Holocene. The Cta Eugenia site was rapidly inundated by a rise in relative sea level at c. 8.1 ka. The sediment record shows the very abrupt deposition of marine sediments with no evidence for a gradual transition from terrestrial to marine conditions. The timing and very rapid nature of the mid-Holocene marine incursion has important implications for understanding the spatial and temporal distribution of archaeological sites of early human occupation along the northern coast of Isla Navarino. The oldest site thus far identified is dated to c. 6.9 ka which is consistent with the peak of the mid-Holocene marine incursion. Later Holocene sites are found along the emergent shorelines that provided ideal locations for occupation in the coastal zone. Following the emergence of the site after c. 6.8 ka moderate to strong effective moisture levels dominated during the early Holocene until c. 6.6 ka, followed by a sustained period (c. 6.6–3.9 ka) of drier climatic conditions. After c. 3.9 ka an expansion of the forest suggests a return to more humid conditions during the late Holocene. The vegetation records indicate a period of relative climatic stability during phases of human occupation along the coastal zone (c. 6.6–3.9 ka). It is likely that early Holocene sites of occupation that predate the marine incursion have been submerged.

Detecting primary climate drivers of shoreline change along Southeast Queensland, Australia using historical Landsat imagery

Joshua Kelly^{1,2}, Sarah McSweeney³, Jamie Shulmeister⁴, Allen Gontz¹

¹San Diego State University, San Diego, USA. ²Scripps Institution of Oceanography, La Jolla, USA. ³The University of Melbourne, Parkville, Australia. ⁴The University of Queensland, St Lucia, Australia

Abstract

Understanding of the teleconnection between global climate and regional shoreline change in southeast Queensland, Australia has been poorly understood due to a lack of historical shoreline position data. Previous attempts at relating shoreline change to variability in the El Niño-Southern Oscillation (ENSO) cycle relied on datasets that were limited in either their spatial coverage or temporal resolution (i.e. local beach profiling and infrequent aerial photography acquisition). We have attempted to overcome the limitations of these techniques by using Landsat satellite imagery. We have constructed a very-high temporal resolution shoreline dataset covering the Cooloola Sand Mass (CSM) from January 1996 through December 2017. 147 historical positions were extracted for the 62 km-long CSM shoreline amounting to a total of 9,000 km of mapped shoreline. Shoreline positions were delineated from Landsat imagery using the Modified Normalized Difference Water Index, a spectral index that uses the middle-infrared and green visible bands to extract pixels containing water surfaces. A strong tidal influence was observed on the shoreline positions as the tide stage varies during the synchronous Landsat flyover time. Horizontal offsets due to variable tide stages were removed using local tide data available back to 1996 and by extracting seasonal intertidal widths from equilibrium beach profiles. Beach profiles were created for the austral seasons using hindcast wave data from the NOAA WAVEWATCH III dataset and known grain sizes for the CSM. Total shoreline movement over the 21 years was calculated every 500 meters along the CSM shoreline using the Digital Shoreline Analysis System. These values were used to separate the CSM shoreline into four geomorphic compartments, for which shoreline change curves were constructed and then correlated to five climate indices: ENSO, Southern Annular Mode, Pacific Decadal Oscillation (PDO), and the Subtropical Ridge Latitude and Pressure. The presence and strength of statistical relationships between the four shoreline segments and five climate indices were assessed using Pearson correlation coefficients and their associated p values. PDO shows the strongest correlation across all four shorelines, with r values ranging from 0.22 to 0.31 within the 99% confidence interval, indicating shorelines retreat (prograde) during negative (positive) PDO phases. The observable response of the shorelines to PDO variability could be linked to large-scale anomalies and trends in cyclone and anticyclone behavior in the Tasman Sea, where negative PDO phases are host to more frequent and intense cyclones. This novel and statistically significant coupling between PDO and shoreline change provides significant insight into how the CSM and other sand island shorelines in southeast Australia could respond to a potential PDO phase reversal expected within the next 4 to 7 years. Additionally, the orientation and heights of strandplain beach ridges could be used as a possible indicator of Holocene PDO phase variability.

Abstract

Postglacial relative sea level rise flooded much of the low lying landscapes of southern Scandinavia submerging the coastal shelves. These drowned landscapes potentially hold well preserved archaeology together with palaeoenvironmental archives that could allow for detailed study of past human-environment interactions. Due to restricted accessibility it is not often possible to excavate at a scale large enough to allow the necessary detailed investigation of the cultural remains together with the landscape/palaeoenvironmental reconstruction to examine these interactions. A rare opportunity to investigate just such a site has recently been possible due to a combination of historical land reclamation and the construction of the tunnel beneath the Femern Strait between Denmark and Germany. Rising relative sea levels submerged the coastal zone in the south of the island of Lolland on the southern tip of Denmark where archaeological investigations at the 187 ha site (Femern Project) suggest cultural use of this environment from the very earliest Mesolithic (from c. 11700 cal BP) and with sustained human presence beginning in the late Mesolithic, through the Neolithic and on into the Bronze age (between c. 7400 and 2500 cal BP). The cultural material is preserved in reed peats and lagunal muds which encroach landward until at least c. 1700 cal BP and here we show a series of 3D reconstructions (based on an extensive borehole survey) showing the association of the archaeological material with this dynamic coastline. The reconstructions show two fjords both containing brackish shallow water which were connected when relative sea level reached c. 1.5 m b.s.l. forming one large lagoon. The larger lagoon phase is associated with two fixed fish weirs and several other fish weir fences. Six sediment profiles/boreholes were further selected to represent the whole time period and to reconstruct both the aquatic (macrofossils, diatoms, geochemistry) and the terrestrial (pollen) palaeoenvironments. This data shows, for example, a shallow, brackish lagoon edged with reed beds which is associated with long-term ritual use of the interface between land and sea, and the economic use of the landscape with the onset of grazing c. 5700 cal BP and the later changing spatial distribution of grazing intensity and land use.

This work is attempting to place cultural activities within their spatial and temporal framework by combining sedimentological, stratigraphic and palaeoenvironmental data with archaeological evidence and landscape modelling. Although work is ongoing, this approach is showing what new knowledge can be gained when we have the unique opportunity to closely examine the relationship between coastal communities and their environment.

Abstract

Coastal environments are directly and uniquely impacted by storms, extreme weather events, and changing sea-levels. Future climate change and sea level rise will exacerbate the vulnerability of coastal habitats, infrastructure, heritage and communities. Evidence of coastal dynamics and storm activity during the Holocene provides a long term context for managing future change. CHERISH (Climate, Heritage and Environments of Reefs, Islands and Headlands) is an EU funded project which aims to investigate the past, present, and future impacts of climate change, storminess and extreme weather events on the rich cultural heritage of the Irish and Welsh coasts.

Here we present palaeoenvironmental and geochronological evidence from 3 sites on the southwest of the Isle of Anglesey, North Wales, where the coastal zone is fully exposed to the prevailing Atlantic south-westerly winds. At Llyn Maelog, Rhosneigr, a 4.5m core preserves an early Holocene record with a lacustrine environment developing into alder-carr woodland prior to c. 7.6 cal kyr BP. The alder-carr phase was terminated by a marine incursion before reverting to a fresh-water lake environment which persists to the present day. Five kilometres southeast, Llyn Coron is a small dune-impounded lake behind the 360 ha Aberffraw dune system. Previously published optically stimulated luminescence (OSL) indicate the earliest sand unit identified in the Aberffraw dune sequences was dated to 680 ± 140 years (Bailey et al., 2001). New evidence from a 3m sediment core from the lake indicates 2 clear episodes of sand inundation, the earliest of which is provisionally dated to c. 2.6 cal kyr BP, based on radiocarbon dating of wood immediately below a 4cm layer of fine sand that built up prior to lake development. A more recent sand unit overlying 26cm of lake sediment, indicates a separate, period of increased dune activity. Optically stimulated luminescence (OSL) dating is being used to establish a more detailed chronology for the sand deposition through this sedimentary sequence.

Further south along the coast at the early medieval settlement at Rhuddgaer, archaeological excavations reveal up to 1.4m of wind-blown sand sitting directly on top of ridge and furrow plough soil. Archival records refer to a severe storm in 1331 CE that destroyed agricultural land and led to abandonment of the site. OSL dating is being used to date the sand sequence, to establish the rate of accumulation and also whether there were multiple phases of sand mobilisation.

Our research highlights several major phases of Late Holocene sand mobilisation at the coastal sites examined. The integration of multiple lines of palaeoenvironmental, archaeological, and historical evidence provide valuable information on the rate and magnitude of environmental change over past millennia, and highlights the present day challenges for coastal communities located on the margins of the North Atlantic.

Abstract

Dispersal of hunter gatherer populations from continental Europe into Britain followed the Last Glacial Maximum when sea levels were lower, southern Britain was connected with northwest Europe and the ice sheets melted with climate amelioration. Britain and Ireland became islands by the early Holocene, which raises questions as to how later agricultural practises and cultural changes took place. Consensus suggests a combination of indigenous transition and colonisation from continental Europe. The Isles of Scilly off the South West Peninsula, Cornwall play an important role due to their position in the western seaways, their possible archaeological affinities with northern France and Belgium, and their high concentration of archaeological sites compared to the UK mainland. Sea levels continued to rise on Scilly throughout the Holocene creating a gradual fragmentation of the island group and changes in resource availability. Understanding the roles of climate, land area, land cover and coastal resource is vital in the story of hunter gatherer to Neolithic and other cultural transitions. The aim of the Lyonesse Project was to reconstruct the physical environment of Scilly for the past 12,000 years in order to progress the discussion behind human migratory and behavioural transitions through the Holocene. We present a new relative sea-level curve for Scilly that is supported by a database of >100 precise and limiting sea-level index points. These data are used here alongside a new glacio-isostatic adjustment (GIA) model to develop verified land motion and sea-level histories for the region from deglaciation to present day. The GIA model is combined with simulated changes in tidal amplitudes of the region to calculate state-of-the-art palaeogeographies for Scilly, which provide estimates of land area and intertidal zone changes. Pollen analyses of sediment cores taken from subtidal, intertidal and subaerial exposures are combined to develop community tables of ecological biomes that existed across Scilly throughout the Holocene. Archaeological data from the Cornwall and Scilly Historic Environment Record were combined with a regional radiocarbon summed probability distribution curve to synthesise evidence of human activity. Cross-correlation of these new palaeoenvironmental time series with regional climate (temperature and precipitation) records reveal significant land cover changes occurring shortly after 7000 yrs BP that cannot be explained by climate or sea-level change alone. However, the onset of the transition from a climax ecosystem towards open, possibly cleared, grassland predates cultural evidence of Neolithic practises on Scilly by over a millennium. Cultural transitions throughout the Holocene are characterised by observed changes in natural resource availability and land cover variation that coincide with changing human occupation and land practises. This study reveals new insight into how climate and sea-level changes have influenced human migration and settlement and, in turn, how humans have shaped a previously natural environment.

Abstract

An understanding of the nature and drivers of long-term vegetation dynamics is important for anticipating future ecosystem response and for identifying factors that might contribute to resilience in the face of climate and environmental change. Earlier attempts at reconstructing vegetation composition during and since the Last Glacial Maximum (LGM) in northern Russia have been limited by the lack of well-dated, high-resolution and continuous records. Here we present a new record of vegetation dynamics over the last 24,000 years based on relatively high-resolution pollen and ancient DNA extracted from the sediments (*sedaDNA*) of the largest and deepest lake in the Polar Ural Mountains of the Russian Arctic, Lake Bolshoye Schuchye. Preservation of both proxies are excellent throughout the sediment core. A high number of AMS radiocarbon dates ensures a good age model. Floristic richness and compositional turnover are inferred based on the pollen and *sedaDNA* data. The combined record reveals several important features of late Quaternary vegetation dynamics which earlier attempts have failed to detect; a diverse arctic-alpine herb flora in the Last Glacial Maximum (25 - 17 k yrs BP) which continues to persist through the Holocene, a switch in the dominance of functional groups and turnover in grass genera over the Pleistocene-Holocene transition, a response to Younger Dryas (YD) cooling (13 - 11.8 k yrs BP) and numerous Holocene species additions (11.8 - 1.3 k yrs BP). Of particular interest are the abrupt and short-lived fluctuations in the vegetation and land cover before and during the YD. This is observed especially in *Alnus*, *Betula*, *Artemisia*, *Dryas*, grasses and sedges, possibly an effect of local climate change. In general, over the full 24,000 year period little turnover (< 3 Stdev) is observed in both the *sedaDNA* and pollen records. Instead, a reshuffling in the dominance of individuals within and between functional groups is indicated without any loss of species. A comparison of turnover and floristic richness estimates based on *sedaDNA* and pollen highlight differences in their productivity, dispersal and taxonomic resolution. Whilst pollen shows no long-term change in floristic richness, *sedaDNA* shows a 48 % increase in richness between the LGM (25 - 17 k yrs BP) and Lateglacial (17 - 11.8 k yrs BP), and a further 4 % increase in floristic richness at the onset of the Holocene (ca. 11.8 k yrs BP). The flora has shown remarkable persistence in the face of changing climate and environmental conditions over the past 24,000 years and thus, we might expect only minor changes in floristic diversity with future climate warming.

Abstract

Past interglacial periods are important case studies in that they can help us understand the future evolution of our current warm stage. In particular, Marine Isotope Stage (MIS) 11 is the closest analogue for the Holocene since the Middle Pleistocene Transition and, being an unusually long interglacial period, can provide a good analogue for how the Earth system could operate under anthropogenically prolonged warm conditions (Tzedakis *et al.*, 2012). Intermontane basins in the Central Apennines are key sites to study past environmental and climate changes in the Mediterranean Region (*e.g.* Regattieri *et al.*, 2017). Among these, the Fucino Basin hosts a long, continuous and climatic sensitive lacustrine sedimentary succession including numerous volcanic ash (tephra) layers (Mannella *et al.*, 2018). Here we present a new 17 m long record from palaeo-lake Fucino spanning the whole of MIS 11, from Termination V to its final demise. The record is studied by means of a multi-proxy approach: a high resolution elemental profile is complemented by biogeochemical (total inorganic and organic carbon, total sulphur and nitrogen) and stable isotope ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) analyses on discrete samples. Preliminary geochemical analyses and high-precision $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the rich tephrostratigraphic content (5 out of 34 tephra layers) allow us to compose an independent age model spanning ca. 440 to 368 ka.

Our record shows prominent long-term environmental changes superposed with short-term oscillations. We explore the regional climatic framework by correlating our record with other published terrestrial and marine climatic archives. We observe an initial cold phase pervaded with arid events (ca. 440-424 ka – MIS 12), which is abruptly followed by a warmer and moister phase (ca. 424-402 ka – early-middle MIS 11). This warm phase is articulated in a first part (ca. 424-417 ka), characterised by subdued short-term variability, and in a second warmer part (ca. 417-402 ka), characterised by enhanced short-term variability. In particular, we observe 3 major millennial scale cold-arid events (at ca. 417-415, 410-408 and 406-404 ka) interrupting full interglacial conditions (MIS 11c). Finally we observe a slow and progressive demise of warm conditions (ca. 402-368 ka – late MIS 11) punctuated by abrupt cooling events. Our independent chronology suggests that precession and obliquity were the main forces shaping the general structure of MIS 11, while sub-orbital scale oscillations became relevant only during the later part of MIS 11.

Persistent millennial-scale climate oscillations in Southern Europe during the Penultimate Glacial

Graham Wilson¹, Mick Frogley², Chronis Tzedakis³

¹University of Chester, Chester, United Kingdom. ²University of Sussex, Brighton, United Kingdom. ³University College London, London, United Kingdom

Abstract

Highly-resolved $\delta^{18}\text{O}$ analysis of Greenland ice cores reveal the existence of large magnitude changes in regional climate on millennial timescales during the last glacial period. Concomitant changes in European temperature and in the strength of the Asian Monsoon (AM), for example, demonstrate the range of influence of these so-called Dansgaard-Oeschger (D-O) events emanating from the North Atlantic region, and likely propagated via changes in the strength of Atlantic meridional overturning circulation (MOC). It is important to determine the presence, spatial expression and regional character of 'D-O-like' climate oscillations during earlier glacial episodes. Such knowledge will help us to refine our understanding of Earth system sensitivity and behaviour under differing orbital and ice sheet configurations. The orbital configuration of the penultimate glacial (PG) (c.185–135 ka) differed markedly from that of the last glacial. Although beyond the temporal extent of the Greenland ice core record, the synthetic record of Baker et al (2011) predicts multiple D-O-like oscillations during the PG. Empirical evidence from Southern Europe, a region influenced by MOC variability, supports the existence of millennial-scale climate variability during the early PG, although mid-late PG climate variability appears muted in existing records (e.g. Margari et al., 2010). This contrasts somewhat with recent Chinese speleothem data, in which highly-resolved $\delta^{13}\text{C}$ measurements revealed the existence of up to 15 Chinese interstadials during the late PG (Wang et al., 2018). Here we present the first complete high resolution Southern European diatom record capturing the PG interval, from Lake Ioannina core I-284 (NW Greece). We have previously demonstrated the sensitivity of I-284 diatom assemblages to millennial-scale variability during deglaciations (e.g. Wilson et al., 2015). We find multiple discrete episodes of high planktonic diatom species abundance throughout the entire PG, likely reflecting intervals of lake thermal improvement and perhaps episodes of higher lake level. When compared with absolutely dated Chinese speleothem records, we find correlatives of many Chinese Interstadials in our diatom planktonic record. The dataset presented here provides firm evidence for the persistent influence of millennial-scale climate oscillations in mainland Europe during the PG and provides important empirical evidence for the geographical extent of millennial-scale climate variability.

Abstract

Within the European Plains, the Garwolin area occurred to be a part of the Eemian fossil great lakeland of Central Poland (Źarski et al. 2005). More than 20 new palaeolakes of this age were found during the cartographic work for the needs of the Detailed Geological Map of Poland, scale 1:50 000. The investigated sites are located in two geomorphological positions (depressions without outflow and valleys of small contemporary watercourses). Preliminary results of palynological investigations revealed some abrupt vegetation changes recorded in the course of pollen curves resulting probably from abrupt climate changes. In general, vegetation composition during the climate optimum of the Eemian interglacial had more plant species associated with the oceanic climate (i.e. *Taxus baccata*, *Buxus sempervirens*) than the vegetation of the same age from Belarus (Granoszewski et al. 2012; Kupryjanowicz et al. 2018). According to expectations, pollen percentages of the mentioned taxa were smaller than in the German diagrams. Proximity of the deeply incised valley of the Vistula river, very active during the Eemian interglacial, additionally could have affected the climate of the fossil lakeland. The results of palynological analyses have been supported by diatoms and plant macrofossil data. Significant variation in diatom species composition and its relative abundance explained marked environmental and climatic changes during the time of deposition. The presence of taxa typical of the Eemian macrofloras (*Brasenia* sp., *Aldrovanda vesiculosa*, *Najas minor*) testifies to high air temperature. Of special importance is the occurrence of megaspores of the water fern *Salvinia natans*, that grows in warm sub-Atlantic climate zone and in a tropical climate (Aalbersberg, Litt 1998).

This research was financially supported by the research project (number 2017/27/B/ST10/01905) financed by the National Science Centre (Poland).

Eemian environmental changes recorded in lake deposits from Hinterste Mühle (NE Germany) and Rzecino (NW Poland) - subfossil Cladocera data

Monika Niska¹, Anna Hrynowiecka², Andreas Börner³

¹Pomeranian University in Słupsk, Institute of Geography and Regional Study, Słupsk, Poland. ²Polish Geological Institute National Research Institute, Gdansk, Poland. ³State Bureau for Environment, Natural Protection and Geology, Güstrow, Germany

Abstract

In the current study the result of subfossil Cladocera analysis of the lake sediments from two sites: Hinterste Mühle (H-M) (NE Germany) and Rzecino (NW Poland) of the Eemian Interglacial and the inferred environmental alterations are presented. The aim of the study was to reconstruct and compare the development of Eemian lakes located within north of Poland and Germany as determined on the basis of the changes in subfossil Cladocera composition in the context of local conditions, climate change and natural evolutionary processes. The studied reservoirs, fully developed during the Eemian Interglacial, were formed at the end of Late Saalian (MIS 6).

The Hinterste Mühle profile is located in Mecklenburg-Western Pomerania. The site lies in the southeastern edge of the gravel pit, at about 48 m a.s.l. The Eemian sequence is situated in a local kettle hole depression overlying basal till and glaciolacustrine deposits of the Late Saalian and finally covered by Weichselian till. The Rzecino paleolake is located near Połczyn-Zdroj, which is situated in the West Pomerania Lakeland (NW Poland), at an elevation of 104.5 m a.s.l. The sediments fill a tectonic graben, which was formed along a large faulting zone that borders the Połczyn-Zdroj salt dome in the southwest. At the initial stage of lake development, sediments within the lake basins consisted mainly of sands and silts. The full lake development periods were associated with sedimentation of gyttja and organic silts followed by peat at the Hinterste Mühle sequence.

The subfossil cladoceran fauna from the H-M palaeolake is represented by 14 species belonging to three families: Chydoridae, Sididae, Daphnidae. Three of them belong to a benthic group inhabiting mainly the bottom sediments, one to the open water zone, while the remaining species the dominant group occur among aquatic plants. Such a species composition marks a shallow water body or the littoral, macrophyte zone of a deeper lake. The Cladoceran fauna of deposits from the Rzecino paleolake are represented by 22 species that belong to four families: Bosminidae, Chydoridae, Sididae and Daphnidae. The majority of the remains consist of Chydoridae and Bosminidae. In the deposits, the ephippial eggs of the *Daphnia longispina* group, *Ceriodaphnia* spp., *Chydorus* spp., and *Bosmina* spp. are also identified. *Bosmina longirostris* is the dominant species during all development periods of the Rzecino paleolake.

Summing up, in the studied reservoirs there were identified similar stages of development on the basis of the Cladocera analysis resulting from the impact of regional climate changes. However, the time of the creation of the reservoirs and its terrestrialization was related mainly to the size and depth as well as local conditions of the lakes.

The climatic change and human adaption at Yuncheng Salt Lake in Loess Plateau since 30 ka BP

Xiaoqiang Li¹, Guiling Zhang², Xinying Zhou¹, Jian Wang¹

¹Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China. ²Tianjin University, Tianjin, China

Abstract

Base on the high-resolution records of pollen and charcoal from the lacustrine deposit at Yuncheng salt lake in the south of Loess Plateau, combining high precision ¹⁴C chronological data, the climatic change, climate events and controlling factors are reconstructed for the last 30 ka BP. The climate is cool and dry during period of 36.7-28.6 ka BP in Salt Lake of Yuncheng. The last glacial maximum can be divided into two periods. The climate is cold and dry between 28.6 and 21.7 ka BP. The vegetation coverage increased and climate is still cold and dry between 21.7 and 15 ka BP. Since the last 15 ka BP, the vegetation changed significantly, and the East Asian summer monsoon gradually increased and reached its peak between 7.8 and 5.3 ka BP. The climate events of Younger Dryas, 8.9 ka, 8.2 ka, 5.3 ka, 4.3 ka, 2.8 ka also occurred during the intensification of monsoon. After about 4.3 ka BP, the monsoon receded rapidly, and the climate developed cooler and drier. The climate change in Yuncheng has been mainly controlled by summer solar radiation in the northern hemisphere for the last 30 ka, but the peak of the East Asian summer monsoon lagged behind the solar radiation maximum, which possibly affected by the regulation of ice volume in the high latitudes of Northern Hemisphere. The warm-humid climate promoted the prosperity of Neolithic culture and the development of agriculture during the mid-Holocene. Since 5 ka, Longshan Culture has developed rapidly and improved the adaptive capacity to cope with the climate changes.

⁶University of Padova, Dept. of Geosciences, Padova, Italy

Abstract

Long and continuous lake records are renowned archives of ecosystems, climate and anthropic history over different time scales. They accurately witness paleoenvironmental and paleoclimate variability, as shown by hundreds of researches worldwide. Northern Italy hosts the first continuous archive of the environmental and climate history of the southern alpine foreland; the core drilled at Lake Fimon (Venetian Plain) contains the whole Late Pleistocene represented by lake sediments, making this record an exceptional evidence of the effects of climate variability and humans on past biodiversity (Pini et al., 2010).

We focus here on a specific time interval, corresponding to the coldest extreme of the last glacial cycle, the LGM (Last Glacial Maximum). During the LGM, Earth experienced the development of continental ice sheets complexes over Antarctica, Eurasia, North and South America. Sea-level recorded phases of relative stability followed by abrupt decreases. Terrestrial ecosystems faced major reorganizations.

The Lake Fimon paleoecological record describes vegetation changes that occurred regionally during the LGM. Boreal forests thrived for most part of the Middle Würm up to ca. 27.5 ka BP, replaced by open woodlands with xerophytes until the first part of the Lateglacial, and later on followed by broad-leaved forests. Locally, a sedge mire developed between ca. 31-27.5 ka BP, then the mire was buried beneath detrital deposits formed under deep-water conditions (Monegato et al., 2011), an evidence for the abrupt onset of fluvio-glacial activity related to the culmination of the Brenta Glacier within the valley (Rossato et al., 2018). Lake level rose suddenly, triggering slope instability and higher sedimentation rates throughout the LGM.

Pollen-based quantitative reconstructions of past climate parameters (January and July temperatures, and annual precipitation) were obtained through the application of the Modern Analogue Technique (MAT). For each fossil pollen spectra, the 5 best modern analogues were identified among a calibration set of 239 sample sites of the Euro-Siberian orbiome extracted from the larger EMPD (European Modern Pollen Database: Davis et al., 2013). Climate parameters associated to the 5 best analogues were weighted-mean according to their respective similarity coefficient and attributed to the fossil sample. Climate reconstructions were then compared and fine-tuned with other proxies of climate at alpine and global scale. Warmer T_{jan} reconstructed at Fimon are related to Greenland Interstadials 3 and 2, with minor shifts between chronologies remaining within the error associated with the radiocarbon determination. Colder reconstructed T_{jan} seem to be indeed the expression on land of cooling related to massive iceberg discharge in the North Atlantic (Heinrich events 2 and 1, the latter in the early Lateglacial). As soon as the Atlantic Meridional Overturning Circulation resumed, pollen-based climate reconstructions point to warmer and moister conditions, favoring the spread of thermophilous forests from the Lateglacial interstadial onwards.

Transformations of socio-economic and environmental phenomena during the late antique Migration Period in Europe

Walter Dörfler

Institute of Prehistoric and Protohistoric Archaeology, Kiel, Germany

Abstract

Migrations in the Late Antiquity of Europe have concerned scholars for several centuries. These migrations are connected to different socio-economic crises. Internal and external triggers and driving forces are discussed as being responsible for these processes during the 4th to the 6th century CE. The breakdown of the Roman Empire and its shock waves are generally blamed but on a local or regional scale this might have been expressed by supply shortfalls, social stress, famines or plagues. As external drivers extreme weather events (caused by volcanic eruptions or meteorite impact) but also a longer lasting climatic shift and the spread of pathogenic germs are discussed. Most modern authors speak for a multi-factorial explanation of socio-economic and environmental changes but the order of causes and effects keep mostly unclear. In the frame of this talk I will compare data from palaeoenvironmental studies from northern Central Europe with historical data and climate proxies from the northern hemisphere. Signals for abandonment of fields and settlements during the Migration Period will be further compared to older phases of woodland regeneration in the Neolithic and Bronze Age as examples for crises and transformations.

Late Holocene climate implications and later prehistoric landscape modifications in the tropical and semi-arid regions of Indian Peninsula

ARJUN RAVINDRA RAO

School of Business Studies and Social Sciences, CHRIST (Deemed to be University), Hulimavu 560076, Bangalore, India

Abstract

This paper stress on the number of cultural features studied as a signature for micro studies in our archaeological projects to understand the changes in economy, politics of south Indian later prehistoric population resulted at major landscape modifications, and site formation processes associated with frequent climatic variations occurred during the late Holocene. Paleoclimate studies on reconstructing the Indian Summer Monsoon (IMS) from various lakes, river and ocean sediment cores identified aridification of climate in the Indian subcontinent during last c. 4500 to 1500 ka. Unstable river behaviors such as weakening of river dynamics and occurrence of recurrent flash floods determined by the monsoon precipitation in the rivers of Western Ghats originate (example Kaveri, Krishna and Tungabhadra) in Indian Peninsula have implications on the developments of later prehistoric societies during the last three millennium BCE (Neolithic, 3000-1200 BCE and Iron Age during 1200-300 BCE). Such developments in the environment coincided with the nature of expansion of agricultural population, crop suites, subsistence changes and settlement established away from the riverine environs. However, recent archaeological studies by the present author in South India focusing on two different ecology, such as the tropical Western Ghats (Koppa Archaeological Research Project) and semiarid region of central Deccan plateau (Brahmagiri Landscape and Settlement Survey project) are showing differences in population adaptability to regional ecologies and resources. Their commonalities are relatively contemporary in the expansion of sites at such above dynamic environments bearing with similar production of cultural materials in the society. Yet in the terms of their landscape modification and how they managed space within the sites and nearby sites have major variations to record from the cultural features (stone tools, ceramics and burials) and spatial patterning beyond the cultural materials; which are associated with the ritual and economic practices invariably governed by fluctuating climate and nature of landscapes. Number of key distinctions is evident on this regards from the various sites in above study areas; one, water collection and management led by fluctuating monsoon precipitation taking shape in local politics and resource of economic importance regulated through the introduction of artificial pools/ reservoirs. Two, sites shifting from riverine to non-river environs and surrounding the natural springs in shaping the site economy; three, living in the rock shelters and open scrubs on whether imprints of rock art and sonic production due to nature of denudational and pediplain landscapes etc. They collaterally indicate at the development of new cultural landmarks with changes in climate and availability of suitable landscapes.

Late Holocene Deltaic Progradation Preceded the Early Southward expansion of Intensive Rice Agriculture

Ting Ma¹, Zhuo Zheng¹, Barry Rolett²

¹Sun Yat-Sen University, Guangzhou, China. ²University of Hawaii, Hawaii, USA

Abstract

The expansion of early rice agriculture along coastal regions of South China (SC) and into Southeast Asia (SEA) remains poorly understood despite the fact that the chronology of rice domestication and the transition to rice-dependent economies is now well documented for the lower Yangtze River area. In this study, we reconstruct the mid-late Holocene history of rice agriculture for the coastal lowlands of SC and SEA, highlighting the role of coastal plain transformation as a driver in the development of intensive agricultural systems. First, we present a comprehensive study of 23 palynological records to show that the onset of widespread rice agriculture was a broadly synchronic event throughout coastal regions surrounding the South China Sea (SCS). Next, we demonstrate that this major shift in subsistence economies accelerated with rapid deltaic progradation and the formation of coastal flat plains at around 3–2 ka. Drawing upon the available archaeological evidence, we propose that the lack of lowlands and wetlands suitable for rice farming is a vital factor that inhibited the transition to rice-dependent economies during the mid-Holocene sea level high-stand. Large-scale rice farming expanded southward rapidly following the formation of deltaic and coastal plains. This hypothesis accords well with recent ancient genome studies in SEA suggesting an additional mixture of incoming genetic material from China at around Bronze Age, which, however, is usually thought to be resulted from the civilization advance in southern China.

Upland economy, heathland and fire dynamics in the mountains of northern Portugal from the middle Ages to the Modern period

Carla Ferreira¹, Gill Plunkett², Luis Fontes³

¹University of Stirling, Stirling, United Kingdom. ²Queen's University Belfast, Belfast, United Kingdom. ³Universidade do Minho, Braga, Portugal

Abstract

In Europe, mountain landscapes have evolved in a long-term relationship with human communities and present-day landscapes are the reflection of that ancient interaction. The present study aims to reconstruct human activity in two mountain areas in northern Portugal using palynological analysis and integrating its findings with the available regional historical, archaeological and palaeoenvironmental resources.

Both sequences span the Medieval and Modern periods and the pollen records show that mixed agriculture and livestock grazing were consistently present in both regions throughout these times. Variations in cultural indicators show that the extent of farming fluctuated throughout time, with a general increase in cultivation during the medieval period but with contractions likely coinciding with times of social disturbance. Social-political factors and population pressure were fundamental in the utilisation of upland spaces. This study did not find any evidence to suggest that fire was ever widely used as part of a land-management strategy nor that it was a factor in heathland spread. Landscape change was more dramatic in recent centuries, following population and economic decline.

We conclude that long-term occupation of the uplands was sustained by low-intensity land-use throughout the Medieval to post-Medieval periods, and that the present landscape has assumed a very different character following depopulation of the mountain areas and a shift towards commercial forestry.

Anthropogenic activity shifts an ecosystem's main driving forces

Renée Enevold^{1,2}, Peter Rasmussen³, Mette Løvschal¹, Jesper Olsen¹, Bent Odgaard¹

¹Aarhus University, Aarhus, Denmark. ²Moesgaard Museum, Hoejbjerg, Denmark. ³National Museum, Copenhagen, Denmark

Abstract

Ecosystem resilience and ecological tipping points may be influenced by anthropogenic activity. Relating temporal variation of multiple palaeoenvironmental proxies to find consistent trends can additionally provide an interesting tool to study the main driving forces of ecological change through time. This temporal approach also avoids the danger of circular argumentation based on falsely assumed modern analogy, obviously present in studies based on modern ecology. This paper presents a comparative study of pollen, macrofossils and non-pollen palynomorphs (NPPs) that was done on a 5500-year sedimentary record from Tårup Lund Denmark (Enevold *et al.* 2018).

Samples were prepared for NPP analysis using a non-aggressive preparation procedure which produced very rich NPP assemblages. Changes in NPP composition were then compared to changes in pollen and macrofossil frequencies from independent preparations. This led to indications about the source of NPPs; ecological affinities of some frequent NPP types and to the identification of main driving forces of NPP composition change. The results also indicated that a significant change in main drivers of NPP composition occurs at the onset of the Pre-Roman Iron Age. Evidence of an extensive Celtic Field system covering the area was furthermore found during the archaeological surveys.

Enevold R., P. Rasmussen, M. Løvschal, J. Olsen and B.V. Odgaard. 2018. Circumstantial evidence of non-pollen palynomorph palaeoecology: a 5,500-year NPP record from forest hollow sediments compared to pollen and macrofossil inferred palaeoenvironments. *Vegetation History and Archaeobotany* in press.

Environment and Culture Change in Kiawa, Southeastern Sokoto-Rima basin, Nigeria.

Aliyu Adamu Isa

University of Dar es Salaam, Dar es Salaam, Tanzania, United Republic of

Abstract

Several studies on palaeo-and contemporary environment and culture change in Nigeria emphasized the impact of climate change on livelihood rather than its causes and effects to the environment. This is due to problems of unambiguous climate change indicator, as recorded in plant pollen as well as the scarcity of comparable available sites. Thus, despite records and effects of climate change on environment between the Sahara and equatorial zones of Africa, some scholars have opined that no proof yet exists of a feedback relationship between land use (at the regional level) and environmental change. However, major vegetation changes in neighbouring sites and their corresponding culture change has been recorded since the late Holocene. For instance, an abrupt biostratigraphical and sedimentological change at c. 3300 B.P. in the Lake Chad basin is interpreted as a major shift towards drier climatic conditions. Corresponding culture change from archaeological excavations reveals the introduction of pastoralism and ceramics around 4000 B.P. and the domestication of *pennisetum* from at least 3000 B.P. onwards. Since the discovery of fossil fishes, crocodile and giant turtles as well as records of fossil woods from shallow marine beds in the 1920s and the 1970s in the adjacent Sokoto-Rima basin, this area is seen as a promising build up to supply a more substantial picture of environmental change in West Africa and in relation to other parts of the African continent. Various archaeological discoveries including hand axe, disc cores and flakes along main rivers, where settlements seem to be concentrated, after the return to drier conditions indicates continuous human activity since the Late Stone Age. Recent pilot investigations as part of a PhD research at the archaeological site of Kiawa reveals Pearl millet (*Pennisetum glaucum*) as the most important staple crop in the marginal rain-fed agrarian system and is sometimes combined with corn (*Sorghum*). Tree pollen from winter thorn (*Acacia albida*), Black plum (*Vitex cchenkowskii*), Locust bean (*Parkia filicoidea Balanites*) and Shea butter (*Butyrospermum parkii*) have also been recorded. The aim of the project is therefore to recover information pertinent to reconstructing human impact, climate and vegetation change in relation to other West African sites.

O-1175

Abandonment as adaptation: prehistoric food production, settlement abandonment, and Holocene hydrological changes in the southern Yangtze Delta, China

Tengwen Long^{1,2}, Jungan Qin², David Taylor³

¹University of Nottingham Ningbo China, Ningbo, China. ²Trinity College Dublin, Dublin, Ireland. ³National University of Singapore, Singapore, Singapore

Abstract

Low-lying geomorphology in lower, often densely populated, reaches of the world's large rivers is especially sensitive to changes in the equilibrium between fluvial and marine processes and variations in human activities. This paper reports sedimentary evidence from the Yangtze Delta, China, that provides a (pre-)historic analogue of human responses to this type of changing environment. We focus on two important archaeological sites – Majiabang and Chuodun – within the broader context of evidence of post-glacial environmental changes and early food production in the lower Yangtze. The Majiabang sequence records the initiation of rice-based agriculture at 7,230 cal BP. The onset could have been associated with a decline in wetland resources, indicating the possible role of population growth in triggering early agriculture. However, occupation of the site was ephemeral; agricultural practice seems to have terminated after only ca. 200 years, ¹⁴C dated to 7,070 to 6,840 cal BP. Evidence of dinoflagellate cysts and Chenopodiaceae pollen suggests a major episode of marine intrusion at this time, which might account for the decline in agriculture. Abandonment within a relatively short period of first occupation appears to have been a feature of early settlement on the Yangtze Delta, and may have been an adaptation strategy to an environment characterised by high variability. Despite some investments in settled agricultural technologies, rice was not yet fully domesticated in 7,000 cal BP, and hunting for and the collection of wild foods were important for ensuring food security. Such a strategy would have required a level of mobility and this together with a relatively low population density, abandonment and migration might have been easier adaptation choices than remaining and attempting to mitigate the adverse effects of major environmental changes. Even in the late Holocene, abandonment of settlements due to environmental change was not uncommon. The Influence of an expansion of freshwater lakes on the southern Yangtze Delta – notably associated with formation and subsequent inundation of the Taihu Depression – is recorded in the Chuodun sequence, where increases in microfossils indicating the onset of lacustrine conditions correspond with evidence of a decline in traces of human activities between 2,750 and 1,950 cal BP. The expansion of lacustrine conditions may correspond with early Chinese texts that describe the southern Yangtze Delta as a less inhabitable region characterised by extensive wetlands that made large-scale farming difficult. Intensified land use activities do not appear to have occurred until relatively late in the Holocene, and may have only been established after the arrival of migrants from the Yellow River Basin, which increased population pressure. These migrants may also have possessed relatively advanced environmental management technologies. In the lower Yangtze, the change from mobility to sedentarism was a more prolonged process than previously thought.

O-1176

How palynology and a great Dane contributed to the development of Quaternary palaeoecology

Richard Bradshaw

University of Liverpool, Liverpool, United Kingdom. Lund University, Lund, Sweden

Abstract

Palynology became a major sub-discipline within Quaternary palaeoecology during the first decades of the 1900s under the European leadership of amongst others, Lennart von Post, Gunnar Erdtman, Knud Jessen, Johannes Iversen, Franz Firbas, Knut Faegri, Harry Godwin and Frank Mitchell. Correspondence between these scientists indicates that the Danish Geological Survey (DGU) became the pre-eminent centre where many researchers came to learn the latest techniques. Jessen recruited Iversen to the DGU in 1932 and Iversen became a central figure in the international palynological network. Study of his voluminous correspondence with other researchers during 1930-70 shows how palynological research carried out in Iversen's group contributed to the development of several new ecological insights that included 1. revelation of the extent of human impact on European vegetation as a complement to archaeology; 2. the drivers of long-term plant succession and 3. the role of climate change in ecosystem dynamics.

One measure of international interest in his research is shown by the guest book records between 1948 and 1980 of 220 researchers from 14 countries that made the trip to the remote Draved Forest field station in southern Jutland, where many of Iversen's palaeoecological theories were developed and tested, including the re-enactment of a Neolithic forest clearance using flint axes and fire. Archived letters show the international reputation of Iversen's group developed from 1. The effort and care that Iversen gave to his correspondence; 2. methodological developments that others were keen to learn; 3. acquisition of the latest top quality equipment; 4. a strong internationalisation policy; 5. a research group comprising complementary skills and interests and 6. a diverse, targeted outreach and communication policy. The establishment of Draved Forest as a field laboratory and long-term monitoring site became a well-used and influential demonstration site.

The events, factors and personalities behind the growth and subsequent decline of a successful, international research group include several lessons that are still relevant for the planning and execution of Quaternary research today.

INQUA 2019
DUBLIN
IRELAND

G. F. MITCHELL,
24. ~~23~~ TRINITY COLLEGE,
DUBLIN.

10th March, 1951.

Dear Iver,

Many thanks for the paper that reached me this morning.

After I got back to Dublin I persuaded the University to order a Leitz Ortholux microscope for me and I hope to get delivery of it without much further delay. Now I find that no one in Dublin has ever heard of Anisol. Can you tell me what the composition of this emersion fluid is ?

Yours sincerely,

Frank

Marginalia: Gunnar Erdtman's annotations in his copy of Fægri and Iversen's *Text-book of Modern Pollen Analysis*

Kevin J Edwards

University of Aberdeen, Aberdeen, United Kingdom. University of Cambridge, Cambridge, United Kingdom

Abstract

The annotation of books by users may be seen as an act of vandalism. By the same token, 'marginalia' or 'apostils' may be regarded positively as a potential source of insight and/or a reflection of the mindset of the defacing/conversing author.

This paper examines the annotations within a copy of the first edition of the 'bible' of palynology – *Text-book of modern pollen analysis* – by the Norwegian botanist Knut Fægri and his co-author, the Danish botanist Johannes Iversen, published in 1950. The marginalia are the work of Swedish geobotanist Gunnar Erdtman. All three palynologists were major figures in the history of this particular Quaternary science – indeed, a discipline-specific award within the field is the Erdtman International Gold Medal.

At the risk of indulging in academic voyeurism – after all, Erdtman was presumably unaware that his 'scribbles' would be open to scrutiny – this paper seeks to assess his written, though unpublished, observations of two would-be ecologically-orientated usurpers of his palynological crown. Erdtman himself had earlier (1943) produced *An Introduction to Pollen Analysis* and very much saw himself as the font of wisdom concerning the discipline, and especially so in the area of systematics.

Erdtman's marginalia, inscribed in pencil and ink, include notes, underlinings, drawings, exclamation and question marks. Their greatest concentration is to be found in connection with pages addressing pollen morphology. He also queries or contradicts factual statements and, pedantically, English usage and reference order. He approvingly ticks items according to primacy to himself or to his palynomorph terminology. His use of such disfigurement is to be found elsewhere within his archives, although not to the same extent as seen in Fægri and Iversen's classic tome.

Such interest might be regarded as an addition to the critical apparatus available for the appraisal of an academic's work – a more personal augmentation to such sources as reviews or commentaries of draft papers published by some journals as part of the editorial process. Whatever else it does, it allows an insight into the thinking of a pioneering Quaternary scientist, as well as revealing a spontaneity and a persona which might otherwise be hidden.

Pollen databases: from von Post to Neotoma

Eric C. Grimm

University of Minnesota, Minneapolis, USA

Abstract

In 1916, Lennart von Post introduced the pollen diagram at the 16th Convention of Scandinavian Naturalists in Kristiania (Oslo, Norway). However, not only did he introduce the pollen diagram as a means of visualizing data from single stratigraphic profiles, he also presented a transect of diagrams that depicted pollen and vegetation changes through time and space as well as a diagram of averages that summarized regional pollen changes. To construct such diagrams, von Post had to organize and summarize data, and thus assemble a “database,” a word that was not coined until the computer age in the late 1960s.

The first large computer database of pollen data was that assembled by the Cooperative Holocene Mapping Project (COHMAP). Under the direction of Thompson Webb III, original pollen-count data from North America were solicited from investigators and organized into individual flat files with defined formats for pollen data and chronologies. At the same time in Europe, John Birks and Brian Huntley assembled pollen percentage data digitized from published pollen diagrams to produce a massive compendium of isopoll maps for Europe. These projects established not only the indubitable value of pollen databases, but also the need for open access and for organization into a relational database structure. Thus, in the early 1990s, the North American Pollen Database (NAPD) and European Pollen Database (EPD) were established, and in following years a number of other database projects were launched, including pollen databases for Africa, Latin America, and other regions. Although internet technology was not yet to the point where a single global database could be contemplated, these databases established a common structure and were deployed in the same relational database management software.

The pollen databases had become essential cyberinfrastructure for global change research. Nevertheless, weaknesses included limited interoperability with databases for other paleo datatypes, limited ability for those outside the data center to upload and manage data, limited online capability to query the database, and long-term sustainability. For these reasons, the Neotoma Paleocology Database (www.neotomadb.org) was launched by the coordinators of existing databases for pollen, plant macrofossils, diatoms, ostracodes, vertebrate fossils, and others. The existing pollen databases have been or are being incorporated into Neotoma, along with data from other databases. However, existing database projects, such as the NAPD and EPD, still exist within Neotoma as constituent databases and are responsible for their own data upload and management. A common web-based portal to the database has been developed, and a common software interface for remote data upload and management is being developed. The scientific merit of assembling pollen data demonstrated by von Post a century ago is well positioned for the next century.

O-1179

A short history of Bayesian chronology-building

Maarten Blaauw

Queen's University Belfast, Belfast, United Kingdom

Abstract

Well before Darwin, Lyell and von Post, the English statistician Rev. Thomas Bayes (c. 1701-1761) developed a scientific approach that has proven to be very useful in Quaternary research. Bayes aimed to establish how our understanding of phenomena should be updated with new evidence, for example if new dates become available for a sedimentary sequence. In the Bayesian framework, everything is expressed as probabilities – this is especially useful in areas such as Quaternary research where data points are often sparse and come with sizable uncertainties.

Bayesian models can be seen as simulations of real-world phenomena that adapt to the available data within the constraints set by prior information. For example, simulations of sediment accumulation can be used as age-depth models for lake cores with several radiocarbon-dated depths, with prior information set such that that age-reversals or abrupt changes in sedimentation rate are avoided. Millions of these simulations, each based on slightly different random numbers for the parameters involved in the sediment accumulation, will together provide estimates of the ages and their uncertainties at any core depth.

After remaining largely unused for centuries, the Bayesian approach became feasible since the 1990s as fast computers and efficient algorithms were developed. Dedicated on-line Bayesian age-modelling tools such as BCal and later OxCal were widely adopted by the archaeological and wider Quaternary community as *de facto* standard chronology-building tools, especially for users of terrestrial radiocarbon dates. However, other communities have been more reluctant in adopting the Bayesian framework for their chronology-building, even if doing so could have the potential to enhance their quantitative understanding of the uncertainties inherent to their datasets and interpretations.

Here we will discuss the history of Bayesian chronology-building tools, outline their advantages over more classical statistical tools, and explore possible reasons why they have become popular in some Quaternary communities yet less so elsewhere.

New $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology of Armenian volcanism

Katie Preece¹, Darren Mark², Keith Wilkinson³, Jenni Sherriff³, Rhys Timms⁴, Christina Manning⁵

¹Dept. of Geography, Swansea University, Swansea, United Kingdom. ²Scottish Universities Environmental Research Centre, East Kilbride, United Kingdom. ³Dept. of Archaeology and Anthropology, University of Winchester, Winchester, United Kingdom. ⁴Dept. of Geography, Royal Holloway, Egham, United Kingdom. ⁵Dept. of Earth Sciences, Royal Holloway, Egham, United Kingdom

Abstract

The Southern Caucasus forms part of a land bridge between Africa and Eurasia and is the location of archaeological sites where the earliest human fossils outside Africa (Dmanisi, Georgia) [1,2] and the earliest evidence for advanced human behaviour (Nor Geghi 1, Armenia) [3] have been found, transforming understanding of the relationship between the European and African Palaeolithic. However, it is presently unclear what mechanisms drove *Homo* sp. dispersal to geographic regions beyond Africa and how technological innovations (i.e. stone tools) and ecological adaptations developed along the way.

Here we present new $^{40}\text{Ar}/^{39}\text{Ar}$ ages of volcanic deposits (lava flows and domes, pyroclastic deposits and discrete tephra layers) in the Hrazdan and Debed gorges in Armenia. These areas comprise volcanic deposits, intercalated with alluvial, lacustrine and aeolian sediments. Detailed geological mapping, $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology, and geochemical / petrological characterization of the volcanic deposits, shed new light on the volcanic history of the region. In addition, these results provide a stratigraphic link between archaeological sites in the Southern Caucasus and contribute towards understanding how hominin populations responded to dynamic volcanic landscapes.

Abstract

The PAGES project (Pleistocene Archaeology, Geochronology and Environment of the Southern Caucasus), aimed to develop a robust and independent geochronological framework for the Southern Caucasus, to combine the emerging archaeological and environmental record in the region, with a focus on the mid to late Pleistocene. A key component of this project was an attempt to identify, classify and where possible correlate distal tephra from archaeological and environmental sequences in the Hrazdan and Debed river valleys, Armenia with tephra from local (Armenian and Turkish) volcanic centres, and potentially from more distal volcanoes in the eastern Mediterranean. Here we present the results of the analyses of multiple archaeological and palaeoenvironmental records for visible and cryptotephra deposits between ~30,000 and ~400,000 ka BP. The results include the identification of cryptotephra deposits in multiple sites, along with numerous visible tephra deposits. Grain specific glass shard chemical data for these tephra are presented along with new glass analyses from proximal tephra outcrops associated with volcanic complexes in the Sevan-Hrazdan basin. These results are used to test potential correlations between: (i) archaeological and palaeoenvironmental sites within the study regions of the PAGES project; (ii) records that are being analysed as part of other ongoing collaborative projects across Armenia, and; (iii) sites of similar age within the wider region beyond the Southern Caucasus. This study highlights the challenges with dealing with multiple volcanic centres with limited geochemical and chronological information. However, it also reveals potential tephra-based correlations between a number of sites within Armenia and beyond, and suggests that the Southern Caucasus is a key region in the development of a much wider tephrostratigraphic framework that could eventually link with records from the Eastern Mediterranean, Turkey and the Greater Caucasus region.

O-1183

Source-specific biomarkers as sea ice proxies - current status and future directions

Simon Belt

University of Plymouth, Plymouth, United Kingdom

Abstract

Dramatic changes in sea ice extent and thickness during recent decades have prompted attempts to decipher longer-term palaeo sea ice variability, in order to place modern observations into a better context. Such knowledge should also aid our understanding of sea ice within the broader climate system, and improve the reliability of various climate forecasting and hindcasting models. Reconstruction of palaeo sea ice conditions has been achieved largely through analysis of various proxies in marine sedimentary archives. Over the last decade or so, certain source-specific C₂₅ highly branched isoprenoid (HBI) lipid biomarkers have emerged as useful proxies for both Arctic and Antarctic sea ice. Thus, IP₂₅ (Ice Proxy with 25 carbon atoms) and IPSO₂₅ (Ice Proxy for the Southern Ocean with 25 carbon atoms) represent binary measures of past seasonal sea ice in the Arctic and Antarctic, respectively. A further tri-unsaturated HBI (generally referred to as HBI III) appears to provide proxy evidence for the region of open water adjacent to sea ice (i.e. the marginal ice zone (MIZ)) for both the Arctic and the Antarctic. However, several questions about the use of HBIs as sea ice proxies remain, not least, the extent to which they can provide more detailed information of sea conditions such as sea ice concentration, duration or type (e.g. landfast ice, drift ice, first-year ice, multi-year ice, etc). This presentation will provide a state-of-knowledge account of the use of HBIs as sea ice proxies, drawing on a decade of research activity. The salient features of each HBI as sea ice proxies will be described, along with their currently perceived limitations. By considering some knowledge gaps and previously unexplored areas, some avenues for possible future research efforts will also be identified.

Holocene records of sea-ice, sea-surface temperature and primary productivity in the North Water polynya and offshore Upernavik, northwestern Baffin Bay

Audrey Limoges¹, Sofia Ribeiro², Kaarina Weckström³, Xavier Crosta⁴, Kelsey Koerner¹, Arto Miettinen⁵, Guillaume Massé⁶

¹University of New Brunswick, Fredericton, Canada. ²Geological Survey of Denmark and Greenland, Copenhagen, Denmark. ³University of Helsinki, Helsinki, Finland. ⁴Université Bordeaux, Bordeaux, France. ⁵Norwegian Polar Institute, Tromsø, Norway. ⁶Université Laval, Québec, Canada

Abstract

The observed changes in Arctic sea-ice thickness, extent and dynamics (e.g. onset of melting, length of open-water season) during the last few decades raise important concerns regarding the future functioning of Arctic marine ecosystems. The North Water (NOW) polynya (i.e. open-water area surrounded by sea ice) located in northern Baffin Bay plays a key role in fostering local biological productivity, and its intrinsic link to sea ice makes it particularly sensitive to climate change. While a number of studies have documented changes in the physical, chemical and biological characteristics of the polynya over the last decades, little information about its multi-centennial and millennial evolution is currently available.

Here, we present results from a multiproxy study including diatoms, dinoflagellate cysts (dinocysts) and sea-ice biomarkers (IP₂₅ and triene) from two Holocene sediment cores collected in the NOW polynya (AMD15-Casq1) and offshore Upernavik (AMD14-204) (see figure 1) to determine the relationship between sea ice and primary productivity at local and regional scales. These sedimentary proxy-records were further compared to atmospheric temperature reconstructions from the Agassiz ice cap and Greenland ice sheet to place the observed trends into a regional climate context. During the past ca. 4000 years, primary production has persistently been higher in the NOW polynya compared to the Upernavik site, but rapid and synchronous shifts in the sea-ice conditions, summer sea-surface temperature and productivity regimes between the two regions were recorded. These synchronous shifts were accompanied by changes in the phytoplankton community structure, as illustrated by changes in the diatom and dinocyst species composition and abundances. Our results support the notion that sea ice exerts a strong control on primary production and that future warming will likely be associated with changes in the net primary production and phytoplankton community structure in northern Baffin Bay.

Figure 1. Location of the study sites and main ocean currents. Abbreviations: WGC: West Greenland Current; BC: Baffin Current. The white dashed line corresponds to the approximate extent of the NOW polynya.

Abstract

One of the most striking consequences of current climate change is the abrupt decrease in Arctic sea ice extent. Current projections indicate a blue Arctic Ocean during summers already within the next few decades. Despite its importance, sea ice is one of the most poorly understood components of the Earth System, stressing the urgency to develop new proxies for reliable past reconstructions. Here we demonstrate the potential of the sea ice dinoflagellate *Polarella glacialis* as a seasonal sea ice indicator. The species is known to inhabit sea ice in the Antarctic but only a few sightings have been reported from the Arctic. Based on microscopic observations in surface sediment, sediment traps, and sea ice we confirm that this species has a pan-Arctic distribution closely tracking first year sea ice. It forms characteristic resting cysts during its life cycle that are present in large numbers in both sea ice and sediment trap samples. Within seasonal sea ice, it can represent up to 82% of the microalgae communities while it is absent from multi-year sea ice. Although the cysts are exported from the sea ice/sea surface to bottom sediments, there are few reports of this species in sediment records. This is likely due to problematic identification, its size smaller than 20 µm, and its sensitivity to harsh palynological treatment (e.g. using warm HF) and/or cyst degradation in the sediments. Therefore, we chose to explore a paleo-DNA approach for tracing this species in sediment core records.

We designed species-specific primers of the ITS1 gene-region to detect and quantify sedimentary ancient DNA (sedaDNA) from *P. glacialis* in two dated marine sediment cores collected off West Greenland spanning the past ca. 12,000 years. Our results demonstrate that DNA of the ITS1 gene-region in *P. glacialis* can be amplified and quantified using either a standard qPCR or droplet digital PCR approach. We also quantified *P. glacialis* DNA in 53 surface sediment samples from marine and fjord settings around Greenland. The *P. glacialis* DNA results were compared against “classical” proxies such as microfossils and the isoprenoid biomarker IP₂₅ in both sediment cores and the surface sediments. Our findings are particularly relevant to fjord systems, where *P. glacialis* appears to reflect sea ice conditions more reliably than IP₂₅. We suggest sedaDNA from *P. glacialis* as a novel and reliable sea ice proxy that can improve sea ice reconstruction both in marine and near-shore environments of the Arctic and Antarctic regions.

Paleo Arctic sea ice evolution during Dansgaard-Oeschger events 7 to 10: a multidisciplinary approach.

Federico Scotto¹, Carlo Barbante¹, Alfonso Saiz-Lopez², Paul Vallelonga³, Dorte Dahl-Jensen³, Andrea Spolaor⁴
¹Ca' Foscari University of Venice, Venice, Italy. ²Department of Atmospheric Chemistry and Climate, Institute of Physical Chemistry Rocasolano, CSIC, Serrano 119, Madrid, Spain. ³Copenhagen University, Niels Bohr Institute, Centre for Ice and Climate, Copenhagen, Denmark. ⁴Institute for the Dynamics of Environmental Processes, IDPA-CNR, Via Torino 155, 30170, Venice Mestre, Italy

Abstract

In the last four decades, Arctic sea ice is experiencing an overall decrease with a notably faster rate than predicted by numerical models. Despite a huge amount of observations has been acquired since the advent of satellite era (1979) there is still a lack of knowledge about past sea ice coverage. Thus, in order to enhance future scenarios predictions, it is fundamental to combine recent observations with past long-term reconstructions. A focus on the mechanisms controlling sea ice dynamics during past abrupt temperature shifts might be crucial to better understand current changes.

A recent study identifies bromine in ice cores as a potential proxy for past sea ice conditions¹. At polar latitudes in fact, the photochemical recycling of bromine is extremely efficient over first year sea ice (FYSI), resulting in enhanced concentrations of gas phase bromine (e.g. BrO) compared to the ocean surface, multi-year sea ice or snow-covered land. The net effect of this process (commonly referred as "Bromine explosion") can be detected in snow and ice samples as enrichment in bromine concentration compared to the seawater Br/Na ratio.

The Bromine Enrichment (Br_{enr}) record from the NEEM ice core (77.45° N, 51.06° W,) has been linked to sea ice conditions in the Canadian Arctic showing a maximum during the Holocene climate optimum (about 9000 years ago) and the lowest values during the glacial stadials, suggesting a complete coverage of the Arctic Ocean by multi-year sea ice¹. However, the time resolution used in that occasion (20-60 years) was unable to resolve in detail the Dansgaard Oeschger (D-O) events which occurred in a matter of decades .

Here, we present a new Br_{enr} high resolution dataset across the transitions of D-O 7, 8, 9 and 10 sub-sampled from the NEEM core. The increased resolution of 3-5 years for each sample might allow to better distinguish the amplitude of each transition, while the comparison with stable oxygen isotopes will provide information about the time lag between atmospheric warming and sea ice response. In conclusion, pursuing a multidisciplinary approach, the experimental results will be used to constrain a chemical-transport numerical model for Br_{enr} that will help to deepen the insight about sea ice extent variations during rapid climate fluctuations.

A seasonally sea-ice free eastern Arctic Ocean during the early-mid Holocene

Anne de Vernal¹, Claude Hillaire-Marcel¹, Cynthia Le Duc¹, Philippe Roberge¹, Robert Spielhagen², Jens Matthiessen³, Rudiger Stein³

¹Geotop-UQAM, Montréal, Canada. ²GEOMAR, Kiel, Germany. ³AWI, Bremerhaven, Germany

Abstract

The pre-satellite history of sea-ice cover in the Arctic Ocean is still poorly documented and the effective age of the onset of perennial sea ice remains an unresolved issue. Even at the scales of last millennium and the Holocene, information is rare and mostly indirect. We have addressed this question by the detailed examination deep-sea cores collected along the Lomonosov Ridge in the Arctic Ocean. These cores show contrasted sedimentary regimes. In the western and central part of Arctic Ocean, extremely low sedimentation rates, < 5 mm/kyr, and good preservation of calcareous microfauna characterize the present-day perennial sea ice environments. In the east, close to the Laptev Sea, relatively high sedimentation rates ranging up to ~5 cm/kyr relate to high sediment supplies from the shelf since their submergence ice and to an active Transpolar Drift. At sites near the easternmost edge of the Ridge, early-mid Holocene sediments are characterized by low to nil biogenic carbonates but contain organic-walled dinoflagellate cysts. These features indicate phytoplankton productivity but poor CaCO₃ preservation that we link to intense brine production rates leading to surface water convection with CO₂ transfer from surface to bottom water. Such conditions record an interval with seasonal sea ice in the eastern Lomonosov Ridge area until ca. 4000 years ago instead of perennial sea-ice. Hence, whereas highly resilient perennial sea ice on long time scales characterizes the western Arctic Ocean, seasonal sea ice in the Russian Arctic might be a recurrent feature of warm episodes.

Reconstructing sea ice in the Iceland-Norwegian seas during the Late Quaternary

Erna Ósk Arnardóttir¹, Esther Ruth Guðmundsdóttir¹, Jón Eiríksson¹, Ívar Örn Benediktsson¹, Yanguang Liu²

¹Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland. ²First Institute of Oceanography (FIO), State Oceanic Administration, Qingdao, China

Abstract

The role of sea ice in the climate system is becoming increasingly clear. Obtaining information on past sea ice cover and variations is important for understanding the climatic system.

The aim of this study is to advance the knowledge on sea ice in the Iceland-Norwegian sea by studying ice rafted debris (IRD). The focus of the study is on changes in IRD flux and tracing the IRD source in order to obtain additional data on sea ice coverage in the region and increase our understanding of oceanographic and climatic changes during the Late Quaternary.

Two marine sediment cores (IS-4C and IS-1C), retrieved from 1598 m water depth and 821 m water depth, are used in the study. Preliminary age models and tephra investigation indicate that the 4m long IS-4C core spans the early Holocene back to the Eemian. Work on the age model of the 6m long IS-1C core is in progress and will be based on radiocarbon dates and tephrochronology.

Both cores have been investigated with regard to source and quantity of IRD. Other proxies investigated are planktonic foraminifera and oxygen isotopes. IRD (grains larger than 125 μm) are counted and initially divided into three components: crystals, rock fragments and tephra. Concomitantly, planktonic foraminifera are counted and identified to species level. To attempt to differentiate sea ice and iceberg rafting, material larger than > 250 μm have been separated from the remainder of the material.

Preliminary results show that these proxies display high amplitude variability throughout the investigated period indicating a complex history of sea ice flux. The IRD analyses show that the most common IRD are quartz crystals with sharp edges. For the most part the quartz crystals are divided into three groups: translucent quartz with sharp edges, whiteish matte and rounded quartz and hematite stained quartz. The hematite-stained quartz could indicate a source from the Devonian red beds of east Greenland. The highly weathered, rounded and matte quartz indicate fluvial or wind erosion before being transported to the ocean. These types of grains are common on the plains in north-western Siberia. Other types of IRD identified are feldspar crystals, rock fragments such as granite, sandstone and basalt. Ash and tephra grains are counted separately.

Last glacial maximum to Holocene biogeochemical cycling and sea ice dynamics in the Bering Sea

Henrieka Detlef¹, Sindia Sosdian², Simon Belt³, Lukas Smik³, Caroline Lear², Ian Hall², Sev Kender^{4,5}, Melanie Leng⁵, Christof Pearce¹

¹Department of Geoscience Aarhus University, Aarhus, Denmark. ²School of Earth and Ocean Sciences Cardiff University, Cardiff, United Kingdom. ³School of Geography, Earth, and Environmental Sciences Plymouth University, Plymouth, United Kingdom. ⁴Camborne School of Mines University of Exeter, Penryn, United Kingdom. ⁵British Geological Survey, Keyworth, United Kingdom

Abstract

The Bering Sea is characterized by a seasonal sea ice cycle. Together with upwelling along the eastern continental margin, sea ice provides important nutrients to maintain high rates of primary productivity. As such, low oxygen concentrations are pervasive in mid-depth waters. Changes in the ventilation and primary productivity in the past, however, are expected to affect this oxygen minimum zone. On glacial/interglacial (G/IG) timescales, sea ice likely plays a pivotal role for intermediate water ventilation in the Bering Sea. Firstly, enhanced sea ice cover limits the light availability and contributes to surface ocean stratification, restricting the nutrient supply from below and limiting the primary productivity in the surface ocean. Additionally, evidence from the Bering Sea points towards glacial formation of well-ventilated North Pacific Intermediate Water (NPIW) via brine rejection during sea ice freezing. Enhanced formation of NPIW may have important implications for the efficiency of abyssal North Pacific carbon storage, however the spatial and vertical extent of glacial NPIW remains poorly constrained.

We use a multi-proxy approach to study the interactions of sea ice and biogeochemical cycling at International Ocean Discovery Program Site U1343 in the eastern Bering Sea across the last glacial maximum (LGM) to Holocene (7-30 ka). Sedimentary redox chemistry, dysoxic benthic foraminiferal assemblages, and the $\delta^{18}\text{O}$ composition of seawater all point towards periodic entrainment of NPIW at 2000 m water depth across the LGM and early Heinrich Stadial 1 (HS1). This is supported by biomarker-based sea ice reconstructions, demonstrating enhanced seasonal sea ice cover during the LGM and early HS1, indicating that NPIW may have been formed locally in the Bering Sea. Furthermore our results demonstrate that LGM to Holocene eastern Bering Sea sea ice dynamics are in-phase with deglacial North Atlantic climate oscillations.

Sudden environmental changes recorded in Late Pleistocene loess-palaeosol sequences in Poland and western Ukraine

Zdzisław Jary¹, Piotr Moska², Przemysław Mroczek³, Marcin Krawczyk¹, Jerzy Raczyk¹, Kamila Ryzner¹, Jacek Skurzyński¹

¹Department of Physical Geography, University of Wrocław, Wrocław, Poland. ²Institute of Physics – Center for Science and Education, Silesian University of Technology, Gliwice, Poland. ³Department of Geomorphology and Palaeogeography, Maria Curie-Skłodowska University, Lublin, Poland

Abstract

Discovery of sudden short-term climate changes during the last glaciation in the Northern Atlantic sea sediments and Greenland ice cores caused enormous interest among Quaternary researchers. An extensive research program has been initiated to find proofs of abrupt climate changes in terrestrial archives of climate proxy data, in particular in Europe. Loess is an exceptional source of paleoclimate data, because its lithological and structural features constitute an indirect record of changing environmental and climatic conditions prevailing during deposition and early diagenesis.

Late Pleistocene loess covers in Poland and western part of Ukraine were created in the proximal part of the extraglacial zone of the Scandinavian Ice Sheet, particularly exposed to changes of the meridional thermal gradient. They contain a rich inventory of deformation structures associated with dynamic climatic conditions in the periglacial zone of the Pleistocene glaciations. Relatively large latitudinal extension (about 800 km) of the study area allows to verify previous hypotheses that the development of loess cover in Central Europe reflects contemporary and Pleistocene climate: continental in the east and more oceanic in the west. This affected the spatial and stratigraphic differentiation of periglacial phenomena. Because of the intermediate geographic position of this region they form a bridge for the loess research between the western and eastern Europe.

There are a few proxies indicating rapid environmental changes within loess-palaeosol sequences (LPS) of the study area (e.g. initial soil horizons, grain-size, geochemistry, environmental magnetism, periglacial phenomena) which are discussed. However, we mainly present the problem of ice-wedge pseudomorphs in LPS. There is no agreement on some crucial questions such as the number of ice-wedge cast horizons and paleoclimate interpretation of periglacial structures. The research results obtained to date indicate the occurrence of minimum three generations of ice-wedge pseudomorphs in the Late Pleistocene LPS in study area. They are a proof of threefold permafrost development and degradation phases.

The common occurrence and large size of the youngest generation of ice-wedge casts (upper Pleniglacial = MIS 2) indicate continuous permafrost in the central and eastern parts of the research area. However, ice-wedge casts in the western part of Polish loess area were probably developed within both continuous (northern part) and discontinuous permafrost (southern part). This record indicates a considerable climatic gradient between western and eastern parts of the investigated area as well as meridional changes of periglacial climate conditions during the last glacial period.

The research was performed under the National Science Centre project No. 2017/27/B/ST10/01854 entitled “Sudden COLD events of the Last Glacial in the central part of the European LOESS Belt - in Poland and in the western part of Ukraine (COLD LOESS)”.

Abstract

Loess deposits contain exceptional information on the activity of past windblown dust sources. Constraining these dust sources is an essential step in understanding the complex feedbacks between dust and climate change in the past, and allows for better interpretation of loess climate and environment proxies such as grain-size and mass accumulation rate. However, deciphering source information rests upon the ability to discriminate the different sediment sources to loess, based on some intrinsic property of the material or constituent minerals (provenance indicator). Many such provenance indicators exist but in most loess areas the results from these methods often yield conflicting or ambiguous results. In recent years, considerable breakthroughs in understanding the provenance of Chinese loess deposits have been achieved through the use of single-grain provenance indicators, particularly through the use of detrital zircon U-Pb age dating. However, in European loess, comparatively little single-grain provenance work has been conducted to date, and the specific sources of loess in different parts of European loess belt are often poorly known. Here we report on new research that seeks to address this through detailed single-grain provenance analysis of loess deposits in Eastern Europe and Russia. Using initial new detrital zircon U-Pb age data from southern Poland, the Lower Volga River area of Russia and southern Hungary we show how the technique can be used to pinpoint specific dust sources of loess deposits in Europe, and examine their temporal changes. We also discuss the limitations of this approach and ambiguities over interpretation, as well as considerations regarding the number of grains analysed and statistical treatment. In general, the results demonstrate the importance of multiple dust sources and multi-step fluvial transport of silt material in European-Russian loess formation, but also highlight the possibility of highly dominant, localised mountain sources for some loess deposits. Finally, a perspective on future challenges in deciphering loess source in Europe is given, and suggestions presented for emphasis on multi provenance proxy studies.

Northern European Loess belt in Germany: Distribution, similarities and differences

Frank Lehmkuhl

Department of Geography, RWTH Aachen University, Aachen, Germany

Abstract

Pleistocene loess and loess derivatives are distributed along the mountain front of the Central European Mountain Belt in northern and central Germany. The geographical distribution of aeolian sediments is characterized and controlled by different topographical situations, tectonic settings, climate, the distance to large river systems, the distance to the Scandinavian ice sheet and the distance to the shelf of the North Sea. The distribution of loess shows an increasing elevation southwards whereas sandy loess displays a characteristic elevation below 200 m. A new loess map from Germany indicates that geomorphological features like mountain ranges, valleys and graben structures variously act as barriers or sinks for loess accumulation. These features and the distribution of the aeolian sediments as well as their potential source areas, allow conclusions about the paleogeographical conditions in Germany. Such conditions could have been suitable for Paleolithic hunter and gatherer communities. In addition, examples from two regions, the Lower Rhine Embayment (LRE) and the Northern foreland of the Harz Mountains (FHM) show differences in the development of the loess-paleosol sequences (LPS). In the more humid and oceanic LRE higher humidity enhanced the periglacial processes which increased erosion, but also led to preservation of the sediments in accumulative positions. In contrast, in the more continental FHM the sediments were affected by less intensive periglacial processes and not such strong solifluction features can be detected. Finally, a synthesis of typical sediment sequences for both regions is given as an example of paleoenvironmental (landscape) development in northern Central Europe.

Abstract

The climate of the last glacial period is characterized by the occurrence of numerous centennial-to-millennial interstadials. Marine and lacustrine pollen records as well as isotopic speleothem records already benefit from precise chronologies based on radiocarbon and Uranium/Thorium dating methods, which were still lacking for loess sequences.

In Last Glacial loess sequences of the European Plain, typical loess units alternate with hydromorphic (tundra gleys) or pedogenic (arctic/boreal brown soils) horizons. Grain size analyses and molluscan communities respectively highlight decreased wind dynamics and higher humidity and temperatures during the formation of these horizons. Comparisons between loess grain size records and Greenland dust records led to correlate these two types of soil horizons with Greenland interstadials owing to their lower dust content compared to stadials. Nevertheless, luminescence-based chronologies were still not precise/accurate enough to define an undisputable correlation scheme.

Owing to the scarcity of organic remains (wood, charcoals and bones) in west-European loess, we developed an appropriate protocol to obtain radiocarbon ages from earthworm calcite granules. These granules, as well as terrestrial mollusc shells, are indeed present in large amounts in both types of soil horizons. This protocol has been tested on 46 samples taken from all soil horizons of the loess sequences of Nussloch (Rhine Valley, Germany), which present one of the most comprehensive records of the last glacial period in Western Europe.

The resulting chronology confirms the link between each tundra gley and arctic/boreal brown soil formed between 47 and 20 ka ago with a unique Greenland interstadial (Figure). Furthermore, we also dated minor cryogenic horizons formed between 27 and 20 ka characterized by changes in grain size and in the molluscan fauna composition comparable to those of the main soils. Despite the absence of synchronous oxygen isotopic excursions, they surprisingly correlate with dust concentration minimums in Greenland ice cores, and with changes in several other marine and continental proxy records. These results reflect the high sensibility of loess environment to climate changes and a more complex climate variability at mid-latitude than in Greenland during the Last Glacial Maximum (Moine *et al.*, 2017).

This new dating protocol thus led us expect precise correlations between distant loess sequences and, combined with other proxies, the mapping of palaeoenvironmental conditions associated with each interstadial phase across Europe for the Middle and Upper Weichselian.

Paleoclimate implications from grain-size analysis of loess/paleosol sequences from the Carpathian Basin

Ágnes Novothny¹, Tamás Országh¹, György Varga², Gabriella Barta¹, Diána Csonka¹, Tamás Végh¹, Erzsébet Horváth¹
¹ELTE Eötvös Loránd University, Budapest, Hungary. ²Research Centre for Astronomy and Earth Sciences, Budapest, Hungary

Abstract

Great areas in the Carpathian Basin are covered by Quaternary eolian deposits, providing excellent archives for paleoclimatic and paleoenvironmental studies.

Detailed grain-size investigation of five loess-paleosol sequences (Süttő, Basaharc, Hévízgyörk, Villánykövesd, Beremend; Hungary) were carried out with sampling resolution of 2 cm. Time frame for the investigations were elaborated by luminescence (post-IR IRSL) and Amino Acid Racemization (AAR) dating.

The samples were only treated by 1% ammonium hydroxid, therefore they can be considered bulk samples. Test measurements were also carried out on samples which were also treated by HCl or H₂SiF₆ in order to dissolve carbonates, or any other minerals but quartz, respectively. Grain-size distributions were determined using a Beckman-Coulter LS 13320 PIDS laser diffraction particle size analyzer, covering the range of 0.02-2000 μm, at the Leibniz Institute for Applied Geophysics (LIAG), in Hannover.

Clay- and sand content and U-ratio were calculated from the grain-size distribution of each sample and these values were plotted against the depth of the profiles. Comparing the variation of these values and trends, temporal and spatial changes could be concluded. Most of the individual grain size distribution curves were polimodal, therefore numerical partitioning using Weibull distribution can be applied to separate finer and coarser components of the curves. Changes in the relative proportions of these components throughout all sequences can be interpreted as temporal and spatial changes of the different transport mechanism. Limitations, practicability of the method, as well as results and their interpretation will be presented in this study.

Thanks to the Leibniz Institute for Applied Geophysics, Hannover for the grain size measurements and to the Hungarian NRDIO projects K119366 and 100315. This study was also funded by the ÚNKP-17-4 and ÚNKP-18-4 New National Excellence Program of the Ministry of Human Capacities.

Correlation of the loess-paleosol bassets in a short distance: reconstruction of the 350 ka development of Basaharc section, Hungary

Horváth Erzsébet¹, Ágnes Novothny¹, Gabriella Barta¹, József Szeberényi², Diána Csonka¹, Tamás Végh¹, Balázs Bradák¹

¹ELTE, Eötvös Loránd University, Department of Physical Geography, Budapest, Hungary. ²Geographical Institute of Research Centre for Astronomy and Earth Sciences, Budapest, Hungary

Abstract

The loess-paleosol series at Basaharc superimposes the fluvial sediments of the II/b terrace of the Danube River in Northern Hungary (Gábris et al. 2012). The yard of the former brick factory exposes different parts of this series in different paleogeomorphologic positions and development. The identification and correlation of the paleosols is especially important because here are the type sections of two of the three paleosols Basaharc Double (BD₁₋₂) and Basaharc Lower (BA) (Horváth - Bradák 2014).

The complex and multiproxy investigation was carried out in the last years including descriptions of new profiles, detailed and systematic sampling for granulometry, for secondary carbonate and for stable isotope investigation. Macro-, meso- and micromorphology of the paleosols, diffuse reflectance spectroscopy, magnetic susceptibility, luminescence and radiocarbon dating, amino acid stratigraphy were used in order to make a clear identification of the different units. The statistical analyses of the results and the precise determination of the elevation and gradient of the paleosols from different outcrops provide a complex understanding of the environmental development of the last 350 ka at Basaharc.

The existence of the characteristic BD₁₋₂ paleosols has been refuted by some new studies of the Basaharc profile (Sümegi et al. 2011). Denying the existence of this pedocomplex would seriously influence the loess lithostratigraphy of Hungary. The western wall of the quarry is a very significant part because the whole loess-paleosol succession could be identified with all paleosols. The first correlations of the new profiles with the type section of BD already provided striking results. The MS curve and the pedogenic character of the macroscopically similar paleosol showed high degree of similarity. The other proxies and the absolute ages also support the correlation of the loess and paleosol units located in distinct parts of the quarry. Thus, the BD₁₋₂ obviously exists and it can be applied further as a lithostratigraphical marker of the Hungarian loess stratigraphy. The multiproxy analyses allow the correlation among the bassets based on the identification of the isochronous heterotype of MF, BD and BA paleosols.

Research was funded by the Hungarian NRDI K119366 project.

The spatial differentiation of chemical composition of the Late Pleistocene loess-palaeosol sequences in Poland

Jacek Skurzyński, Zdzisław Jary, Jerzy Raczyk, Marcin Krawczyk, Kamila Ryzner
Department of Physical Geography, University of Wrocław, Wrocław, Poland

Abstract

Loess-palaeosol sequences (LPSs) in Poland, because of transitional localisation in central part of Northern European Loess Belt, spatially differ in their characteristics from the west to the east. It is confirmed by different loess properties. However, little attention was paid to the geochemistry.

Concentrations of major elements in six Late Pleistocene LPSs across Poland (Biały Kościół, Dankowice, Skarszyn, Złota, Tyszowce and Strzyżów) were studied using unified AAS method (pre-processed by lithium borate fusion). All studied sequences are characterized by uneven distribution of major elements (Si, Al, Fe, Ca, Na, Mg, K, Ti and P) and geochemical indexes values (CIA - Chemical Index of Alteration, ICV - Index of Chemical Variability, Mg/Ca, K/Ca, Na/K, K/Al, Si/Al, Ti/Al, etc.) in the vertical sequences, clearly referring to palaeoclimatic conditions which control the intensity of pedogenesis. That variability is clearly visible on UCC-normalized spider-diagrams.

The most interesting are the differences in chemical characteristics between eastern and western Poland. That variability may be summarized e.g. by the CIA index, which is one of the most commonly used indicators for the reconstruction of palaeoclimatic and palaeoenvironmental conditions during the formation of LPSs. It is assumed that the CIA in the range of 50–65 corresponds to weak chemical weathering under a cold and dry climate, and the values 65–85 represent warm and moist palaeoclimatic conditions.

The results reveal that the western LPSs are much more chemically weathered and more abundant in elements commonly associated with weathering and soil processes in comparison with LPSs of eastern Poland. In western profiles, both for loess and pedocomplexes, CIA reaches values typical for moderate weathering in relatively warm and humid climate (for example in Biały Kościół the range is from 63.3 to 82.6). In eastern LPSs there is clear distinction between younger loess and older parts of the profiles. For example, in Tyszowce the S0 soil and the majority of the L1LL1 loess (up to 13.5 m in depth) were classified as weakly chemically weathered. The rest of the profile shows a similar, relatively high degree of chemical weathering (reaching a maximum value above 70 in L1SS1).

The spatial variability may be attributed to different climatic conditions during the deposition of loess, loess recycling process, different source areas or even disproportion between the thickness of the loess covers.

To explain that problem, the second stage of research began - the analysis of the major and trace elements is conducting exactly right now. The research of trace elements is performed under the National Science Centre project No. 2017/27/N/ST10/01208.

Digital data collection methods applied to Quaternary Sediments mapping in Ireland

Xavier Pellicer, Michael Sheehy

Geological Survey Ireland, Beggars Bush, Haddington Road, Dublin, Ireland

Abstract

Quaternary geological mapping field record descriptions have been traditionally collected with field notebooks and field maps often eschewing standardized field record descriptions. Technological developments during the last decades have allowed the incorporation of Global Positioning System data and enabled deployment of ruggedized field computers for field mapping. Several geology mapping software tools have been developed during the last decade and are currently used by Geological Surveys, mapping agencies and industry, with software often developed for, or tailored to, the organization's needs. The increased computational capacity of tablet computers and the migration of GIS software from desktop/laptop programme to ubiquitous tablet app have further streamlined the process of data gathering.

Historically the mapping of Quaternary features by geological surveys was presented as a map which focused the interpretation of field and desk-compilation data. Under this paradigm, the data underlying the interpretation was often retained in an ad hoc manner. The inaccessibility of these data restricted the ability of other users to develop alternative interpretations. In contrast with the former situation, field data gathered during current mapping campaigns is often a companion product to the map interpretation. Central to a useful field-data product is the use of standardised data collection protocols and forms in the mapping process. These, sometimes large, datasets can be easily manipulated using database query language or incorporated into conventional GIS software for visualisation and analysis.

The Geological Mapping Programme of the Geological Survey of Ireland has been developing, since 2014, a tablet computer GIS based field-data collection tool dedicated to mapping Quaternary deposits and landforms. Offline basemaps including, topographic and cadastral datasets, aerial photography, desk-compilation data and Digital Elevation Maps (DEMs) are produced for the area of interest and loaded to the computer tablet in advance of the field campaign. These datasets provide useful contextual information to the field geologist. Field records are collected via map and form-centric data gathering GIS apps. Geomorphological, mass-movement and groundwater features are collected using a map-centric application allowing for features delineation. Quaternary sediments exposures and borehole logs including descriptions of photographs, logs of individual layers, erratics, periglacial features, and samples are gathered with a form-centric relational database enabled app. This data is collected for every field site, and synchronized daily with other field geologists working in the area. This field data collection approach allows for the collection of standardized field descriptions, de-risks data security issues, reduces data processing time, enables data quality control during the field campaign and facilitates data interpretation, map unit delineation and reporting.

Leaving its mark; diverse Quaternary records abound in new geological survey mapping of the UK seabed.

Dayton Dove, Joana Gafeira, Rhys Cooper, Heather Stewart, BGS Marine Geoscience
British Geological Survey, Edinburgh, United Kingdom

Abstract

The usage of remotely-sensed acoustic data (e.g. multibeam echo-sounder [MBES] bathymetry, and CHIRP sub-bottom profiler) have become common, and still powerful tools in characterising submarine records of the Quaternary environmental change. For example, geomorphological assessment of extensive high-resolution bathymetry datasets has led to paradigm shifts in our understanding of the style, configuration, and relative timing of former glaciation around NW Europe. Simultaneously, large volumes of data have driven scientists to explore alternative approaches to characterising the seabed to improve mapping efficiency, but also accuracy, with a better measure of map uncertainty. The British Geological Survey (BGS) is using a range of publicly available bathymetry and backscatter data to provide baseline geospatial mapping of the seafloor to underpin original research, resource development (e.g. offshore renewables), and marine-spatial-planning (better-informed management of the seabed environment). To undertake the geomorphological mapping, BGS scientists are developing and adapting semi-automated approaches to detect, delimit, and classify geomorphological features, importantly including basic morphological description. Within a large case-study area off the east coast of Orkney, a method based on the unsupervised clustering of bathymetric derivatives (e.g. bathymetric lows vs. highs) at multiple spatial scales is very effective at efficiently mapping current-induced bedforms, ice-marginal moraines, and larger glacial landforms. A further case-study area off the west coast of Anglesey is testing how including categorical co-variables (like Quaternary geomorphology – e.g. drumlins) affect the power of geostatistical and machine-learning models in predicting seabed sediment and habitat distribution. The continued development and improvement of further quantitative mapping approaches is certain (e.g. learning algorithms), but agencies like the BGS also have a pragmatic remit to actively produce maps. The BGS is therefore concentrated on producing consistent geospatial products using novel semi-automated approaches, that importantly, also prove effective when applying across multiple, diverse submarine environments.

Geomorphological mapping and analysis of topography using digital elevation models and their implications to Quaternary sciences

Takashi Oguchi¹, Yuichi Hayakawa²

¹The University of Tokyo, Kashiwa, Japan. ²Hokkaido University, Sapporo, Japan

Abstract

Digital elevation models (DEMs) are one of the most widely used raster GIS data. They are acquired using surveying or geospatial methods and represent terrain characteristics with various spatial resolutions. Although almost all DEMs represent topography at present or in the very recent past, geomorphological mapping and analysis based on them may provide implications to Quaternary sciences which deal with long-term processes and environments in the past. We present three examples of such research conducted in Japan. The first case is topographic representation using shaded-relief maps from a 50-m DEM for a steep mountainous area in central Japan. The result indicates the presence of an unknown active fault displacing both hillslopes and small river terraces in a V-shaped valley. Terrace ages and the amount of displacement by the fault suggest a high rate of tectonic activity since ca. 50 ka. The discovery of the fault also led to a revision of glacial chronology in the area since the Middle Pleistocene, because previous studies mistook the fault scarp for a terrace scarp. The second case is an application of a 10-cm DEM obtained with terrestrial laser scanning for a coastal valley in northeast Japan. This valley was severely affected by the huge tsunami caused by the 2011 earthquake off the Pacific coast of Tohoku. The high-resolution data enabled us to detect small cliffs along the valley-side slopes, and their distribution tends to correspond to the highest inundation by the 2011 tsunami. Knowledge about regional tectonics and sea level change implies that the small cliffs were formed due to repeated wave erosion by some 100 large tsunamis since the mid-Holocene. The third case is research on a Middle Pleistocene marine terrace in northeast Japan using a 20-cm DEM obtained by SfM-MVS (structure from motion - multi view stereo) photogrammetry applied to drone photographs. The detailed topographic representation using the DEM and field surveys revealed geomorphological and sedimentological processes on the marine terrace surface induced by past large tsunamis. These examples indicate that DEMs become useful for Quaternary sciences when knowledge about paleoenvironments is appropriately introduced for effective and multidisciplinary interpretation of topography.

Simplifying GPR interpretations of coastal geomorphology using an image segmentation approach

Luis Rees-Hughes¹, Dr Adam Booth¹, Dr Natasha Barlow¹, Dr Jared West¹, Tim Grosse², Dr George Tuckwell²

¹University of Leeds, Leeds, United Kingdom. ²RSK Geophysics, Hemel Hempstead, United Kingdom

Abstract

During the last two decades, Ground-Penetrating Radar (GPR) methods have grown in popularity for acquiring high-resolution images of the buried stratigraphy and internal structure of geomorphologic features (Switzer *et al.* 2010). GPR provides a complement to established techniques, including sediment core-logging and in-field mapping of exposures which provide sparse 2D insight into the architecture of a study area. In geomorphological settings, GPR surveys have been used alongside core sampling where they typically link transects of boreholes but cannot reveal the full morphology of a site. A more comprehensive GPR survey can expand this insight into 3D, offering rapid, non-invasive characterisation of the shallow surface (~10 m maximum depth), with data interpretable in terms of the thickness, lithology, structure and extent of subsurface depositional environments (e.g. coastal, aeolian and deltaic deposits).

However, for all these advantages, GPR data interpretation can be non-intuitive: the technique seldom gives images that immediately resemble the expected subsurface geometry. Interpretations can be especially challenging when handling the large 3D data volumes that are commonly available with modern GPR technology. Most GPR analysis approaches rely on a manual processing, which can be laborious and subjective (Tronicke and Allroggen, 2015). Approaches involving automation are therefore attractive, but current approaches can be computationally intensive and have yet to be optimized for the full suite of typical GPR responses (Dou *et al.* 2017). In this paper, we outline the first steps toward the development of a user-friendly, automated GPR analysis tool that utilizes the image processing techniques *Edge Detection* and *Thresholding*. Developed initially for medical image analysis, we investigate them as a means of assisting the analysis of GPR data for subsurface geomorphic features. By segmenting and extracting the primary reflections of interest, such algorithms provide a first-pass appraisal of the structure of a site.

Here, we present the results of the segmentation algorithm applied to a coastal geomorphic GPR dataset. The algorithm is capable of rapidly delineating reflections from lithological layers and buried sedimentary structures (Fig. 1), hence it offers a useful tool for the GPR user to appraise the content of their GPR dataset.

Geological heterogeneity, impeded groundwater drainage and enhanced meltwater erosion in the formation of Stargard drumlin field, NW Poland

Piotr Hermanowski¹, Jan A. Piotrowski², Izabela Szuman³

¹Institute of Geology, Adam Mickiewicz University, PL-61-680 Poznań, Poland. ²Department of Geoscience, Aarhus University, DK-8000 Aarhus, Denmark. ³Institute of Geoecology and Geoinformation, Adam Mickiewicz University, PL-61-680 Poznań, Poland

Abstract

Drumlins are landforms vital to our understanding of ice sheet movement over soft beds, sediment transport along the ice/bed interface, and the formation of a wide range of glacial deposits. Although investigated more than any other glacial landform, the origin of drumlins remains contentious leaving some fundamental questions of the interactions between ice sheets and their beds open. The Stargard drumlin field is one of the biggest drumlin fields in the North European Lowland - it consists of over 1300 drumlins and related streamlined bedforms nested in the terminal part of a major Weichselian palaeo-ice stream. The drumlins are typically 600-800 m long, 200-250 m wide, 3-6 m high and have elongation ratios of mostly around 2. Several morphometric subzones in the drumlin field are distinguished reflecting different ice flow dynamics. The Stargard drumlins are composed of a great variety of glacial deposits including various types of tills and meltwater sediments, which are either undisturbed or heavily deformed. The spatial characteristics of the drumlins are unrelated to the drumlin deposits and drumlin surfaces often truncate these deposits suggesting that the drumlin shaping post-dates the deposits inside the drumlins.

Numerical modelling of subglacial groundwater flow during the drumlin-forming ice advance shows a total re-organization of groundwater dynamics to a depth of up to ~200 m. A mosaic of intervening groundwater recharge and discharge areas originates whereby some areas experience multiple shifts in groundwater flow directions. A prominent time- and space-transgressive pressure pump recharges groundwater in a subglacial zone up to about 20 km within the ice margin and releases it in front of the ice sheet. Simulations suggest that the drumlins occur preferentially where groundwater upwells and discharges at the ice/bed interface.

The proposed drumlin-forming mechanism involves an excess of pressurized water at the ice/bed interface. The drumlin field was likely generated by some combination of direct glacial erosion and turbulent subglacial meltwater erosion removing antecedent material from the inter-drumlin areas and streamlining the resultant bumps. Our data yield support to the quest for a unifying theory of drumlin formation and suggest erosion as the most plausible single mechanism generating drumlin landscapes, which also explains the enigmatic diversity of drumlin deposits and the frequent lack of obvious deposit/landform relationships.

O-1202

Erosional origin of sediment-cored drumlins and megascale glacial lineations: upper tills as thickened erodent layers

Nick Eyles¹, Riley Mulligan², Kirsten Kennedy¹, Shane Sookhan¹

¹University of Toronto, Toronto, Canada. ²Ontario Geological Survey, Sudbury, Canada

Abstract

The origin of drumlins is widely studied but not well understood because modern formative processes are hidden under ice and where exposed the geology of their cores is highly variable. Urban construction activity and aggregate mining across Late Wisconsin drumlins and megascale glacial lineations (MSGs) near Peterborough, Ontario, shows that they are streamlined remnants of antecedent bouldery till and (mid-Wisconsin?) proximal outwash. Cores are capped erosively by a thin (< 2 m) cap of 'upper till' formed by deformation and re-transport of antecedent sediment. The deforming till bed acted as a thin 'erodent layer' preferentially removing sediment from poorly-drained swales and flowing around stiffer, better-drained remnant drumlin highs. A bedform continuum of megadrumlins, drumlins, 'grooved' or 'cleaved' multi-crested drumlins and MSGs is evident on high-resolution LiDAR imagery and records progressive elimination of higher-standing drumlins by a faster-flowing channeled erodent layer below a developing ice stream during deglaciation.

The geological variety of drumlin cores in areas of Pleistocene glaciation has hitherto retarded development of a single formative model but the necessary conditions for erosion of many millions of genetically-related 'remnant' drumlins and MSGs with a thin upper till draped erosively over cores of widely varying antecedent sediment types (and rock) were satisfied over large parts of the glaciated mid-latitudes in North America and Europe as consequence of ice standstill and/or withdrawal and widespread proglacial sedimentation during the mid-Wisconsin. Expansion of ice sheets after 30,000 ybp resulted in overriding and subglacial re-transport of sediment and re-deposition as thick till sheets that were subsequently streamlined into drumlins that in turn, were re-fashioned into MSGs in areas of fast ice flow. Laboratory experiments on surfaces in frictional contact and observations of the surface morphology of fault planes of increasing net slip show the evolution of erosion surfaces from elongate bumps (i.e., drumlins) to geometrically simple surfaces characterized by long striations and grooves (i.e., MSGs) to reduce friction and aid movement of wear debris (i.e. deforming till) . Ice sheet beds are essentially continental-scale faults that evolve through time in a predictable manner.

Climate changes at Matuyama-Brunhes boundary as reconstructed from the Račiška pečina cave flowstones (SW Slovenia)

Helena Hercman¹, Marcin Błaszczuk¹, Michał Gąsiorowski¹, Jacek Pawlak¹, Pavel Bosák², Šarka Matoušková², Petr Pruner², Paula Sierpień¹, Nadia Zupan-Hajna³, Andrej Mihevc³

¹Institute of Geological Sciences, Polish Academy of Sciences, Warsaw, Poland. ²Institute of Geology of the Czech Academy of Sciences, Praha, Czech Republic. ³ZRC SAZU Karst Research Institute, Postojna, Slovenia

Abstract

Račiška pečina is a relict cave located in the Matarsko Podolje (SW Slovenia), a part of the Classical Karst massif. Unique series of sediments composed of interbedded flowstones and red clastic sediments have been preserved in the main cave passage. The studied sediment section is about 13 m long with the cumulative thickness nearly 6.5 m. Detailed paleomagnetic studies, combined with mammalian zoopaleontology and some numerical dating, allow to estimate the start of flowstone deposition on over 3.4 Ma and the termination at ca 6 ka, i.e. from early Pliocene to Holocene, with some hiatuses. Reddish light brown flowstone, ca 23.5 cm thick, was collected from the upper part of the section. The boundary of Matuyama and Brunhes Chrons (M/B) was found there at the depth of ca 17.5 cm.

Speleothems are valuable source of information on environment condition in the past. Calcite stable isotopes (O and C) composition, calcite fabrics as well as trace elements content provide data on depositional conditions of speleothems, including mean annual temperature, precipitation intensity, water drip intensity in the cave, water flow character or the amount of allogenic material supplied to the cave.

Most of studied flowstone is built of calcite micro-facies similar to dendritic fabric with characteristic high porosity, significant content of detrital material and V-shaped appearance of branching polycrystals. The most significant changes were related to the M/B boundary zone, where dendritic open fabric changed to columnar microcrystalline one (with the highest calcite crystals purity throughout the analyzed flowstone) on a relatively short distance. Other transitions are less noticeable.

Oxygen isotopic composition ($\delta^{18}\text{O}$) of analyzed flowstone changes within the range of 3 ‰ (from -4.5 to -7.5 ‰). Characteristic rapid and short-lasting decrease in the $\delta^{18}\text{O}$ value (ca. ~ 1 ‰) was observed at the M/B transition. Carbon isotopic composition ($\delta^{13}\text{C}$) changes within similar range (~ 2.7 ‰) from -8.3 ‰ to -11 ‰. The $\delta^{13}\text{C}$ values drop of ~ 1 ‰ at the M/B transition, i.e. similar to the oxygen isotopic record. Isotopic record was correlated with other proxies from studied flowstone section, i.e. trace elements relative content or magnetic susceptibility. All proxies have indicated clear change of paleoenvironmental conditions at the M/B boundary, namely higher amount of precipitation and decline in mean annual air temperature.

The study was supported by "OIS" - an internal project of IGS PAS and by the bilateral mobility cooperation PAN-17-22 between Czech Academy of Sciences and Polish Academy of Sciences.

¹School of Archaeology, Geography and Environmental Sciences, University of Reading, Reading, United Kingdom.

²Institute of Archaeology, University College London, London, United Kingdom. ³British Geological Survey,

Nottingham, United Kingdom. ⁴School of Biosciences, University of Nottingham, Nottingham, United Kingdom

Abstract

A number of factors make the eastern Fertile Crescent (present day north-east Iraq) inherently suitable and attractive for palaeoclimatic investigations. Firstly, it is located at the transition zone between two major climate regimes, North Atlantic Westerlies and the Indian Summer Monsoon system, making it especially susceptible to shifts in climate. Secondly, it has a long and rich history of human occupation throughout the Holocene, making it ideal for the investigation of human-environmental relationships. Thirdly, the Fertile Crescent has been identified as a climate change 'hotspot' and palaeoclimate reconstructions can help to place modern climate into a meaningful perspective. The production of high resolution palaeoclimate records can therefore be used to test model simulations to help predict future shifts in climate, particularly changes in water availability. However, no well dated, highly resolved and long Holocene records currently exist covering the eastern Fertile Crescent.

Here we present the first high resolution multi-proxy speleothem palaeoclimate record covering the entire Holocene from northeast Iraq in an attempt to identify and investigate the presence and magnitude of Holocene climate variability. The stalagmite (SHC-03) is 3.17m long and was collected from Shalaih Cave, Iraqi Kurdistan. It is sampled at a ~5-10 yr resolution and covers the last ~10,300 years. We use a multi-proxy approach through the use of oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotopes and trace element (Mg/Ca and Sr/Ca) analysis.

There is a strong link between the long-term changes in the SHC-03 $\delta^{18}\text{O}$ profile and changes in the $\delta^{18}\text{O}$ of the Eastern Mediterranean Sea, implying a strong 'source effect'. Changes in the $\delta^{18}\text{O}$ of the Eastern Mediterranean Sea during the Holocene are controlled by the amount of freshwater outflow from the River Nile related to monsoon intensity. As a result, we propose some caution should be taken when interpreting $\delta^{18}\text{O}$ from the Eastern Mediterranean paleoclimate records as a proxy for rainfall amount.

Overall our data (including $\delta^{13}\text{C}$, trace element concentrations and $\delta^{18}\text{O}$ (on shorter timescales)) provide an important understanding of variations in effective moisture throughout the Holocene as well as the environmental context for significant archaeological developments that occur during this period in this region.

Control of climate characteristics on accumulation of pedogenic carbonate: observations and modeling

Onn Crouvi¹, Tali Horowitz^{1,2}, Lior Siman-Tov^{1,2}, Efrat Morin², Craig Rasmussen³, Jon Pelletier⁴, Ravid Rosenzweig¹

¹Geological Survey of Israel, Jerusalem, Israel. ²The Institute of Earth Sciences, Hebrew university of Jerusalem, Jerusalem, Israel. ³Department of Soil, Water and Environmental Science, The University of Arizona, Tucson, USA.

⁴Department of Geosciences, University of Arizona, Tucson, USA

Abstract

Calcic soil is one of the most widespread aridic soil groups, covering an estimated area of 10^6 km² in arid to semi-arid regions worldwide. Calcic horizons form through airborne supply of calcium to the soil surface with dust and rainfall, leaching of carbonate from the surface and upper horizons of the soil, and subsequent precipitation and accumulation of carbonate in lower soil horizons at a depth controlled by soil moisture and texture. In general, climatic control on soil carbonate accumulation is known for decades: depth of calcic horizon increases with increasing mean annual precipitation (MAP). This relationship is being used to estimate Quaternary (and older) MAP from buried soils. However, the effects of other climate characteristics, mainly intra-annual rainfall properties and evapotranspiration (ET), on pedogenic carbonate accumulation were rarely examined in the past. Although mostly overlooked as a controlling factor, previous preliminary qualitative results suggest that rainfall seasonality might be important in controlling the distribution and depth of calcic horizons. In this study we examine the importance of intra-annual rainfall properties in controlling the distribution of soil carbonate using two approaches: 1) Meta-analysis of hundreds profiles of soil carbonate from two arid and semi-arid regions: Israel, in which rainfall occurs only during winter, and from south-western US, in which summer rains prevail in addition to winter rains. 2) Modeling long-term soil water distribution and wetting depths, and examining how rainfall properties, such as daily rainfall, rainfall event duration and number of rainfall events, control the wetting depths (served as a proxy for pedogenic carbonate accumulation). The results of the meta-analysis reveal that 1) soil carbonate content in Israel is higher (<40%) comparing the American soils (<20%), probably due to the presence of carbonate-rich bedrock in Israel; 2) For a given MAP range, areas with higher percentage of winter rainfall exhibit lower soil carbonate content and deeper calcic horizons, comparing regions with more pronounced summer rains. This is probably due to the fact that for winter rainfall, water arrives when cool (greater CO₂ solubility) and less ET demand, thus water reach deeper depths, while for summer rainfall, water arrives when hot (lower CO₂ solubility) and most water is contributed to ET, thus shallower carbonate accumulation is observed. Our modeling results suggest that for a constant MAP, varying rainfall properties can greatly influence the depth of pedogenic carbonate accumulation. Thus, both observations and modeling results call for cautious in estimating MAP from buried calcic soils as additional rainfall properties can greatly affect the distribution of calcic horizons.

Farmed calcite $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ at Ascunsă Cave (Romania) and its relation with cave ventilation and drip rate

Virgil Drăgușin¹, Bety Burghele², Nicolae Cruțeru¹, Vasile Ersek³, Ionuț Mirea¹, Laura Tîrlă⁴

¹Emil Racoviță Institute of Speleology, Bucharest, Romania. ²Babeș –Bolyai University, Cluj-Napoca, Romania.

³Department of Geography and Environmental Sciences, Northumbria University, Newcastle upon Tyne, United Kingdom.

⁴University of Bucharest, Faculty of Geography, Bucharest, Romania

Abstract

During calcite precipitation in caves, its carbon and oxygen stable isotope signature could be modified by the ventilation regime of the cave (namely the PCO_2 gradient between drip water and cave atmosphere) and drip rate. Here, we present measurements of these parameters within Ascunsă Cave (Romania), where they were determined following the methods described in Drăgușin et al. (2017), at the growth sites of neighbouring stalagmites POM2 and POM X.

Since early 2015, drip water PCO_2 was always higher than in the atmosphere. At the POM2 monitoring site, the highest value was 0.007 atm, whereas the highest atmosphere value was 0.003 atm. Over the monitored period, the average PCO_2 difference between drip water and cave atmosphere was 0.004 atm. At the same time, average drip rate was 15 drips/min, but experienced an extended baseline period between July 2017 and March 2018, at ~ 2 drips/min.

To gain more insight into cave ventilation processes Radonova Radtrack² radon detectors were used to measure Rn concentrations in cave air and water-air equilibrators. Drip water has a much higher Rn concentration than the cave air. Between May and August 2018, cave air had a concentration of 3700 Bqm⁻³, whereas inside the equilibrator we found 27000 Bqm⁻³. Such a large difference was also seen between August and October 2018, with 2600 Bqm⁻³ and 15400 Bqm⁻³, respectively.

Whereas in Drăgușin et al. (2017) we observed a good correlation between farmed calcite stable isotopes and a theoretical degassing gradient possibly produced by cave ventilation, here we discuss for the first time the relationship between measured stable isotope values and cave ventilation as revealed by direct observations. These insights will help us better understand Holocene stable isotope time series from these two stalagmites.

Quaternary thermophilous land snails: early climate change “immigrants” during interglacial periods in Northern France ?

Nicole Limondin-Lozouet, Julie Dabkowski

UMR CNRS 8591, Laboratoire de Géographie physique : Environnements quaternaires et actuels, Meudon, France

Abstract

Quaternary climatic cycles have had a strong effect on species distributions in general and on continental mollusc expansion in particular. During glacial periods most non-marine molluscs vanished from North-Western Europe but during interglacial episodes, they progressively spread from refugia to recolonise these once periglacial territories. Interglacial malacofaunas thus provide a good proxy for evaluating biogeographical and biodiversity changes during the Pleistocene. Calcareous tufas are key-deposits for both malacological successions and palaeoclimatic reconstructions of Interglacials since they are characteristic deposits of temperate periods, favourable to shell preservation and resulting of calcite precipitation from meteoric water. In Northern France, several calcareous tufas have yielded rich molluscan successions allowing the reconstruction of faunal history for three interglacial periods from the Middle Pleistocene to the Holocene. Specific assemblages of land and aquatic snails, including several species that are now extinct or beyond their modern range, can be recognised for each temperate episode. Detailed Middle Pleistocene malacological successions described from two thick tufa sequences, respectively dated to MIS 11 (424-374 ka) and MIS 5e (~125 ka) show common features in the malacological recolonisation. At both sites, the appearance of forest species occurs as successive events related to the present-day geographical ranges of the component species. Those of the earliest forest phase at the beginning of the interglacial consist of species with North and West European ranges. Species with Central European distributions appear just before the warmest phase, whereas Eastern and Southern European species appear only later during the optimum itself. Similar successive arrival of forest land snails are registered during the Holocene but lacks the eastern and southernmost faunal elements. The very same sequences have been investigated for variations in the $\delta^{18}\text{O}$ and the $\delta^{13}\text{C}$ of tufa calcite to reconstruct changes in regional air temperature and rainfall amount. Geochemical data highlights the similarities and differences between the studied interglacials. While warm and wet optima are clearly identified during MIS 11 and MIS 5e, Holocene records show a distinct pattern. Diachronic comparisons show similar to slightly warmer conditions during MIS 5e compared to the Holocene, while MIS 11 interglacial appears clearly warmer. Both MIS 5e and MIS 11 were wetter than the Holocene, especially when comparing optima. In terms of amplitude, ambient moisture recorded during MIS5e shows little variations compared to MIS 11 and the Holocene. These differences have affected continental species distribution revealed in mollusc expansion and diversity.

O-1209

The late-Holocene tufa decline in Europe: myth or reality?

Julie Dabkowski

CNRS-Laboratoire de Géographie Physique, Meudon, France

Abstract

In 1993, Goudie and co-authors named the postulate that there would be a marked decline in the deposition of calcareous tufa in Europe since c. 2500 BP 'the late-Holocene tufa decline'. The concept got a certain success in the community of researchers working on travertines and tufas and the paper has been then extensively and regularly cited. However, its main topic was actually not to demonstrate the existence of such a decline but to discuss the role of various natural and anthropogenic changes that may have affected tufas; the authors themselves wrote: "In many parts of Europe there appears to be evidence for a decline in tufa deposition rates since the mid-Holocene. However, the veracity of this trend needs to be investigated further". Nevertheless, the 'late-Holocene tufa decline' rapidly became nearly a paradigm and then, most discussions have concentrated on its causes and mechanisms or, in the case of long Holocene sequences including recent to modern tufa depositions, on the reasons justifying the absence of a such decline. Parallel, it was also debated by authors showing that active tufa deposition were considerably underreporting; an observation that in turn suggests that the same has occurred for fossil sites.

In the last decades, the growing development of investigation on calcareous tufas in Europe and considerable improvement in dating methods, especially radiocarbon dating, have provided reliable evidence of deposits developing until our present days. Including relative dating (through bio-stratigraphy), we here discuss the reality of the 'late-Holocene tufa decline' and distinguish various cases depending on tufa types and size, and geographical settings. We show that a decline is systematically observed in riverine tufa deposits but not when (slope or mire) spring-fed tufas are considered, which emphasises the variety and complexity of involved mechanisms. Such a clarification thus appears mandatory prior discussions on the (climatic or anthropogenic?) causes of such a decline.

Facies characterisation of Quaternary spring-related stromatolite build-ups discovered in the Tunceli Region (East, Turkey)

cihan aratman¹, Gamze Karvar², Calibe Koc Tasgin², Rudy Swennen¹

¹KU Leuven, Department of Earth and Environmental Science, Leuven, Belgium. ²Firat University, Department of Geological Engineering, Elazig, Turkey

Abstract

Systematic relationship between Quaternary stromatolite facies and their C and O isotopic composition are used to mark changes in environment conditions with regard to vent location in the Tunceli region carbonate factory. The study area consists of various facies developed from pool to barrage, and towards high gradient slope environment as follows: subaerial stromatolite, domal oncoidal stromatolite (DOS) interfingering with phyto boundstone of moss-stems, domal non-oncoidal stromatolite (DNOS), wavy laminated stromatolite (WLS), respectively. WLS and DNOS facies form upward from the bottom of slope environment, respectively. The WLS comprises of a regular alternation of sparitic dendrite to arbustiform shrubs fabric with micritic chrinomoid larval laminae; whereas, the DNOS facies consists of entirely radial palisade shrubs fabric. DOS facies, formed in a slope environment, possesses the alternating fan-shaped sparitic dendrite shrubs and thin micrite laminae. The latter facies, occurred in a barrage environment, contains a nucleus with tree trunk or phytoclasts interfingering with lime muds and a crust with chironomid larvae laminae, surrounded by sparitic dendrite shrubs and calcite spherulites. Subaerial stromatolite facies in the pool environment has a cross-bedded alternation of calcrete laminar crust containing microcodium and extraclasts, and massive peloidal micrite, with vaterite spherulites growing within lime muds, in shallow, high energy environments. Phyto boundstone composed of the stacked moss layers with rhombohedral calcites, which clumped around the eroded microbial filaments, along with oviform bacteria living in EPS in the barrages to pools environment where alluvial conglomerates wedge to the DOS facies. Etching with Hydrochloric acid revealed many microbial communities between shrub branches in the DNOS facies, besides released abundant detrital clays in the DOS facies. These communities consist of microcolonial fungi, oviform- or tabular-shaped heterotrophic bacteria and cyanobacteria filaments. The latter filaments are accompanied by clumped peloids growing in subaerial biofilm.

The $\delta^{13}\text{C}$ values display a wide distribution stretching from +0.57‰ to +5.84‰; whereas, the $\delta^{18}\text{O}$ has a narrow range of -9 ‰ to -11‰. The $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ signatures become heavier and much lighter, respectively, from the pool environment with subaerial stromatolite facies towards the barrage environment with the DOS and phyto boundstone facies. Moreover, the $\delta^{18}\text{O}$ values decreases gradually, while the $\delta^{13}\text{C}$ values remain stable from DNOS and DOS facies in the slope environment towards DOS with abundant chrinomoid larval laminae, formed in the barrage environment. These values correlate well with the observed facies and environment variations and create an inversed-L trend indicating (i) high discharge from a vent issuing closer to slope environment and (ii) an increase of CO_2 degassing and precipitation temperature. These results are reported for the first time and indicate biotic-induced and spring-related carbonate build-ups, developed locally along NW-striking dextral strike-slip faults in the East Anatolian Plate of Turkey.

Abstract

The Neotoma Paleoecology Database (<http://neotomadb.org>) contains 32,000 unique datasets representing 266,000 individual physical samples and 5.3 million unique observations. Sample ages in Neotoma are related to one (or several) of the 18,000 chronologies in the database that are modeled, based on a range of chronological controls that are calibrated using various calibration models, and reported with varying degrees of accuracy. A strength of the Neotoma Database is that, in most cases, the raw data associated with these chronologies is preserved, allowing users to re-build chronologies as new methods become available, or reassess individual dated elements as new evidence becomes available.

Recent efforts to understand biological change in the northeastern United States provided an opportunity to investigate the artifacts that these varied chronologies may have on interpretations of change in the region at an aggregate scale. This presentation highlights the workflow required to undertake such an effort and several key findings. In particular we highlight treatments for missing 210Pb uncertainty estimates. We show that newer chronologies that account for artifacts of methods and data within Neotoma show higher rates of turnover in the post-settlement period, and we present new methods for dealing with broad-scale uncertainty and variability among chronologies.

This work has been developed in close collaboration with Neotoma, and resulted in an open workflow for undertaking similar efforts globally (<https://github.com/neotomadb/bulk-baconizing>). We highlight both the findings, and the utility of community data repositories in making these findings available and reusable for the entire paleoecology community.

A database for annually laminated lacustrine climate archives

Arne Ramisch¹, Alexander Brauser^{1,2}, Mario Dorn¹, Rik Tjallingii¹, Achim Brauer¹

¹GFZ German Research Centre for Geosciences, Potsdam, Germany. ²Freie Universität Berlin, Berlin, Germany

Abstract

Annually laminated (varved) lake sediments provide a unique opportunity to investigate causes and effects of past climate change on seasonal to millennial time scales. So far, most studies focused on individual records and a synthesis of varved lake records is still lacking. However, precise synchronization of such sediment records remains the main challenge to re-evaluate pre-existing records in a comprehensive synthesis and to evaluate different proxy responses to climate change. We generated a database for high-resolution climate proxies obtained from varved lake archives. It currently comprises of 150 climate proxy records (e.g. varve thickness, element composition and stable isotopes) from 55 varved lake archives, ranging in length from 41 to 47000 years. Based on varve thickness and counting, we provide estimates of sedimentation rates to modify existing age models. In combination with published ¹⁴C dates, these improved estimates are used for Bayesian age-depth modeling to quantify age uncertainties. The refined age models were synchronized using event layers (e.g. tephra layers) if available. All records and refined age-depth models are standardized and stored in a graph database that allows fast access for Big Data analysis techniques.

To assess the role of local lake, catchment and environmental characteristics in modifying proxy responses to climate change, we collected and standardized lake (water body characteristics), catchment (geology and topography) and environmental (climate and vegetation) parameters from the literature and freely accessible online sources. The information is used to re-evaluate variations of varve thickness records during the last 2000 years with respect to the role of lake-catchment characteristics. We demonstrate that comprehensive databases have a great additional value for refining chronologies of paleoenvironmental archives and are essential to decode paleoclimatic information from sediment proxy records.

Reading past landscapes: quantified reconstructions of past land cover from pollen data

Michelle Farrell¹, Jane Bunting², Phil Barratt³, Alex Bayliss⁴, Henry Chapman⁵, Kim Davies³, Ben Gearey⁶, Willem Koster⁷, Peter Marshall⁴, Nika Shilobod³, Nicki Whitehouse³, Alasdair Whittle⁸

¹Coventry University, Coventry, United Kingdom. ²University of Hull, Hull, United Kingdom. ³University of Plymouth, Plymouth, United Kingdom. ⁴Historic England, London, United Kingdom. ⁵University of Birmingham, Birmingham, United Kingdom. ⁶University College Cork, Cork, Ireland. ⁷Utrecht University, Utrecht, Netherlands. ⁸Cardiff University, Cardiff, United Kingdom

Abstract

Land cover is an important component of the earth system, both through the habitats it provides for living organisms and via its interactions with other major components (e.g. with the hydrosphere via modification of water flow, and with the atmosphere and climate system through albedo and evapotranspiration). Land cover is variable in both space and time, and reconstruction of past land cover is important for research into the long-term dynamics of the earth system (e.g. testing regional climate models), as well as for smaller-scale studies of ecosystem processes (which may feed into conservation management and predicting the effects of future environmental change), or of controls on and environmental impacts of past human activity.

Reconstruction of past land cover from pollen records has traditionally taken a broadly narrative approach, with relatively few attempts at hypothesis testing or formal assessment of uncertainty. The Multiple Scenario Approach (MSA) offers a radically different way to synthesise existing pollen data and reconstruct past land cover (Bunting et al. 2018) by generating spatially explicit land cover reconstructions for identified isochrones (“time windows” or “timeslices”) which can be presented visually, e.g. as maps or virtual reality reconstructions of particular sites or landscapes, or as quantitative measures of landscape properties (e.g. amount of open land) tracked over time. This method depends critically on the availability of pollen data which can be assigned to specific isochrones, and given the costs of producing high-resolution pollen records that are well-constrained chronologically, the MSA is heavily reliant on archived data.

An ideal data point for the MSA has the following properties:

- counts of all pollen taxa with clear taxonomic naming to allow for resolution of any taxonomic differences between records
- position information to <100m accuracy
- contextual information on the formation of the pollen assemblage (e.g. nature of any local vegetation, size of sedimentary basin)
- sufficient chronological information to confidently assign it to an isochrone

We present our experiences with three MSA case studies in the UK (the Somerset Levels and Moors, the Heart of Neolithic Orkney World Heritage Site, and the Humberhead Levels) and consider the challenges encountered in retrieving data and the implications for data loss more generally (for example, we identified 28 suitable pollen records for the Neolithic in the Somerset Levels and Moors, none of which were archived in the European Pollen Database or Neotoma).

What if fossil pollen records had more things to say?

Manuel Chevalier¹, Brian M. Chase², Lynne J. Quick³, Basil A.S. Davis¹

¹Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland. ²Institut des Sciences de l'Evolution-Montpellier (ISEM), University of Montpellier, Centre National de la Recherche Scientifique (CNRS), EPHE, IRD, Montpellier, France. ³African Centre for Coastal Palaeoscience, Nelson Mandela University, Port Elizabeth, South Africa

Abstract

Of all the fossil proxies that have been developed over the last century by Quaternary scientists, pollen has been the most commonly employed across a large array of environments. However, the multivariate nature of these data makes interpretations complex, and their full potential is rarely realised. To facilitate optimised interpretations and make the most of these rich datasets, robust statistical methods may be used to extract an array of significant palaeoenvironmental signals. Unfortunately, the most commonly used transfer functions (*e.g.* MAT (modern analogue technique) and WA-PLS (Weighted Averaging Partial Least Squares)) can only be used in areas where extensive datasets of modern samples are available, such as North America and Europe, have therefore have a strong spatial bias. This has led to the creation of *large quantification deserts*, *i.e.* regions where no or very few quantified reconstructions have been produced, often despite an abundance of fossil records.

The new statistical transfer function we have developed, entitled CREST for Climate REconstruction SofTware, proposes a new global solution regarding this issue. CREST uses probability density functions (*'pdfs'*) fitted on modern occurrence data to reconstruct environmental parameters, and offers many advantages over these classical approaches, such as 1) a higher flexibility of application, 2) a better capacity to estimate uncertainties, and thanks to some recent developments that will be presented in this paper, 3) is now applicable at a global scale by employing freely-available datasets. The method will be presented through a series of case studies based on the reinterpretation of southern African pollen records. These records have been extracted from the pre-existing African Pollen Database, their chronologies recalibrated and the pollen taxonomy harmonised. In these examples, we have reconstructed past temperature and rainfall dynamics from the quantification desert of southern Africa, which has led to an improved understanding of the glacial-interglacial dynamics of the African rainbelt.

In today's 'big data' world, CREST offers a unique potential to reconstruct climate from the re-evaluation of large compilations of pollen records (European Pollen Database, the Neotoma database, the Latin American Pollen Database, *etc.*) and to provide new insights about past environmental dynamics at different spatial and temporal resolutions across the globe.

Early to Middle Holocene paleolandscapes along the Scheldt estuary. Regional subsurface reconstruction through archaeological, geological and geotechnical legacy data

Jeroen Verhegge, Philippe Crombé
Ghent University-department of archaeology, Ghent, Belgium

Abstract

During the last two decades, large infrastructure works along the Lower Scheldt river in NW-Belgium, in particular in the Waasland Scheldt polder region, have revealed deeply buried and well-preserved Late Glacial to Middle Holocene wetlands and associated Final Palaeolithic to Early Neolithic archaeological sites [1]. The combination of paleoenvironmental and archaeological data retrieved from these locations provides a unique image of the intimate relationship between prehistoric hunter-gatherers or early farmer-herders and the contemporary environment as well as the impact of rising sea- and ground water levels on both vegetation and humans [e.g. 2]. This paper presents results of new research, which has collected all available legacy lithological data from geoarchaeological coring projects, geological core descriptions and geotechnical cone penetration testing data [3]. The systematic approach to interpret these largely diverse data within a single informal lithostratigraphic framework will be addressed as well as the creation of a regional lithostratigraphic subsurface model with particular attention to uncharted Early Holocene tributaries of the river Scheldt. The potential and limitations of using such legacy data will be reviewed, perspectives and guidelines proposed for future data collection e.g. in development-led (geo-)archaeology. The results will be used to review and improve existing paleogeographic reconstructions by Missiaen *et al.* [4]. They will also illustrate changing landscape resource exploitation strategies, such as the settlement focus on sand ridges along beforementioned Early Holocene tributaries by Early Mesolithic hunter-gatherers. Next, the occupation of the floodplain gradually decreases as it is covered by (alder carr) peat and focuses on the Scheldt river banks during the Middle and Late Mesolithic. Subsequently, the floodplain is re-occupied by Early (to Middle) Neolithic farmer-herders at the time of a short period of freshwater (supra-)tidal influence [5], after which peat development resumed and the floodplain is largely abandoned by humans until historic times.

Predictive site modeling for pre clovis buried materials in central Texas

Rebecca Taormina, Lee Nordt
Baylor University, Waco, USA

Abstract

Deciphering the timing and migration of the settlement of early Americans has been an important question in archaeology for decades. Buried site potential models allow researchers to save time, money, and resources when searching for new excavation sites. Different layers of surface data, including landform age, landform stability, and landform type, combine in Geographic Information System (GIS) to create a map that indicates areas of low to high potential for buried materials of a particular time interval. Expediting the search for more pre-Clovis components will increase hypothesis testing to improve theories on the timing of the arrival of first Americans, including understanding migration pathways from Asia, and reconstructing settlement patterns and understanding subsistence strategies as the early settlers moved across the continent. Also, finding more pre-Clovis materials is essential to a better understanding of lithic technologies and how they compare to Clovis material. We can then see how Clovis originated and if Clovis technology developed from the earlier tools rather than independently. Reconstructing climate indicators at new sites can explain how the environment may have affected the early settlers and how they adapted their technologies. Finding more pre-Clovis sites increases the chances of finding pre-Clovis skeletal remains that will extend the genomic history of the early Americans as well as fortify the Siberian dispersal theory.

The target of this site prediction model was central Texas, specifically the Salado Creek Watershed that includes Buttermilk Creek where the Debra L. Friedkin and Gault sites are located. The location was selected because it has evidence for successive occupations dating back to, and including, pre-Clovis peoples between 13,200 and 15,500 yr BP. Because these sites are well documented, they provide an ideal background for creating a predictive model for locating other buried pre-Clovis remains in the region. Surface features determine the likelihood of locating the same buried stratigraphy as described for the Debra L. Friedkin Site in our preliminary model. Landform age and stability is delineated by flood frequency data, erosion data, soil types from soil maps, and elevations from topographic maps, or more precisely Web Soil Survey.

The preliminary buried site potential model indicates areas of high-buried site potential in the northern portion of the Buttermilk Creek-Salado Creek Subwatershed. These locations indicate the highest potential to locate subsurface data similar, if not the same, as the Debra L. Friedkin and Gault sites. Eight transects with both high and low potential were selected to validate the model. Samples were measured for particle size, organic carbon, calcium carbonate, pH, extractable cations, and most critically optically stimulated luminescence (OSL). Age dating was used to determine the relationship to the Buttermilk Creek Complex. The model shows that surface maps successfully aid in finding buried materials.

Commonality and variation in British MIS 9 handaxes.

Luke Dale^{1,2}, Aaron Rawlinson¹, Mark White¹, David Bridgland¹

¹Durham University, Durham, United Kingdom. ²The British Museum, London, United Kingdom

Abstract

The notion that handaxe refinement and 'sophistication' evolved throughout the Lower Palaeolithic was largely discredited by improvements in the dating of terrestrial archaeological sites, which showed that relatively well made, refined handaxes could be substantially older than cruder, less refined types. This in turn created a justifiable reluctance to assign any chronological significance to handaxe morphologies or technological variation. However, the idea has been cautiously rehabilitated in recent studies, where certain 'diagnostic' forms have been shown to be strongly related to the age of the deposits in which they are found. Examples of this are the 'twisted' ovate handaxe (Marine Isotope Stage [MIS] 11), the first appearance of Levallois technology (MIS 9-8), and the *bout-coupé* handaxe (MIS 3). MIS 9 has only been recently identified in the terrestrial archaeological record, with the flagship site of Purfleet showing a tripartite archaeological succession (Clactonian, Acheulean, Levallois) suggestive of an important transitional phase in early prehistory. Roe's seminal (1968) study in handaxe morphometrics included several sites now thought to date to MIS 9. His sorting of these sites, based on a statistical similarity between a number of indices including planform, tip shape and elongation, successfully grouped the MIS 9 sites together (Group I) even before the 'expanded' Quaternary chronology was known. Other research into the British Lower Palaeolithic which focused on typology (notably Wymer, 1968) appeared to show a diagnostic co-occurrence of *ficrons* (pointed handaxes with biconcave edges) and *cleavers* (handaxes with a long transverse 'chisel' tip) associated with sites subsequently assigned to MIS 9. Here we will outline the preliminary results of a large scale morphometric, typological and technological study of handaxes from British MIS 9 sites based on data collected from the substantial collections held in the British Museum and elsewhere. In particular, we will outline aspects of commonality across the range of handaxes studied, testing whether Roe's groupings hold true for all MIS 9 sites, and whether *ficrons* and *cleavers* are indeed chronologically significant. We will also outline instances of significant intersite variation, and suggest how these results might be useful in reconstructing ancient culture, society and cognition in the latest Lower Palaeolithic.

Bedrock landsliding and fluvial landscape evolution: a field perspective

Anne Mather¹, Laura Evenstar², Martin Stokes¹, James Griffiths¹, Adrian Hartley³

¹University of Plymouth, Plymouth, United Kingdom. ²University of Brighton, Brighton, United Kingdom. ³University of Aberdeen, Aberdeen, United Kingdom

Abstract

Bedrock landsliding is a common landscape process in moderate-high relief landscapes, particularly dryland areas, and yet is often overlooked in terms of its role in landscape evolution. This may be due to mis-interpretation/lack of recognition of older events (and thus under-representation) within the Quaternary record, mainly due to the loss of distinctive morphology by erosion post-emplacment, or due to the compound nature of some landslide complexes. Most commonly, fluvial systems are portrayed as the drivers of hillslope processes, yet conversely there is increasing evidence that hillslope processes such as landsliding can have a significant long-term (10^4 - 10^6 yr) impact on channel and hillslope morphology, and thus associated fluvial landscape processes and evolution. For example the early phases of mountain growth are commonly associated with river gorge incision into uplifting areas, and subsequent expansion by landsliding (a consequence of slope oversteepening increasing stress on slopes, weathering reducing shear strength, and excess porewater pressures generated along discontinuity surfaces during seismic events or periods of high intensity rainfall). The topographic signature of that landsliding (in scars and deposits) will impact upon the associated developing fluvial system, often persisting over long (10^4 - 10^6 year) timescales within the landscape.

Within fluvial catchments the status of bedrock landsliding as a landscape evolution process will vary as a function of environmental factors such as climate, seismic activity, local topographic relief and attitude of the bedrock geology. Landslides may facilitate catchment expansion via drainage re-routing through capture between (and within) catchments. The landslides may influence upstream areas through the generation of new local base levels and the creation of new lacustrine environments. Downstream of landslides catchments may be impacted by significant changes in sediment flux (both suspended and bedload), as a result of direct sediment supply from the landslide itself, and landslide lake outburst flooding and flushing of upstream fines.

Through a series of field examples we will examine the role of landsliding at different landscape scales across the dryland spectrum from semi-arid (inter-montane sedimentary basin SE Spain; High Atlas Mountains, Morocco) to hyper-arid (Coastal and PreCordillera of the Atacama Desert, Northern Chile). Such examples can inform our approach to landscape evolution modeling.

Modelling last cycle fluvial landscape evolution of the Rio Bergantes using PARALLEM.

Darrel Maddy¹, John Wainwright², Becky Briant³, Stephen McGough¹

¹Newcastle University, Newcastle, United Kingdom. ²Durham University, Durham, United Kingdom. ³Birkbeck College University of London, London, United Kingdom

Abstract

Landscape-evolution models (LEMs) attempt to use modern day process knowledge to derive numerical formulations of how landscapes might evolve over time in response to both extrinsic and intrinsic system drivers. There are many LEMs available for the end user and these vary in complexity dependent upon the intended use. For our intended use i.e. modelling fluvial system behaviour over a full glacial-interglacial cycle (~140 ka) with comparative high spatial resolution there are many constraints that limit our options. Using event-based models over these extended timescales, which use complex representation of flood hydrology and sediment transport, is computationally challenging. More significantly, parameterization of these complex models would require synthesized data at a spatial and temporal resolution (seconds) well beyond any reasonable use of the available 'real-world' data. A more pragmatic approach is to use a reduced complexity model, which uses simplified hydrological and sediment system representations. These models tend to use annual time steps calculating annual budgets for both water and sediment discharge. Even this temporal resolution presents challenges to find climate time series inputs at matching temporal resolution.

In this paper we will present results from modelling the Rio Bergantes catchment in northern Spain using our newly-developed fluvial landscape-evolution model called PARALLEM. PARALLEM has been developed to leverage the immense computing power of General Purpose Graphics Processing Units (GPGPUs) using the NVIDIA CUDA development environment. Although PARALLEM has an event-based option in development, here it is deployed in its reduced complexity mode. The numerical formulation of PARALLEM is based upon Wainwright (2006) but with some significant process additions e.g. gelifluction, similar to those developed for CLEOPATRA (Briant *et al.*, 2018). The input climate timeseries (annual timestep) and the initial DEM (20m resolution) are those developed specifically for the FACSIMILE model-data comparison project.

The model outputs general statistics every iteration and more detailed data matrices every 500 iterations. The 140k iteration simulation currently takes ~7 weeks to complete. Here we present, for the first time, the outputs from a complete model run. Although this represents only one simulation for one parametrization set (with many more necessary to establish model sensitivity etc.) the data does nevertheless provide insight into how the processes act upon this landscape. Perhaps most significant is the critical role played by vegetation change in modulating erosion in this catchment, a key finding as many LEMs do not explicitly model vegetation feedbacks.

Abstract

Field geologists and geomorphologists are increasingly looking to numerical modelling to understand landscape change over time, particularly in river catchments. The application of Landscape Evolution Models (LEMs) started with abstract research questions in synthetic landscapes. Now, however, studies using LEMs on real-world catchments are becoming increasingly common. This development has philosophical implications for model specification and evaluation using geological and geomorphological data, besides practical implications for fieldwork targets and strategy. The type of data produced to drive and constrain LEM simulations has very little in common with that used to calibrate and validate models operating over shorter timescales, making a new approach necessary. Here we argue that catchment fieldwork and LEM studies are best synchronised by complementing the Pattern Oriented Modelling (POM) approach of most fluvial LEMs with Pattern Oriented Sampling (POS) fieldwork approaches. POS can embrace a wide range of field data types, without overly increasing the burden of data collection. In our approach, both POM output and POS field data for a specific catchment are used to quantify key characteristics of a catchment. These are then compared to provide an evaluation of the performance of the model. Early identification of these key characteristics should be undertaken to drive focused POS data collection and POM model specification. Once models are evaluated using this POM / POS approach, conclusions drawn from LEM studies can be used with greater confidence to improve understanding of landscape change.

Late Quaternary landscape evolution of the Bergantes catchment: LAPSUS sensitivity in response to tectonic and lithological drivers

Jeroen Schoorl¹, Selçuk Aksay¹, Monica Sandoval Ramos¹, Tom Veldkamp², Wouter van Gorp³

¹SGL Wageningen University, Wageningen, Netherlands. ²ITC Twente University, Enschede, Netherlands. ³GIA Groningen University, Groningen, Netherlands

Abstract

Over the past decade the FACSIMILE working group (Field And Computer Simulation In Landscape Evolution) has been working on the synergy between numerical modelling and field-based approaches. The past few years the FACSIMILE working group has been focussing their attention to one single catchment: the Bergantes river, a tributary of the Guadalepe river, that drains the south-east part of the Ebro basin (Northeast Spain). Various experts in the fields of computer simulation, palaeohydrology, geochronology, geomorphology and sedimentology work together in an attempt to improve the synergy and understanding of the Late Quaternary landscape evolution of the Bergantes catchment over the past 140 Ka with a multidisciplinary approach.

The different computer simulation LEM approaches in the FACSIMILE working group mainly focus on erosion and sedimentation dynamics based on the published sedimentation history, stratigraphy and geochronology of the downstream river terrace staircase. Furthermore, important landscape evolution input datasets on palaeo-DEM and palaeo-climate have been reconstructed (see this conference). By working with comparable input datasets, especially the computer simulations of the different model approaches, become more easily comparable and straight forward particularly when compared to the field evidence presented so far.

The focus of this research is to analyse the sensitivity of LEM LAPSUS to 2 unexplored controlling driving factors so far; i) regional tectonics and ii) lithological differences in the Late Quaternary Bergantes landscape development. By constructing multiple-stage scenarios, the relative contribution of each of these factors is first estimated based on field observations, before their interaction is simulated. Although their effects are spatially different and they might vary one order of magnitude, we anticipate that both factors play a role individually and together in shaping the landscape in the Bergantes catchment. Consequently these results infer a further investigation for field evidence, which may be guided by these simulations. Especially by investigating key locations of the spatial explicit erosion and sedimentation rates of these scenarios. Finally, the results serve to inform the other LEM approaches on the need to incorporate these driving factors on lithology and tectonics.

Using lake sediments to test millennial duration simulations of catchment hydro-geomorphology

Katharine Welsh¹, Richard Chiverrell², John Dearing³, Thomas Coulthard⁴, Daniel Schillereff⁵

¹University of Chester, Chester, United Kingdom. ²University of Liverpool, Liverpool, United Kingdom. ³University of Southampton, Southampton, United Kingdom. ⁴University of Hull, Hull, United Kingdom. ⁵King's College London, London, United Kingdom

Abstract

Flooding and sediment/soil erosion are a growing future concern for drainage basins, particularly with changes in climate and increasing pressure on land as populations grow. Quantifying how changes in climate and land use impact can impact on the flooding regime and on sediment delivery within catchments remains challenging. Hydro-geomorphic modelling at a catchment scale can be applied to explore these issues. This research assesses the utility of a reduced complexity hydro-geomorphic model (CAESAR-Lisflood model, Coulthard et al. 2013) in identifying the controls on sediment delivery to lake basins.

Catchment scale simulations using CAESAR (Coulthard et al., 2002) showed that the fluvial erosion and deposition, driven by precipitation and conditioned by land use failed to sustain sufficient sediment flux compared with the lake sediment record for the last 180 years (Welsh et al., 2009). The catchment geomorphology (Foster et al., 2003) revealed substantial hillslope erosion supplying sediment to the fluvial system. The representation of hillslope processes (soil creep, failure and surface erosion) in CAESAR-Lisflood (Coulthard et al. 2013) was independent of land use and changes in soil moisture. Here we present and test updates to the soil erosion, soil creep and slope failure components within the CAESAR-Lisflood model.

The model has been tested for two differing upland catchments, the Petit lac d'Annecy, French pre-Alps and Brotherswater, English Lake District. Existing sediment accumulation and compositional data with well resolved chronologies for the lake basins were pre-requisites for the selection for lake catchments. Climate and land use histories were derived from regional palaeoclimate and pollen datasets to drive the simulations. The palaeoclimate data was used to produce the hourly rainfall input series required by the model which enabled the impacts of short, high magnitude rainfall events on sediment dynamics to be explored rather than being masked within lower resolution daily/monthly values. Thus, this work presents a test of the performance of CAESAR-Lisflood over time periods longer than typical of instrumental series and compares the outputs to existing lake sediment records (Jones et al. 2013; Schillereff et al., 2016)

O-1223

Shaping pre-modern digital terrain models – implications for early medieval human-landscape interactions

Johannes Schmidt¹, Lukas Werther², Christoph Zielhofer¹

¹Institute of Geography, Leipzig University, Leipzig, Germany. ²Chair of Prehistory and Early History, Friedrich-Schiller University, Jena, Germany

Abstract

The use of remote sensing techniques to identify (geo)archaeological features is wide spread. For archaeological prospection and geomorphological mapping, Digital Terrain Models (DTMs) on based LiDAR (Light Detection And Ranging) are mainly used to detect surface and subsurface features. LiDAR is a remote sensing tool that scans the surface with high spatial resolution and allows for the removal of vegetation cover with special data filters. Archaeological publications with LiDAR data in issues have been rising exponentially since the mid-2000s. The methodology of DTM analyses within geoarchaeological contexts is usually based on “bare-earth” LiDAR data, although the terrain is often significantly affected by human activities. However, “bare-earth” LiDAR data analyses are very restricted in the case of historic hydro-engineering such as irrigation systems, mills, or canals because modern roads, railway tracks, buildings, and earth lynchets influence surface water flows and may dissect the terrain. Consequently, a “natural” pre-modern DTM with high depth accuracy is required for palaeohydrological analyses.

In this presentation, we present a GIS-based modelling approach to generate a pre-modern and topographically purged DTM. The case study focuses on the landscape around the Early Medieval Fossa Carolina, a canal constructed by Charlemagne and one of the major medieval engineering projects in Europe. Our aim is to reconstruct the pre-modern relief around the Fossa Carolina for a better understanding and interpretation of the alignment of the Carolingian canal. Our input data are LiDAR-derived DTMs and a comprehensive vector layer of anthropogenic structures that affect the modern relief. We interpolated the residual points with a spline algorithm and smoothed the result with a low pass filter. The purged DTM reflects the pre-modern shape of the landscape. To validate and ground-truth the model, we used the levels of recovered pre-modern soils and surfaces that have been buried by floodplain deposits, colluvial layers, or dam material of the Carolingian canal. We compared pre-modern soil and surface levels with the modelled pre-modern terrain levels and calculated the overall error. The modelled pre-modern surface fits with the levels of the buried soils and surfaces. Furthermore, the pre-modern DTM allows us to model the most favorable course of the canal with minimal earth volume to dig out. This modelled pathway corresponds significantly with the alignment of the Carolingian canal. Our method offers various new opportunities for geoarchaeological terrain analysis, for which an undisturbed high-precision pre-modern surface is crucial.

The role of neotectonics in driving Plio-Pleistocene landscape evolution and drainage development in eastern England

Jonathan Lee¹, Richard Haslam¹, Romaine Graham¹, James Rose^{2,1}, Tim Kearsey³, Chris Williams¹

¹British Geological Survey, Nottingham, United Kingdom. ²Royal Holloway University of London, Egham, United Kingdom. ³British Geological Survey, Edinburgh, United Kingdom

Abstract

The Plio-Pleistocene record of eastern and southern England has hitherto revealed a rich and internationally significant archive of landscape evolution and environmental change. The significance of climate as a key driver of landscape change is well established through the examination of glacial deposits, river terrace records, palaeosols and marine deposits. The role of neotectonics however, remains more poorly understood. This is due to the under-representation of Cenozoic faults on published geological maps and the widely-held belief that the UK has been tectonically passive since the Miocene. Nevertheless, the crust beneath the southern UK has undergone periods of uplift and subsidence during the past 3.5 Ma. This has occurred in response to accelerated weathering and the improved efficiency of earth surface processes at recycling sediment from upland 'source' areas (zones of uplift) to lowland and basinal 'sinks' (zones of subsidence). However, significant questions remain concerning how accommodation space within the landscape was regulated and how this in-turn influenced drainage development.

To explore these questions, a bedrock surface model was constructed using elevation data from +9,000 boreholes and contoured in SKUA-GOCAD using nearest neighbour analysis. Beneath central East Anglia, the modelled bedrock surface exhibits a low-relief 'crenulated' form comprising several elongate, NE-SW trending ridges and asymmetrical troughs that possess steeper southeast flanks. Gradient analysis combined with the consistent asymmetry and orientation of the features imply an underlying structural (fault) control. One potential interpretation is that these faults originated as a Cenozoic-age (post-Eocene / pre-Pliocene) sinistral strike-slip fault system that forms a linear deformation zone extending from central East Anglia southwestwards towards Oxford. Since the Miocene, the compressive stress regime within the upper crust has waned and fault slip analyses suggest that Plio-Pleistocene motion along these faults most likely occurred by dip-slip (normal) displacement, forming a horst and graben type relief.

The overlapping geometry of shallow marine (Red Crag Formation) and coastal (Norwich Crag Formation) deposits demonstrate that sediment accommodation space was restricted to the trough ('graben') areas which were actively subsiding during the Pliocene and earliest Early Pleistocene (c. 3.6-1.8 Ma). Uplift and emergence of this structural relief during the Early Pleistocene (post c.1.8 Ma) controlled the development of major preglacial rivers that drained eastwards into the southern North Sea. Contrary to current thinking, the Ancestral Thames and Bytham rivers appear to have been confluent for much of this interval with the course of the former constrained structurally by the Framlingham Ridge to the east. Confluence of the two rivers continued until accommodation within the landscape was infilled (c.0.9-0.8 Ma) and the Framlingham Ridge was breached.

These insights provide a significant shift relative to current thinking, highlighting the importance of neotectonics and their impact on drainage development and patterns of Plio-Pleistocene sedimentation.

The challenges of extracting pre-instrumental storm patterns from the tree-ring record

Erika Wise

University of North Carolina at Chapel Hill, Chapel Hill, USA

Abstract

Regions where a limited number of seasonal extreme precipitation events account for a large proportion of annual precipitation totals present a challenge for paleoclimate reconstruction. The timing and form of precipitation, which can be as important as the total amount received for water availability, is not always matched well with the recording period in trees. This is particularly true on the North American West Coast, where snow is vital for water supply and atmospheric river events can provide 30-50% of annual precipitation in just a few storms. This study uses an integrated water vapor transport-based record of landfalling atmospheric rivers to assess their contribution in different regions, test if water contributed by these events are reflected in ring-width measures, and evaluate their influence on asymmetries in tree-ring based moisture reconstruction. Results from these analyses are then used to evaluate ways to improve the seasonal capture of extremes, including season-by-season precipitation reconstruction, the use of precipitation frequency as an alternative reconstruction measure, and the integration of alternative tree-ring metrics (including stable isotopes and blue intensity) to derive additional information. Results show that season-by-season reconstructions are possible in regions with abundant tree-ring chronologies. The use of alternative metrics increased our ability to distinguish the form and season of precipitation. The $d_{18}O$ isotopes, in particular, provided more consistent information across seasons. By combining these approaches, we can more clearly resolved patterns of past moisture delivery over multiple seasons.

Atmospheric trigger of a two-phased Younger Dryas in western Norway: indications of local moisture addition by sea ice reduction

David Maas¹, Frederik Schenk², Jostein Bakke³, Oliver Rach¹, Dirk Sachse¹

¹German Research Centre for Geosciences, Potsdam, Germany. ²Bolin Centre for Climate Research, Stockholm, Sweden. ³Bjerknes Centre for Climate Research, Bergen, Norway

Abstract

During the Younger Dryas (YD) stadial, pronounced atmospheric changes influenced hydrological conditions all over Europe. Specifically, it was hypothesised that a southward shift of the westerlies due to an expansion of sea ice in the N Atlantic Sea starved northwestern Europe from moisture through the establishment of a high-pressure system over the Norwegian Sea, pushing the prevailing winds south beginning at ca. 12.8 ka BP.

At around 12,250 yrs BP, during the second phase of the YD apparently wetter and more variable conditions were observed in sedimentary parameters at Meerfelder Maar (W Germany) and 12,100 yrs BP at Kråkenes (W Norway), attributed to a northward retreat of the polar front, potentially driven by an increase in AMOC. These records highlight the time transgressive nature of atmospheric circulation shift. We aim to determine which moisture sources deliver precipitation over the course of the YD stadial in order to characterise the atmospheric influence on a regional scale.

Here we compare stable hydrogen isotope records of leaf-wax n-alkanes (δD_{wax}), which provide insights into characteristics of palaeo-precipitation. We present new data from two records, which span the onset and termination of the YD stadial at Kråkenes and Sluggan Bog (N-Ireland) covering the W-E extent of the North Sea and compare our data to published data from Meerfelder Maar.

Our findings show that the onset of the YD at 12.8 ka BP at Kråkenes was marked by a continuous isotopic depletion, which exceeded the effect of temperature on the isotopic composition of precipitation. The remainder can be explained by changes in the origin of moisture and hence supports the notion of a southward migration of the westerlies at this time. A unique feature of the record at Kråkenes in western Norway is a rapid isotopic enrichment followed by a higher degree of variability of δD_{wax} values, between 12.2 and 12.1 ka BP, persisting throughout the later YD. In the absence of any strong temperature increase or strong aridification, this enrichment suggests the addition of precipitation originating from a local moisture source.

We hypothesise that a reduction in sea ice extent in the Norwegian Sea starting at 12.2 ka BP allowed for evaporation and subsequent transport of local moisture to the Norwegian coast. This is supported by climate model simulations run on a CESM1 model, suggesting a bifurcation of the westerlies airflow over Scotland during the YD, of which the northern branch flows over the Norwegian Sea toward Kråkenes. In case of an increasingly ice-free Norwegian Sea during the 2nd phase of the YD, those air masses would have been able to pick up local and isotopically enriched moisture during their movement.

Variability of the Aleutian Low and Westerly Jet during the Holocene

Kana Nagashima, Naomi Harada
JAMSTEC, Yokosuka, Japan

Abstract

The Aleutian Low (AL), the semi-permanent low-pressure system located over the Gulf of Alaska, is critically linked to environmental change in the North Pacific and surrounding continental areas. For example, recent decadal variability of the AL has been reported to affect salmon abundance in the northeast Pacific, and precipitation and snow accumulation in the western coastal area of North America (e.g., Mantua et al., 1997) by changing the Alaska Current and moisture transport from the North Pacific to inland North America. At longer-timescales, AL intensity is reported to vary on centennial to millennial scales (e.g., Anderson et al., 2005, 2016; Fisher et al., 2008; Jones et al., 2014). However, the ultimate trigger of these intensity changes has not been systematically studied or proven.

Recent meteorological records showed that the Westerly Jet (WJ) over East Asia and the North Pacific links strongly to the AL intensity and position through changes in cyclogenesis, monsoon, and storm track activity (e.g. Lau, 1998; Dole and Black, 1990; Yang et al., 2002; Nakamura et al., 2002; Nakamura and Shimpo, 2004). Here, possible AL-WJ coupled changes and potential triggering mechanisms causing AL variations were examined using proxy records from East Asia, North America, and the Patagonian region. The focus is on WJ records from the Southern Hemisphere because the WJ path of the northern and southern hemispheres trace the expansion and shrinkage of the Hadley Cell during the Holocene, which help to understand dynamic changes in Holocene atmospheric circulation.

The proxy records revealed millennial-scale coupling of the AL-WJ path with weakened AL and poleward WJ shifts in both hemispheres during 7–5.2 and 2.8–1.2 ka, and an intensified AL and equatorward shift of the WJ path during 5.2–2.8 ka and 1.2 ka onward. Centennial scale AL intensification and equatorward shifts of the WJ path in both hemispheres also appeared in the proxy records. Periods of centennial and millennial-scale AL maxima and equatorward shifts of the WJ correlate well with periods of solar activity minima, suggesting solar activity has played a primary role in the generation of the atmospheric circulation changes, possibly through dynamic Hadley cell changes.

Abstract

Precession-forced intensification of the low-latitude summer monsoons and northward migration of the associated rainfall belts during the Early Holocene Humid Period (EHHP) initiated the development of grasslands, wetlands and lakes in today's hyper-arid Saharo-Arabian desert belt. Numerous model simulations and palaeoclimate records draw a consistent picture of the EHHP in North Africa. However, our knowledge about the magnitude, timeframe and moisture sources of the EHHP in northern Arabia during the EHHP is limited due to a lack of robust proxy data.

Here we provide the first high-resolution and precisely dated multi-proxy reconstruction of the hydroclimatic variability during the EHHP for northwestern Arabia, retrieved from annually laminated (varved) sediments of the Tayma palaeolake record. This record reveals a pronounced seasonal variability during the lake's evolution, which was reconstructed through micro-facies analyses of the varved sediments. Changing lake water evaporation and the lake-internal productivity were inferred using stable oxygen and carbon isotope compositions ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$) of primary inorganic carbonates. Sedimentological, biogeochemical and micro-palaeontological proxies complete the dataset. The robust age model is constrained by a floating varve chronology, anchored through ^{14}C -dated pollen concentrates and the well-dated 'S1' cryptotephra.

The results prove the existence of a shallow to max. 15 m deep lake, and subsequent wetland succession in the Tayma basin from ca. 9300 to 4200 years before present (BP, *i.e.* before AD 1950), reflecting the typical scheme of increased humidity in the northern Afro-Arabian region during the early to mid-Holocene. However, maximum humidity in northern Arabia is only evident between ca. 8500 and 7900 years BP, when varves formed in a perennial lake body. This is considerably later and shorter than the EHHP over northern Africa, which is typically defined from 10,000 to 6000 years BP. Moreover, the length and timing of this peak humid phase in the N-Arabian Desert are congruent with a low-latitude, centennial-scale dry anomaly interrupting the EHHP. This 'cool poles – dry tropics' anomaly caused a weakening of summer monsoons and Mediterranean winter rains. We suggest that cooling of the North Atlantic and Mediterranean Sea during this anomaly promoted frequent perturbations of the subtropical jet-stream, which favours intrusions of rain-bearing, winter-spring tropical plumes towards N-Arabia. Today, such synoptic-scale climate patterns contribute significantly to extreme precipitation events in the Middle East. Our findings underpin a complex regional hydrological pattern during the EHHP, and challenge climate model simulations to better explain synoptic-scale regional and seasonal rainfall dynamics.

This study is a contribution to the research project “CLEAR – Holocene Climatic Events of Northern Arabia” (<https://clear2018.wordpress.com/>), financially supported by the German Research Foundation (DFG).

Cenozoic depositional sequence in Weihe Basin (central China): long-term record of Asian monsoon precipitation from the greenhouse to icehouse Earth

Huayu Lu, Hanzhi Zhang, Yichao Wang, Lin Zhao, Hanlin Wang, Wenfeng Sun, Hongyan Zhang
Nanjing University, Nanjing, China

Abstract

Onset and evolution of Asian monsoon has been long-time debated, the timing and monsoon intensity variation is still an open question. The modern Asian monsoon circulation started at Eocene, early Miocene, late Miocene, late Pliocene and early Pleistocene have been hypothesized, on the basis of various geological records and fossil observations, and the proxy indicators of Asian monsoon strength. However, there are many uncertain in previous investigation such as the misinterpretation of proxy indexes' implication, fragment of the geological records and poor age constraints to the depositional sequences; therefore, a long-term and continuous record of Asian monsoon is impulsive needed. Weihe Basin is a middle size basin formed in Cenozoic in central China, where is located at marginal of Asian monsoon impact region and where is sensitive to reflect monsoon precipitation change. Weihe Basin can be regarded as a monsoon rainfall gauge in Cenozoic, since there is more than 7000 meters unconsolidated fluvial-lacustrine deposit accumulated in this basin, which cover timing from middle Eocene to Holocene with nearly continuous depositional sequence. The monsoon precipitation determines runoff of Weihe River catchment, which control erosion and deposition in Weihe Basin, therefore the sedimentary sequence is an excellent archive of long-term Asian monsoon evolution. Our depositional facies and stratigraphy analyses show that Asian monsoon precipitation probably commenced at middle Eocene, and the modern monsoon circulation pattern was established at early Pleistocene, ~2.6 Ma. The collision between Indian Plate and Eurasia Plate at Paleogene could build Asian topography at that time, the great continental landmass and oceans could generate Asian monsoon circulation. This monsoon circulation was stepwise strengthened by close of Tethys Sea at late Eocene and early Oligocene, and by growth forcing of Himalayan-Tibetan Plateau at early Miocene, and high-latitude cooling at Northern hemisphere at late Miocene. The great Northern Hemisphere Glaciation took place at ~2.6 Ma could be the direct driver that push the intertropical convergence zone (ITCZ) toward equator and compress the monsoon rain belt, thus the modern monsoon circulation was finally established. The monsoon evolution has experienced greenhouse Earth and icehouse Earth which shifted at early Oligocene, along with onset of ice sheet in Antarctic, but the global cooling and Asian topography change did not completely modulated Asian monsoon circulation pattern during this time. The Northern hemisphere cooling at late Pliocene and early Pleistocene finally determined Asian monsoon circulation pattern which was finally established at this time.

Alaskan lake oxygen isotopes as recorders of North Pacific atmospheric circulation patterns and variability during the Holocene

Lesleigh Anderson¹, Bruce F. Finney²

¹U.S. Geological Survey, Geosciences and Environmental Change Science Center, Denver, CO, USA. ²Idaho State University, Departments of Biological Sciences and Geosciences, Pocatello ID, USA

Abstract

The coast mountain ranges of Alaska and the southwest Yukon Territory have dramatic elevation gradients in climate and isotopes of precipitation that are caused by their interaction with the atmospheric flow. These effects also lead to regionally complex spatial patterns in hydroclimate, which are also indicated by Alaska-Yukon oxygen isotope proxy records. To overlook regional and elevation differences, and the processes that cause them, will result in erroneous interpretations, which is particularly problematic for the region because current isotope enabled GCMs lack the spatial resolution to accurately simulate topographic effects. Here, we explore comparisons between oxygen isotope proxy records from a range of elevations and locations throughout southern Alaska-Yukon that reflect the interaction between regional atmospheric flow and mountain barriers. The comparisons offer opportunities to obtain more detailed paleoclimatic information such as changes in seasonality, boundary layer dynamics, and rain shadow effects. Previous work from Mount Logan ice cores and leeward Jellybean Lake sediments at ~5000 and 1700 m elevations, respectively, has provided a number of hypothesis about the effects on isotopes in precipitation caused by changes in North Pacific atmospheric circulation during the Holocene, such as variations in the strength and position of the Aleutian Low. A prominent role of the Aleutian Low during the past millennium has recently been corroborated by a new ice core record from Mt. Hunter but the effects at low, windward elevations has yet to be determined. Here we present a new full Holocene record from windward April Fools Lake, located at ~40 m elevation near upper Cook Inlet that serves to test if prominent late Holocene shifts in isotopes of precipitation at Logan and Jellybean are similarly shown to occur near sea level or not. The results will provide points of comparison for precipitation isotope model simulations and have implications for late Holocene climate trends in the Gulf of Alaska region as a long-term context for ongoing North Pacific ocean-atmosphere dynamics.

The timing of Antarctic Ice Sheet glaciation evidenced by Marine Isotope Stage 3 sea-level highstand records

Takeshige Ishiwa¹, Jun'ichi Okuno^{1,2}, Pippa Whitehouse³, Yusuke Suganuma^{1,2}, Hideki Miura^{1,2}

¹National Institute of Polar Research, Tokyo, Japan. ²SOKENDAI, Tokyo, Japan. ³Durham University, Durham, United Kingdom

Abstract

The Last Glacial Maximum (LGM) is known as the period when global ice volume reached its maximum and global temperature was lower than today. The timing of ice-sheet growth toward the LGM is essential to understand the mechanism of each continental ice-sheet glaciation and the accompanying vertical movement in the near-field by glacial isostatic adjustments (GIA). However, the erosive nature of ice-sheet expansion during the LGM and the difficulty of access in Antarctica make it challenging to obtain field-based evidence of ice-sheet and sea-level change prior to the LGM. Sedimentary records from the coastal region in East Antarctica demonstrate that relative sea level during Marine Isotope Stage 3 (MIS 3) was close to the present level (Miura et al., 1998; Hodgson et al., 2009). These relative sea-level records combined with GIA modeling provide insight into the timing of Antarctic Ice Sheet (AIS) glaciation immediately prior to the LGM.

In this presentation, we document the ice loading history in Antarctica based on the W12 model (Whitehouse et al., 2012), which can explain MIS 3 sea-level highstands in the East Antarctic coastal region. We ran over 100 GIA experiments in which we altered the timing of AIS growth before MIS 3 as well as the magnitude of ice loading during MIS 3. Initial results indicate that changing the timing of AIS growth to LGM conditions cannot explain the MIS 3 sea-level highstands. However, increasing the ice loading during MIS 3 so that it is greater than the LGM ice load in the W12 model can explain the MIS 3 sea-level highstands. This excess ice loading event indicates that the large-scale growth of the AIS may have started before MIS 3. We hypothesize that the changes in sea ice expansion and sea surface temperature in the Southern Ocean may be closely related to the growth of the AIS prior to the LGM.

Southwest Greenland shelf glaciation more extreme during MIS 4 than during the Last Glacial Maximum

Marit-Solveig Seidenkrantz¹, Antoon Kuijpers², Jesper Olsen³, Christof Pearce¹, Sofia Lindblom⁴, Johan Ploug^{1,5}, Piotr Przybylo^{1,6}, Ian Snowball⁷

¹Department for Geoscience, Aarhus University, Aarhus, Denmark. ²Geological Survey of Denmark and Greenland (GEUS), Copenhagen, Denmark. ³Aarhus AMS Centre, Department of Physics and Astronomy, Aarhus University, Aarhus, Denmark. ⁴Department of Earth Sciences, University of Gothenburg, Gothenburg, Sweden. ⁵DJ Miljø & Geoteknik, Hillerød, Denmark. ⁶Coleherne Road, Earls Court, London, United Kingdom. ⁷Department of Earth Science, Uppsala University, Uppsala, Sweden

Abstract

Although geological and modelling evidence indicate that the last glacial inception started in NE Canada, only little is known about the glacial response of the nearby western Greenland Ice Sheet (GIS) during the first main glacial advance of marine oxygen isotope stage 4 (MIS4). Moraine ridges on the southwest Greenland outer shelf ('Outer Hellefisk Moraines') are generally assumed to outline the maximum GIS extent during the Last Glacial Maximum (MIS2). Here we present results from a multi-proxy study of a marine sediment core collected about 60 km southwest of the Outer Hellefisk Moraines. Our study demonstrates that the most extreme SW Greenland shelf glaciation occurred during MIS 4, with another prominent glacial advance dated between 38 and 42 kyr BP. In contrast, the MIS2 glaciation appears to have been less severe. Our data further suggest a significant influx of relatively warm Irminger Sea Water transported by the West Greenland Current since MIS 4. This likely limited the extent of the MIS2 glaciation on the SW Greenland shelf. Decreased precipitation over the southwest Greenland region reported in atmospheric modelling studies as a downstream effect of a much larger MIS2 Laurentide Ice Sheet may have played an additional role.

O-1234

Late Weichselian lake sediments with Azorean tephra reveal ice-free interval on coastal northwest Spitsbergen

Willem Godert van der Bilt^{1,2}, Christine Lane³

¹University of Bergen, Bergen, Norway. ²Bjerknes Centre for Climate Research, Bergen, Norway. ³University of Cambridge, Cambridge, United Kingdom

Abstract

Empirical constraints on the style and extent of past glaciation, and its climatic boundary conditions, greatly improve the accuracy of numerical models used to predict the future behavior of Earth's cryosphere. On northwest Spitsbergen, independent lines of paleoglaciological evidence suggest that Late Weichselian ice was either restricted or extending to the shelf edge. We accommodate both these scenarios with the first pre-Holocene lake sediments reported from the Svalbard archipelago. Radiocarbon dating of three terrestrial plant fossils indicate that the investigated low-lying site (Hajeren) was ice-free and vegetated between ~30 and 20 ka BP. The presence of a geochemically homogeneous and distinct horizon of ultra-distal volcanic ash from the Azores islands provides additional evidence for sub-aerial (unglaciated) conditions. Stratigraphic indicators of sediment compaction, as well as a depositional hiatus indicate subsequent coverage by non-erosive (cold-based) ice until deglaciation at the onset of the Holocene ~12 ka BP. Comparison with regional paleoclimate records suggests that sea-ice variability played a critical role in the inferred pattern of ice-sheet evolution by modulating moisture fluxes that control ice accumulation rates. These findings also raise questions about the future stability of the Arctic cryosphere, which faces rising temperatures as well as wetter conditions.

Abstract

Assessments of past sea-level change and climate require precise knowledge of the configuration of ice sheets. However, direct determination of the dimensions of past ice sheets are often not possible due to the paucity of geological evidence, especially prior to the Last Glacial Maximum. Because of this, reconstruction of past ice sheets rely on using glacial isostatic adjustment methods. The spatial pattern of past sea level can be used to infer how much ice was in the ice sheets, and where it was located. We present the results of a preliminary global ice sheet reconstruction covering the past 200,000 years. The ice sheets are constructed using the program ICESHEET, which allows for precise control over the extent and volume of the ice sheet. We also include proglacial lakes, which are used to assess the validity of the reconstructions in areas far from the coast. The 200,000 year period is necessary for accurate modelling of paleo-sea level, as the response time of the Earth's mantle is slow, and there is a memory of the MIS 6 glaciation even on present sea level change. The reconstructions benefit from the recent compilations of ice sheet margin reconstructions (e.g. DATED-1 for the Eurasian ice sheets) and paleo-sea level archives (e.g. HOLSEA and WALIS). We focus on three specific points of time in our reconstructions. The first is determining the late glacial configuration of the southern Laurentide Ice Sheet, using observations of paleo-lake shorelines. The second is to determine the possible configuration of the ice sheets at the Last Glacial Maximum, when there is still upwards of 15 m of "missing" ice to close the sea-level budget. The third target is the sea-level highstand during MIS 5e, which is suspected to have been caused by a partial collapse of the West Antarctic Ice Sheet. We use observations of past sea level in Patagonia to test this hypothesis.

O-1236

Modelling ice sheet – sea level – solid Earth interactions over the Northern Hemisphere throughout the last glacial cycle

Holly Kyeore Han¹, Natalya Gomez¹, David Pollard², Robert DeConto³

¹McGill University, Montreal, Canada. ²Pennsylvania State University, State College, USA. ³University of Massachusetts Amherst, Amherst, USA

Abstract

Retreat or advance of an ice sheet perturbs the Earth's gravitational field, solid surface and the rotational vector, which together lead to spatially variable changes in sea level and deformation of the bedrock, feeding back onto the evolution of the ice sheet over both short-term ($\leq O 10^2$ yrs) and long-term ($\geq O 10^3$ yrs) timescales. Changes in elevation of the bedrock beneath an ice sheet shift the elevation of ice sheet surface, which then affects the accumulation and ablation of the ice sheet (i.e. ice elevation feedback). In the case of a marine-terminating ice sheet, solid Earth deformation and gravitational field perturbations together cause changes in the local water depth, influencing the ice flux across a grounding line and thus the stability of the ice sheet.

Over the last glacial cycle, ice sheets over the Northern Hemisphere have gone through multiple advance and retreat phases, but the dynamics during these phases are not well understood. In this study, we apply a coupled ice sheet – sea level – solid Earth model to simulate the Northern Hemisphere Ice Sheets (NHIS) over the last glacial cycle. We present the evolution of the NHIS and associated geographically variable sea-level changes and deformation of the Earth's surface. Our model captures the details of the short-term ($\leq O 10^2$ yrs) interactions between the three components of the model within a glacial-cycle timescale simulation. We also present the results of additional simulations in which the contributions from gravitational and deformational effects are separated. From our results, we examine the ice volume, spatial and temporal distribution of the NHIS, and attribute each physical process to the growth and retreat dynamics of the NHIS.

¹Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom. ²Norwegian University of Science and Technology (NTNU), Trondheim, Norway. ³Charles University, Prague, Czech Republic. ⁴Department of Zoology, University of Cambridge, Cambridge, United Kingdom. ⁵Durham University, Durham, United Kingdom.

⁶University of Sussex, Brighton, United Kingdom

Abstract

Knowledge of the extent, volume and timing of Quaternary ice sheets is fundamental to studies of sea-level change, Earth rheology, global climate, landscape evolution, sedimentation, palaeoecology, genetic diversity and anthropology. The last few decades have seen unprecedented growth in the size and diversity of empirical datasets used to reconstruct and date palaeo-ice sheet extent, together with major improvements in our ability to simulate their dynamics in numerical models. However, the vast majority of these reconstructions focus on ice-sheet deglaciation from the Last Glacial Maximum (LGM), and comparatively little is known about global changes in ice-sheet configuration in the deeper past. Here, we synthesise available empirical evidence and model outputs related to pre-LGM ice sheets to produce hypotheses of Northern Hemisphere (NH) ice-sheet configuration over 17 key time-slices that span the last ~3 million years. Our hypothesised reconstructions are used to assess spatial differences in ice-sheet configuration within and between glacial periods, produce new first-order estimates of global sea level associated with each time-slice, and explore the implications for NH landscape evolution.

O-1238

'Missing Glaciations' of the Middle Pleistocene: examining controls on global glacier extent during 100 ka glacial cycles

Philip Hughes¹, Philip Gibbard², Jürgen Ehlers³

¹The University of Manchester, Manchester, United Kingdom. ²Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom. ³Hellberg 2a, Witzeze, Germany

Abstract

Ice volume during the last ten 100 ka glacial cycles was driven by solar radiation flux in the northern hemisphere. Early minima in solar radiation combined with critical levels of atmospheric CO₂ drove initial glacier expansion during the largest glaciations. Solar forcing also plays a major role in determining the size and length of glaciations. For example, the amplitude of solar precession associated with peak eccentricity can be linked to failed glacial cycles such as MIS 7d and 15b. However, even during full glacial cycles global glaciations have varied in size and magnitude since the Early-Middle Pleistocene transition (~773 ka), despite the apparent regular and high-amplitude 100 ka pacing recorded in marine isotopic records. The evidence on land indicates that patterns of glaciation varied dramatically between different glacial cycles. Some glacial cycles were characterized by limited glaciation with the terrestrial evidence consequently limited and overran by larger later glaciations. For example, MIS 8, 10 and 14 are all noticeably absent from many terrestrial glacial records in North America and Europe. However, globally, the patterns are more complicated with major glaciations recorded in MIS 8 in Asia, and MIS 10 and 8 in parts of the southern hemisphere, such as Patagonia and Tasmania for example. This spatial variability in glaciation between glacial cycles is likely to be driven by internal climatic, such as ice volume changes in Antarctica and associated interhemispheric connections through ocean circulatory changes. The largest global ice volumes were always associated with large ice masses over North America and Europe whereas smaller ice volumes occurred when glaciations were largely 'missing' from these regions. The weak global glacial imprint in some glacial cycles is related to the pattern of global ice build-up and is often characterized by large interior continental glaciation early in the glacial cycle that is then not matched by the later global glacial maxima. This is caused by feedback mechanisms within glacier systems themselves which partly result from long-term orbital changes driven by eccentricity and a weak North Atlantic conveyor associated with conditions in Antarctica and the bipolar seesaw.

Quaternary Desert Dune Systems – A global perspective

Nicholas Lancaster

Desert Research Institute, Reno, Nevada, USA

Abstract

Inland dune systems of Quaternary age occur on all continents and at all latitudes and are one of the most widely distributed landforms on Earth. Dune systems are dynamic geomorphic and sedimentary environments that respond directly and indirectly to climate change and variability on a range of temporal and spatial scales. The sedimentary and geomorphic record preserved in inland dune systems therefore potentially provides a valuable source of information on past climate conditions, including evidence for periods of dune activity and stability that may be interpretable as records of past aridity, as well as contributing unique data on past wind regimes.

Directly dated chronologies of periods of aeolian accumulation and stability have been developed for many areas since the widespread application of luminescence dating techniques. The INQUA Dunes Atlas chronologic database provides the first global compilation of published luminescence and radiocarbon ages for aeolian sand deposits. Although by necessity it is a work in progress, the database is a valuable resource that can be used to analyze patterns of dated dune deposits at multiple temporal and spatial scales; correlation of these patterns with other paleoclimatic proxies; and assessment of the paleoclimatic and paleohydrologic implications of periods of aeolian deposition. In addition, the dataset can be used to validate earth system and paleoclimate model simulations over the past 30-40,000 years.

Analyses of the dataset at regional and global scales are providing new insights into spatial and temporal patterns of dune system response to changes in sediment supply, availability, and sand transport capacity. More precise correlations of periods of aeolian accumulation and stability with other paleoclimatic proxies and records, enables assessment of the boundary conditions that result in dune building, reworking, or stability. As a result, the paleoenvironmental significance of periods of aeolian sand accumulation and stability can now be better constrained in many areas, highlighting, for example, the importance of sediment supply to periods of late Quaternary dune formation in North America and Europe; and mega-droughts to Holocene reactivation episodes.

The availability of large amounts of chronologic data has highlighted the complexity of dune system response to Quaternary climate change, indicating that there is a need for: (1) a systematic hypothesis-driven approach to dating programs; (2) statistical approaches to distinguish between signal and noise in the dataset; and (3) process-based interpretations of the dune record and its preservation.

O-2001

Different responses and driving mechanisms of H1 event in the Asian Monsoon domination and its marginal region

Liping Zhu^{1,2,3}, Lei Huang^{1,3}, Xinmiao Lv^{1,2}, Yongsong Huang⁴, Qingfeng Ma¹

¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China. ²CAS Center for Excellence in Tibetan Plateau Earth System, Beijing, China. ³University of Chinese Academy of Sciences, Beijing, China. ⁴Brown University, Providence, USA

Abstract

The Tibetan Plateau is affected by the westerlies and the India summer monsoon (ISM), of which the influence might be reflected through climate change signals in sedimentary records in the transition regions. The Nam Co Lake is located at the transitional zone between the westerlies and the ISM on the Tibetan Plateau. Sedimentary records of the Nam Co Lake show that climate shifted from cold-dry to warm-humid, and from the westerly domination to ISM domination reflected by pollen discriminant function since 16.5 ka BP. The same changes were also reflected by pollen records of Tangra Yumco Lake and pollen and biomarker records of Mang Co Lake in this monsoonal margin area. However, unlike the dry condition appeared in H1 event period in East Asia typical monsoon region during this shifting period, lake records in ISM margin area of the Tibetan Plateau showed that climate performed more humid in H1 period than in Last Glacial Maximum. By comparing results of full_forcing TraCE experiment and Freshwater hosing experiment, it is found that the weakening of AMOC results in southward shift of the ascending branch of Hadley circulation. It enhances north toward trans-equatorial wind at upper layer of the troposphere, which transit to the upper-level westerly jet in middle latitude of northern hemisphere. Although the enhancement of upper westerly jet is limited due to warming effect of greenhouse gas and solar radiation in northern hemisphere, there is a structural change similar like convergence center in upper troposphere in East Asia typical monsoon regions. It limits convective activity below and reduces precipitation, while in high elevation area of monsoon margin, it is difficult to limit influence of Indian monsoon by increasing upper westerly wind, which leads to the stability of precipitation in Indian monsoon marginal region.

Climate variability during Late Quaternary in Tangtse Valley, Ladakh, Trans-Himalaya: inferences from grain size, environmental magnetism and loss on ignition

Randheer Singh, Binita Phartiyal
Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

The Tangtse River Valley, Ladakh in Trans-Himalayan range is a cold and arid desert due to the strong influence of westerlies. On the east of valley, Pangong Tso, longest lake in Ladakh has high, distinct palaeo- strand lines give clues about the wider extent of the lake area in the past. Dating of fluvial and fluvio-lacustrine sections by ^{14}C (AMS) and TL(OSL) methods gives us records of changing depositional environments. Two phases of fluvial regime around 48 ka and 30-21 ka (comparatively arid conditions and dry phases) were revealed. A fluvio-lacustrine/flood phase between ~20 to ~5 ka inundating the whole valley is recorded.

In grain size analysis, most of the samples show unimodal sediments this can attribute a stable lake condition and indicates the lack of reworked fluvial, aeolian and eroded lake margin materials. In contrast, the poor degree of sorting is also observed. Fining-upward cycles, variation in mean grain size, varying bed size are the indication of changing of depositional energy. To solve the transport dynamics, End-member analysis (EMA) with 4 Ems were modeled in this study. EM modeling indicates in floodplain pool, with reworked sediments indicating riverine input. On this basis, the depositional scenario can be said a fluvio-lacustrine setting.

During warm periods, decreased catchment weathering led to the deposition of fine sediments) show decrease in values Magnetic Susceptibility (MS), Saturated Isothermal Remanent Magnetization (SIRM) and soft Isothermal Remanent Magnetization (IRM). Results opposite to these reflect a colder phase. The fluvio-lacustrine sections can be divided into 4 zones (Z1-Z4). The setup of zone1 (~20 to ~16 ka) is synchronous to LGM period with a peak around 18 ka. Zone4 (~6.7 to ~5.1 ka) is much colder than that of Z3 (~7.2 to ~6.7 ka) and having short, but intense cold phases. A stable lake condition with a warm climate record is seen in ~16 to ~7.2 ka (Z2) corresponding to a well-known enhancement of Indian monsoon (15.2 ka) and climate amelioration. LOI data shows a trough whereas MS, susceptibility of ARM and SIRM values an enhancement around 8 ka may be the signature of the prominent cold excursion 8.2 ka event in warm Holocene.

A 9.7 m thick exposed section may be a result of a later flood event (~3 ka). The cross-laminated sand, alternating layers of silt and sand as sedimentary features, along well-preserved sub fossilized faunal and wood remain points to a quick burial which was likely a result of a short-term flood event. The signal of SD magnetite which indicates less oxygenated water condition for a short while due to the turbid water, bimodal type sediment and EM modeling also suggest it as a channel or natural levee section.

Appearance of unique tape pine forests in Altai region (southern West Siberia)

Natalia Rudaya^{1,2}, Sergey Krivonogov^{3,2}, Snezhana Zhilich^{1,3}

¹Institute of Archaeology and Ethnography, SB RAS, Novosibirsk, Russian Federation. ²Novosibirsk State University, Novosibirsk, Russian Federation. ³Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russian Federation

Abstract

The Kulunda depression (Altai region, Russia) is located in the southern part of West Siberia and used to provide a paramount environmental connection between the Central Asian steppe and the North Asian forest-steppe and taiga. It is extensive accumulative lowland located at an altitude of 100-140 m asl. Presently, a thick layer of alluvial and eolian sediments (up to 50-60 m) covers the Kulunda depression. A distinctive feature of Kulunda is the high number of salty and freshwater lakes. Kulunda is situated in the Eurasian steppe zone with a prevalence of grass communities. Tape shape forests with *Pinus sylvestris* (so called 'tape bor') stretching from southwest to northeast are unique natural objects with unclear origin. Spreading of these forests is closely linked to existence the sandy dunes in Ob`-Irtysh interfluve.

There are at least three points of view on the origin of tape pine forest: (1) they are relics from the continuous *Pinus sylvestris* forest that was spread in Pleistocene in the humid phases across the whole Siberia; (2) they appeared in arid phase of MIS3 when the loess deposits from Ob River terrace were moved by wind and formed the sandy dunes in direction of westerlies in ancient river beds; and (3) they appeared in arid phase of late MIS2 or early Holocene when the sand dunes were formed and immediately inhabited by Scotch pine.

New pollen records covered late Pleistocene and Holocene from two lakes of Kulunda were studied to resolve this issue: 2.52 m-long core from salty lake Kuchuk (ca 13.8 kyr BP) and 4.97 m-long core from soda lake Maloye Yarovoe (ca 21 kyr BP) were obtained in 2016. *Artemisia* pollen dominates throughout both records reaching together with *Amaranthaceae* up to 90% in late Pleistocene. This reflects dry treeless landscapes. *Pinus sylvestris* pollen has only 1-5% before Holocene that means absent of pine forest in vicinity of the lakes. After ca 11.2 kyr BP in Kuchuk and ca 9.5 kyr BP in M. Yarovoye the amount of Scotch pine pollen sharp increases (up to 20-23%) and then has never disappeared or significant decreased. Broad-leaved taxa that absent in natural modern flora (*Carpinus*, *Fagus*, *Tilia*, *Corylus* and *Ulmus*) appear in low amount between ca 11.2 and 3 kyr BP. Based on this study we can preliminary conclude that the sand dunes formed in terminate arid phase of late MIS2 were inhabited by Scotch pine in early Holocene.

Multi-proxy evidence of palaeoenvironmental and palaeovegetation changes on southeastern Amazonia

Luiza Reis¹, Luiz Pessenda¹, Tasso Guimarães²

¹Center for Nuclear Energy in Agriculture/USP, Piracicaba, Brazil. ²Vale Institute of Technology, Belém, Brazil

Abstract

The Amazon rainforest is a fundamental source of moisture for the atmosphere with implications in the maintenance of the valuable biodiversity contained therein and on the Brazilian economy. Besides that, as a huge carbon reservoir, it plays a key role in the global climate. Many studies have been performed in order to better understand the effects of Northern Hemisphere climatic events over the rainfall regime and vegetation dynamic on southeastern Amazonia. However, there is no broad consensus, since most of the studies used only palynological data. And due to the limitations of this technique, the multiproxy approach is essential to obtain a better interpretation of climatic variations. In this way, isotopic analysis of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, sedimentary facies, palynological, multi-elemental geochemistry, micro and macro-carbon fragments analyzes were performed on a sediment core from Amendoim Lake that covers the last ~22 ka. Relatively dry conditions during the Last Glacial Maximum (LGM) is suggested by very low sedimentation rate and diagenetic formation of a siderite layer under reduced conditions at the sediment-water interface during low lake level. The lowest pollen concentration indicates degradation of pollen and spores grains due to diagenetic process. During LGM, colder Atlantic Ocean SST probably caused a decrease in ocean moisture supply to northern South America and consequently a reduction in the precipitation regime. The Pleistocene-Holocene transition and Early Holocene are characterized by the large occurrence of fire events and precipitation of siderite nodules, besides the decrease in detrital input to the lake basin. On the other way, the record also shows a high concentration of pollen grains from forest formation and palms as well as depleted $\delta^{13}\text{C}$ values, which suggests seasonal (warmer) climatic conditions with prolonged dry seasons. High northern insolation probably caused the northward migration of the Intertropical Convergence Zone and consequently, low precipitation amount over southeastern Amazonia. An expansion of ombrophilous forest over the plateau slopes in Serra Sul de Carajás and a change to predominantly wet climatic conditions similar to the current one was observed during the last 8 ka. Based on a multi-proxy approach, we support the hypothesis of a dipole pattern between western (wet condition) and eastern (dry condition) Amazonia during the last glacial period¹. However, higher resolution records are indispensable in order to identify the palaeoenvironmental and palaeohydroclimatic changes caused by millennial events – e.g. Heinrich stages and Younger Dryas – over Amazonia.

Abstract

The timing of the Holocene Climate Optimum in the Indian summer monsoon (ISM) area and its forcing mechanisms are controversial. In this study, a pollen-based vegetation reconstruction from a subalpine lake (Lake Tianchi, 25°52.4'N, 99°16.8'E, 2550 m above sea level) in the ISM area show that the *Tsuga dumosa* forest zone migrated at least 650 m upwards in the Hengduan Mountains from 18.6 to 7.1 kyr, indicating a gradual rise in mean annual temperature of over 3.9 °C. In response to this warming, grass, deciduous and evergreen broadleaved trees successively colonized this mountainous environment, reflecting the progressive increase in the ISM precipitation. The Holocene Optimum occurred between 10 and 4 kyr and reached a peak at 7.1–6.4 kyr, as evidenced by the maximum abundance of subtropical evergreen trees. The timing of peak Holocene warmth lagged the peak northern hemisphere summer insolation by 3.9–4.6 kyr, due to delayed ice melt in northern high latitudes. Our results indicate a strengthening of the ISM in response to warming-induced northward shifts in the Intertropical Convergence Zone. If global warming continues, the ISM is projected to intensify, the loss of habitat for alpine species is likely to accelerate.

A branched GDGTs-based temperature reconstruction from a tropical Maar Lake

Guoqiang Chu

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

High-resolution quantitative temperature records during the last deglaciation in low-latitude land are scarce but important for understanding rapid propagation of abrupt climate events throughout the northern hemisphere and the tropics. Here, we present a branched GDGTs-based temperature reconstruction from the sediments of Maar Lake Huguangyan in tropical South China. The record reveals that the mean temperature during the Oldest Dryas (18.1-15.5 kyr BP) was 17.8°C, followed by a two-step increase of 2-3°C to the Bølling-Allerød (14.6-12.8 kyr BP), a decrease to the Younger Dryas (19.8 °C, 12.8-11.4 kyr BP), and a rapid warming at onset of the Holocene. The reconstructed temperature was weighted towards the wintertime since the lake is a monomictic lake that mixing process enhances nutrients transportation from lake bottom to whole water column, and greatly facilitates organism growth and multiplication. Additionally, the winter-biased temperature change observed in tropical Lake Huguangyan was more distinct than the summer temperature records in extra tropical regions in the land area of the EASM. Within the limits of the dating uncertainties, the broadly similar pattern of winter-weighted temperature change observed in both tropical Lake Huguangyan and Greenland ice cores. We suggest that cold surges could play an important role in the rapid transmission of the temperature signal from the Arctic to the tropics.

Testing Possible Climatic Mechanisms of Vegetation Turnover and Novelty in North America and Europe

Kevin Burke¹, Simon Brewer², Walter Finsinger³, Thomas Giesecke⁴, Alejandro Ordonez⁵, John Williams¹
¹University of Wisconsin, Madison, USA. ²University of Utah, Salt Lake City, USA. ³University of Montpellier, Montpellier, France. ⁴University of Göttingen, Göttingen, Germany. ⁵Aarhus University, Aarhus, Denmark

Abstract

Multiple climatic mechanisms have been hypothesized to cause community reshuffling and the emergence of novel communities. These include emergence of novel or no-analog climates, high rates of velocity or displacement, and spatial divergence among individual climatic displacement vectors. The detailed record of vegetation and climate dynamics during the last deglaciation enables tests of these hypotheses and insights into current global change. Prior work has linked climate and community novelty, or tested for disequilibrium, but no analyses have yet simultaneously assessed these multiple potential climatic drivers of ecological novelty. Using transient paleoclimatic simulations, we quantify climatic novelty, displacement, and divergence across North America and Europe from the last glacial maximum to present. Then, using over 1,200 records of fossil pollen from the Neotoma Paleoecology Database and European Pollen Database, we quantify community dissimilarity.

We use mixed-effects models and data from adjacent time steps to test hypotheses about which climatic mechanisms are most closely associated with highly novel and no-analog plant assemblages in each region. Climate dissimilarity, displacement and divergence among climate variables (seasonal temperature and precipitation, $n = 8$) are treated as fixed effects, and time as a random effect. Our results suggest that climate dissimilarity is the most important predictor of community novelty for both North America and Europe, while rates of displacement are also significant for Europe. We also explore the effect of directionality and lagged baselines on our climatic mechanism patterns. We find that mid-Holocene climates for both Europe and North America are most dissimilar when compared to late-glacial climates, and that the same pattern holds true when comparing the dissimilarity of plant communities from the mid-Holocene to those of the late glacial. Our results support prior linkages between climatic novelty and community novelty, while suggesting that in some time periods and regions displacement is another important predictive factor. These results suggest that the 21st-century emergence of novel plant associations will be driven by both rapid rates of climate change and emergence of novel climate states.

Palaeoshorelines on the Australian continental shelf and offshore islands

Brendan Brooke, Scott Nichol, Zhi Huang
Geoscience Australia, Canberra, Australia

Abstract

Drowned coastal landforms occur at numerous locations on the Australian continental shelf. These features influence long-term sediment transport on the shelf, provide habitat for a range of marine biological communities, and represent potential areas of human occupation during periods of lower sea level. Similar structures occur at a range of locations globally. In Australia, examples have been mapped using high-resolution multibeam echosounder (MBES) systems. Here we present our updated record of Australian palaeoshorelines, which occur at depths ranging from ~20 m to 120 m below present sea level. Given the tectonic stability of the Australian shelf, these features appear to record the more persistent or frequent stands of the sea in the Middle to Late Quaternary. The type of features preserved varies across the different shelf regions. For example, shore-parallel ridges extend along tens to hundreds of kilometres of the inner and middle continental shelf of south-western (sea level at approximately 30 m and 60 m below present) and central Western Australia (40 m); carbonate banks are common on the north-western and northern shelves (~30 m and 90 m) and outer margin of the Great Barrier Reef (~60 m); channel structures extend across large sections of the northern (80 – 90 m) and eastern shelves (30 – 55 m); and shallow shelves extend around the margins of several offshore islands (~25 – 35 m and 70 m). We present elevation models of these features, based on MBES data, which indicate they represent remnants of drowned beach-ridge strandplains, coastal dune fields, estuarine channels and platform and barrier reefs.

Holocene paleo tidal inlets as markers of the rising sea: a case study from the northern Adriatic shelf (Italy)

Livio Ronchi¹, Alessandro Fontana¹, Annamaria Correggiari²

¹University of Padova, Padova, Italy. ²CNR-ISMAR, Bologna, Italy

Abstract

We recently detected and characterized a series of abandoned and filled incised channels documented in the north-western Adriatic shelf. About 100 of them have been recognized as remnants of paleo tidal inlets which formed during the post-LGM transgression that led to the submersion of the shelf. These features were identified through the re-analysis of about 7000 km of high-resolution geophysical surveys (CHIRP-sonar profiles) and tens of stratigraphic cores carried out in the area during the last 30 years.

The preservation potential of paleo tidal inlets is usually low, as such features are often almost completely erased by the wave ravinement processes. As a matter of fact, only few examples are known in literature and they are usually confined to low-gradients shelves.

Despite their rarity, paleo tidal inlets are ideal markers for the reconstruction of the timing and impact of the sea-level rise on the transgressed coastal plain. A wealth of information can be obtained by analyzing their buried morphology, stratigraphic position and infilling sediments, such as the location of the paleo coast lines, the dimensions of the paleo lagoon systems and, in some conditions, the relative paleo sea-level. These features can therefore represent valid means to reconstruct the last marine transgression.

The paleo tidal inlets identified in the shelf of the northern Adriatic are characterized by a wide range of thickness, spanning from few to almost 20 m, and by the absence of any evidence of lateral or landward migration. These characteristics, along with the great number of recognized features, suggests the recurrent formation and overstepping of large lagoon systems during the last marine transgression.

In particular, these features can be subdivided into clusters based on the depth of their top, thus allowing to infer the position of a series of paleo coastlines and suggesting the occurrence of periods of stasis of the relative sea-level rise, which allowed the formation of such inlets.

By coupling the ages obtained for the infilling materials and the stratigraphic relations intercurring among the analyzed features, it was possible to reconstruct some of these moments and, in particular, a still stand phase of the sea level was identified around 9.5 ka cal BP, as also confirmed by other indicators available for the Adriatic Sea.

This research provides new insights on two main topics: i) it improves our knowledge on the post-LGM marine transgression, therefore contributing to reconstruct the history of sea-level rise and to constrain the modelling of future behavior; ii) it contributes to understand the evolution of tidal inlets and lagoon-barrier island systems under the forcing of high rates of sea-level rise.

High-resolution bathymetry in select Philippine reefs and their implications on the paleosea level changes since the Last Glacial Maximum

Jeffrey Munar¹, Erin Joy Tinacba², Cesar Villanoy¹, Patrick Cabaitan¹, Ma. Angelique Doctor¹, Edwin Dumalagan Jr.¹, Fernando Siringan¹

¹Marine Science Institute, Quezon City, Philippines. ²University of Osaka, Osaka, Japan

Abstract

Coral reefs are effective benchmarks in analyzing past sea levels due to their limited vertical range and good geologic preservation. In the Philippines, most sea level studies are only limited up to 10.2 ky records from emergent reef bodies. In this study, we analyze submerged sea level markers in several localities in the Philippines: Tubbataha Reef, Palawan; Apo Reef, Occidental Mindoro; and Patnanungan Reef, Quezon. High resolution multibeam bathymetry up to 200 m show diverse undersea features including reef mounds, reef ridges and series of multiple terraces and steep scarps. These reefs are further confirmed using diver and drop camera observations. These are interpreted as backstepping reefs that were drowned during an overall rise in sea level from the Last Glacial Maximum (LGM). Comparison of the depth distribution across reefs show clustering in four depth ranges which may correspond to four major sea level stillstands in the past 21 ky in the West Pacific Region. Variations in depth and number of terraces indicate tectonic influence in each site. This provides an opportunity to extend the relative sea level records towards the LGM in the Philippines and elucidate on the history of vertical movements in the region.

New data regarding the evolution of the paleo-shorelines and paleo-hydrography in the northwestern Black Sea

Gabriel Ion¹, Tiberiu Bogdan Sava², Andrei Briceag¹, Mihaela Melinte¹, Maria Valentina Ilie², Florin Duțu¹, Elena Ion¹
¹National Institute for R&D in Marine Geology and Geo-ecology - GeoEcoMar, Bucharest, Romania. ²Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering, Măgurele, Romania

Abstract

Black Sea is a very peculiar basin, due to its character of a semi-enclosed sea and its episodic connectivity with the Mediterranean Sea and further with the world ocean during Quaternary. This peculiarity produced a complex pattern of paleo-shorelines and paleo-hydrography, imprinted in the sedimentary structures deposited and/or eroded, on the actual continental platform and in the shelf break area. The unsteady regressions and transgressions produced by the successive sea level variations (mainly due to the climatic changes) have controlled the formation/destruction of the paleo-shorelines and corresponding hydrographic networks in the above mentioned areas. The sea level variations has been convoluted with other local, regional or global phenomena, as differential compaction of the young sediments, regional active tectonics and glacial isostatic adjustment; as a result the morphology of the seabed and the shallow sub-structure of the sea-bottom, that are the main geological and geomorphological features we can measure and depict in order to decipher the evolution of the paleo-shorelines and paleo-hydrography in general, are very complex in the NW Black Sea.

The NW part of the Black Sea is the widest shelf area of the present basin and consequently the most prone area to record the paleo-shorelines and paleo-hydrography of this sea. This spatial development is both an advantage in studying the above mentioned evolution (being the most sensitive to the controlling parameters), but also a disadvantage, because of the complexity of the morphological patterns and sub-bottom structures that are the results of the paleo-shorelines migration/erosion, incision/filling up/erosion of paleo-valleys, former developed on the continental platform..

In the framework of the uBiogas (24PCCDI/2018) project we used multibeam echosounding and sub-bottom profiling techniques, together with the radioactive dating, in order to decipher the paleo-geography of the area during Quaternary, that further influenced/controlled the development and the deposition of the organic matter, the raw material for the biogenic methane production and accumulation. We searched for structures that could indicate via further sampling and dating the age of the incisions on the continental platform, thus documenting the timing of the large sediment supply towards the continental slope, contributing to the building up of the Danube deep sea fan edifice.

The studied area is closed to the shelf break, where the paleo-valleys are incised on the continental platform and further developed in deeper waters, on the continental slope.

Looking Down Under: GPR, OSL, and LiDAR (GOaL) provide insight on sea-level and coastal change through space and time

Amy Dougherty¹, Jeong-Heon Choi², Chris Turney³, Anthony Dosseto¹

¹University of Wollongong, Wollongong, Australia. ²Korea Basic Science Institute, Ochang, Korea, Republic of. ³The University of New South Wales, Sydney, Australia

Abstract

Change is constant along the coast, driven by small-scale fluctuations in water level associated with waves/tides, greater variation during periodic storms/surges, and sea level movement over longer time-periods. Deciphering coastal change caused by the imperceptible rise in sea level from shifts associated with storms, sediment supply, and human modification is not straight forward. Sensitive environments with long-term continuous records provide the best opportunity to detect past changes in coastal evolution or sea level, as well as any recent shifts related to anthropogenic global warming. Sandy coasts are vulnerable to future sea-level rise and this sensitivity gives them the potential to preserve records of past changes. Barriers that have prograded during interglacial periods preserve within their accreting sands a series of paleo-beachfaces, the elevation of these relic features is intrinsically linked to sea level and their morphology is inherently affected by storms. Utilizing Ground-Penetrating Radar (GPR), Light Detecting and Ranging (LiDAR), and Optically Stimulated Luminescence (OSL) on prograded barriers has documented changes in evolution and determined the influence (as well as extract paleoenvironmental records) of sea level, sediment supply, accommodation space, and storms.

Here we present the potential of combining GPR, OSL, and LiDAR (GOaL) systematically on several prograded barriers in far-field Australia and New Zealand to disentangle local influences of sediment supply and accommodation space from regional patterns of storms or global changes in sea level. Collecting GOaL data across composite barriers that have prograded throughout the Pleistocene and Holocene can extend these records back to when sea level was known to be higher than today, during the Eemian. Furthermore, constructing sea-level curves along these coasts using GOaL produce dense plots of a single proxy that can identify subtle changes obscured by sparse data or amalgamations of different proxies with various error bars. We will present data from multiple sites that maps the elevation of these beachfaces from the present day over millennia. This data have already contributed to ongoing debates about the elevation and duration of the mid-Holocene highstand in New Zealand and Australia. Detailed records from these more geologically stable settings are sought after to identify the relationship of global ice-equivalent and global sea-level changes in order to model their response to future climate change. These projections, combined with refined records of sea level, storm erosion, sediment supply, and human modification gained from GOaL in a coastal system, will enable more accurate models of future beach behaviour resulting from global warming. Ultimately, this can inform vulnerable coastal communities on how best to prepare for the upcoming centuries when climate change is forecast to return sea-level to elevations not seen for thousands to hundreds of thousands of years.

¹Irish Centre for Research in Applied Geoscience, Dublin, Ireland. ²School of Civil Engineering, University College Dublin, Dublin, Ireland. ³Irish Centre for Research in Applied Geosciences, Cork, Ireland. ⁴School of Biological, Earth & Environmental Sciences, University College Cork, Cork, Ireland. ⁵Irish Centre for Research in Applied Geosciences, Dublin, Ireland

Abstract

A number of submarine channel features have been identified on the southern Irish Sea seafloor including Lambay Deep, Codling Deep and Wicklow Trough. These bathymetric features are distinctive from the surrounding seafloor by their steep depth and morphology and have been described as major incisions (Wingfield, 1989), enclosed deeps (Wingfield, 1990) and tunnel valleys (Callaway et al., 2011; Eyles and McCabe, 1989; Whittington, 1977). They are believed to be part of a late- to post-glacial drainage network and likely represent a series of processes with varying stages of ice excavation and meltwater discharge related erosion.

In this study, we focus on data gathered from Wicklow Trough. We use the spatial integration of multibeam echosounder and sparker seismic data, supplemented by benthic grab samples, vibrocores and digital seabed photography, to characterise its present day morphology and sub-surface structure.

The current morphology and stratigraphy of Wicklow Trough exhibits a high-level of lateral variability with over-deepened sections, inferred glacial and post-glacial deposits infilling the Trough with slump deposits found on the flanks. The data invokes a time transgressive model with headward erosion during ice sheet retreat accompanied by pressurised subglacial meltwater discharge. At present the seabed within Wicklow Trough is highly dynamic and variable consisting of large, actively migrating sediment waves throughout along with scour pits and coarse sediment deposits.

With additional analyses, we aim to further investigate the formation and development of Wicklow Trough. In addition, we aim to discern the development of Wicklow Trough within the broader tunnel valley/glacial drainage system and relative to past ice-sheet dynamics. Similarly, we discuss post-glacial environments of the Wicklow Trough and assess its current geomorphology and active processes. As a result of this study, we will contribute to the growing understanding of British and Irish ice-sheet development and post-glacial, Holocene environments in the Irish Sea.

Abstract

Mapping the paleo extent of Greenland glaciers provides tie points for ice sheet models and is important for constraining Greenland's response to climate forcing and contribution to future sea level rise. Here we present a continuous ice core record from the Renland ice cap on the east coast of Greenland and proxies which constrain its local altitude and extent over the past glacial cycle.

The new REnland ice CAP (RECAP) ice core extends 584.11 metres to the bottom of the Renland ice cap located in east Greenland. Due to the unique position on a mountain saddle above 2000 metres altitude, the core archives a climate record including the entirety of the last glacial period, despite the short length. The glacial section is strongly thinned and covers just ~20 meters of the ReCAP core, but nonetheless due to the high resolution of the measurements all 25 expected DO events could be identified. Below the glacial section another ~20 meters of stratigraphically disturbed Eemian ice have been analyzed.

The results from the ReCAP ice core differ from the central Greenland deep ice cores, due to the coastal location and local ice flow. The record was analyzed for multiple ice core proxies including a continuous record (CFA) of insoluble dust particles by means of Abakus laser particle counter and the dust proxy calcium, as well as discrete samples of total air content (TAC).

During both the Holocene and the previous interglacial period (the Eemian), the ice core dust record is dominated by coarse particles from local East Greenlandic sources, whereas the dust from the last glacial period consists mainly of smaller particles from remote sources. The fraction of coarse particles in the record is a proxy for glacier extent in the Scoresbysund area, as the reduction of coarse particles during the glacial indicates that most local dust sources were inactive and/or ice covered.

We find no indication that the Renland ice cap has significantly changed in altitude from the last glacial to the present interglacial period. The Total air content (TAC) in ice cores depend primarily on the altitude and thus we can reconstruct altitude changes for Renland. We find no indication that the Renland ice cap has significantly changed in altitude from the last glacial to the present interglacial period showing the significance on the glacier shape by the surrounding mountains. However high resolution TAC was not possible to obtain in warmest phase of the Holocene as ReCAP was predominantly affected by melt then.

¹⁰Be CRE dating of moraines in the Isortup valley (Greenland): Evidence of limited glacial advances over the last three millennia

Melody BIETTE^{1,2}, Vincent JOMELLI^{1,2}, Vincent RINTERKNECHT¹, Marie CHENET^{1,2}, Laetitia LEANNI³, ASTER Team³

¹The Laboratory of Physical Geography, Meudon, France. ²University Paris 1 Pantheon Sorbonne, Paris, France.

³CEREGE, Aix en Provence, France

Abstract

Glacial fluctuations during the Holocene have not yet been investigated much in southern Greenland. This work aims to establish an absolute chronology using ¹⁰Be cosmic-ray exposure dating from glacial moraines formed by three mountain glaciers located in the Isortup Valley near one of the largest sites colonized by the Vikings at the end of the 10th century. The sample preparation was realized at the CALM laboratory (Meudon, France) and analysed at the CEREGE by the ASTER Team (Aix en Provence, France).

The ages of the moraines suggest at least three phases of glacial advances over the last three millennia. The oldest ice age identified was about 2300 years ago. The second phase synchronous for the three glaciers occurs 1100 years ago, i. e. about 900 CE, and precedes the warm period of the Medieval Climate Anomaly (MCA: ~950 CE to 1250 CE), while the last phase of glacial advance identified corresponds to the Little Ice Age (LIA: ~1450 CE to 1850 CE). Surprisingly, these moraine stages are close to each other and close to the current front (>1 km) for the three glaciers studied. Therefore they show limited glacial extensions and suggest fairly similar climatic conditions to the present one for the three periods identified. Our chronology of glacial fluctuations is then compared with local paleoenvironmental studies of lake sediment core in order to better understand the climatic variations responsible for these glacial advances in relation to Norse settlement patterns.

Our results are consistent with the cold periods identified from other environmental proxies studies conducted in southern Greenland and show that the Norse occupation occurred between two glacial advances. This study provides a new dataset and explores climate variability in southern Greenland. Also provides a better understanding of the factors responsible for the abandonment of Norse settlements.

The expected inception of Icelandic Ice Caps

Leif S. Anderson^{1,2,3}, Áslaug Geirsdóttir¹, Gwenn E. Flowers², Andrew D. Wickert⁴, Guðfinna Aðalgeirsdóttir¹, Thorsteinn Thorsteinsson⁵

¹University of Iceland, Reykjavík, Iceland. ²Simon Fraser University, Burnaby, Canada. ³GFZ German Research Centre for Geosciences, Potsdam, Germany. ⁴University of Minnesota, Minneapolis, USA. ⁵Icelandic Meteorological Office, Reykjavík, Iceland

Abstract

Observational constraints of glacier inception are important because they reveal the timing of past periods of cooling, most notably the Neoglacial period. Inception occurs when the equilibrium line altitude (ELA) lowers and intersects the highest bedrock capable of accumulating ice. While the concept of inception is simple, observational constraints of inception are rare because glaciers override and erode sedimentological evidence. Erosional censoring is especially prevalent for the Pleistocene ice caps. Inception evidence is more abundant from the Holocene, but is known for at most, a few glaciers within a region. Here we present a new, efficient method to assess the timing of glacier birth and apply it to Iceland where constraints of inception are relatively abundant. We model the ELAs of 20 ice caps, and in doing so produce the first regional estimates of inception across a population of glaciers. We force the model with lake-, sea- surface-temperature-, and ice-core-derived temperature reconstructions. We also explore the effect of glacial-isostatic adjustment and variable precipitation. Mass balance parameters are tuned for each ice cap using modern data. We use inception constraints based on lake sediments to evaluate the success of individual model simulations. Icelandic glacier inception likely ranged from before the Holocene to the Little Ice Age.

Topography is the primary control of the timing of glacier inception in Iceland. The onset of Holocene (Neoglacial) cooling could be better established using new, simple topographic metrics to identify the glaciers most likely to form first. Our modeling reveals that these simple metrics, easily measured from global data sets, exert a first-order control on inception, and can be used as a rapid means of contextualizing ongoing and future glacier change.

Changes in the drainage pattern of the Eastern Antarctic Ice Sheet since the Late Miocene

Naki Akçar^{1,2}, Serdar Yeşilyurt^{1,2}, Vural Yavuz³, Marcus Christl⁴, Christof Vockenhuber⁴, Kristina Hippe⁵

¹Institute of Geological Sciences, University of Bern, Bern, Switzerland. ²ITU PolRec, Istanbul, Turkey. ³ITU Faculty of Mines, Istanbul, Turkey. ⁴Laboratory of Ion Beam Physics, ETH Zurich, Zurich, Switzerland. ⁵Institute of Geological Sciences, Freie Universität Berlin, Berlin, Germany

Abstract

The assessment of the stability of Antarctic ice sheets and of their contribution to the global sea level change as a response to climate change requires the reconstruction of their past volume variations. For instance, dramatic surface lowering of East Antarctic Ice Sheet (EAIS) during the last million years have been recently reported. However, the spatial distribution of this lowering remains unexplored. Today, Sør Rondane Mountains in the Queen Maud Land acts as a barrier to the EAIS. This is displayed by the difference in altitude of the ice surface to the south and north of the mountain chain. To the south, ice surface reaches altitudes above 2500 meters above sea level. Lowlands of ice are found at altitudes of around 1500 meters to the north of the mountain chain. In this study, we aimed to use suite of cosmogenic nuclides (¹⁰Be, ¹⁴C, ²⁶Al and ³⁶Cl) in 38 rock surface samples to decipher the timing, magnitude and frequency of the surface lowering history and change in drainage pattern of the EAIS in the western Sør Rondane Mountains.

During the BELARE 2017-2018 Expedition, we identified abandoned valleys situated at elevations few hundred meters above today's ice surface, which point to a dramatic surface lowering of EAIS in the western Sør Rondane Mountains and thus a change in drainage pattern in time. Based on our first results, we propose that the surface of the EAIS was at least 400 meters higher than today. This indicates a linkage between the south and north of the mountain range and a major drainage towards northeast over the mountain range during the late Miocene. At the beginning of Pliocene, ice surface started to decrease, and the south-north linkage was broken by prior to ca. 1.3 Ma as a result of ca. 400 m of lowering. This caused the ice drainage to be channelized into either few main valleys or around the mountain range. Afterwards, the glaciation continued until around 130 ka, when a dramatic decrease in the ice surface elevation occurred in the ice lowlands to the north of the mountain chain. However, the ice plateau to the south seems not to be affected by the dramatic changes occurred on the northern side of the mountain range.

Response of glaciers since last 20 ka in the transitional climate zone of the Southern Zaskar Ranges (NW Himalaya)

Shubhra Sharma¹, Anil Shukla²

¹IISER Mohali, Mohali, India. ²Physical Reserach Laboratory, Ahmedabad, India

Abstract

The transitional climatic zone of the Southern Zaskar Range, NW Himalaya is investigated for the relics of glacier advances and retreats as glaciers responded to the temporal changes in the Indian Summer Monsoon (ISM) and mid-latitude westerlies. Four glacier advances named from the oldest to youngest as the Southern Zaskar Glacier Stage-4 (SZS-4) to SZS-1 are identified. The SZS-4 remains undated, however based on the existing chronology of the stratigraphically equivalent moraines/trimlines in the region; it is conjectured to the Marine Isotope Stage-4 (MIS-4). The SZS-3 is dated using optical chronology to 22.8 ± 1.9 - 19.1 ± 1.9 ka and corresponds to the Last Glacial Maxima (LGM). The SZS-2 is dated to 15.7 ± 1.3 - 14.3 ± 1.3 ka (late Glacial period) whereas, based on the chronology of the recessional moraines (4.9 ± 0.4 - 4.5 ± 0.3 ka) the youngest SZS-1 is assigned to ~ 6 ka (mid-Holocene). The snout proximal moraines are attributed to the Little Ice Age (LIA)/historical times. The recessional moraines and outwash gravel terraces represent the pulsating deglaciation associated with each advance in last 20 ka. The older gravel terrace is dated between 10.8 ± 0.9 and 6.5 ± 0.5 ka and is attributed to SZS-2 retreat which is also manifested by the deposition of sandy facies in a relict lake sequence (6.7 ± 0.6 ka) and development of palaeosol (5.6 ± 0.5 ka). We propose that the glacial advances were triggered by the millennial scale cooling events during the periods of strengthened westerlies and thus, suggest a synoptic scale coupling with the Northern Atlantic. The glacier retreat is suggested to occur during the warmer ISM dominated phases. The late Holocene climatic instability that followed the recession of SZS-1 is manifested by the development of rhythmities (3.8 ± 0.5 ka), loess (2.5 ± 0.2 ka), and palaeosol (2189 ± 296 cal yr BP).

First absolute dating chronology of glaciers variations in the Northern Caucasus

Olga Solomina¹, Vincent Jomelli², Regis Braucher³, ASTER TEAM³, Irina Pavlova⁴

¹Institute of Geography RAS, Moscow, Russian Federation. ²LGP UMR, Meudon, France. ³CEREGE, Aix en Provence, France. ⁴UNESCO, Paris, France

Abstract

The glaciers of the Greater Caucasus (42°N; 46°E) are a vital economic and water resource for indigenous peoples. These glaciers are currently declining but it is still difficult to quantify the impacts of anthropogenic activities on this trend. One of the major issues for such quantification is linked to our poor knowledge of the natural forcing effects on glacier evolution. These glaciers can offer an opportunity to document environmental changes in the past

Here we present the first absolute dating chronology of glaciers variations in this region based on cosmogenic ¹⁰Be dating, ¹⁴C ages from paleo-soils and tree ring sampling. 25 rock samples were collected on the largest moraines close to the front position of 5 glaciers in Elbrus region. ¹⁰Be and ¹⁴C ages span the Late glacial and Holocene period. More than 300 trees were cored at the moraines and glacier forefields either at breast height (1.5 m) or at the lowest possible level near the soil surface in order to identify the minimum age of the landforms.

These methods made it possible identifying the major glacier advances over the last 15 000 years. Our precise ¹⁰Be chronology revealed glacier culmination during the oldest Dryas even if the length of the glaciers at that time remains elusive due to pure moraine preservation. We did not identify any deposit directly related to the Younger Dryas. A second major advance occurred during the earliest Holocene ~11.4 k.y. ago. We did not find so far any moraine deposits of similar amplitude accumulated until ~2 k.y. ago, when the glaciers reached last millennium limits. The age of a soil layer buried between two horizons of the moraines of Bolshoy Azau glacier however indicates that at least one large earlier Neoglacial advance occurred before 2880±20 years BP (IGRAS ams – 6827).

Interestingly, at least one glacier advance is observed during the Medieval Climate Anomaly (~950 to 1250 CE). or during the first stage of the Little Ice Age (late 13th century CE). A number of advances between 500 and 170 yr are documented by ¹⁰Be records. Tree-ring minimum dates indicate that the advances occurred in the late 18th century and in the early-mid 19th century CE. General glacier retreat started in the late 1840s CE. A number of minor readvances are identified in the 1860s–1880s CE, as well as in the 1910s, 1920s and 1970s–1980s CE. Based on this glacier chronology we applied a glaciological model making possible to document past climate conditions responsible for these glacier changes.

O-2021

The significance of interannual variability for paleoclimatic interpretation of glacial moraine sequences

Eric Leonard¹, Mitchell Plummer², Benjamin Laabs³

¹Colorado College, Colorado Springs, USA. ²Idaho National Laboratory, Idaho Falls, USA. ³North Dakota State University, Fargo, USA

Abstract

Mountain glaciers respond to both long-term climate forcing and interannual forcing. Anderson et al. (2014) pointed out that kilometer-scale fluctuations in glacier length may result from interannual variability in temperature and precipitation during a period of “steady” climate with no long-term trends in mean or variability of temperature and precipitation. They cautioned that due to the effect of interannual forcing on glacier length, use of outermost moraines from the Last Glacial Maximum (LGM) as indicators of mean LGM climate will result in overestimation of the magnitude of long-term temperature depression and/or precipitation enhancement. Here we assess the implications of these ideas by examining the effect of interannual variability on glacier length and on the inferred magnitude of LGM climate change from present, under both an assumed steady LGM climate and an LGM climate with low-magnitude, long-period variations in summer temperature and annual precipitation. We use both the original one-stage linear glacier model (Roe and O’Neal, 2009) used by Anderson et al. (2014) and a newer three-stage linear model (Roe and Baker, 2014). We apply the models to reconstructed LGM glaciers in the Colorado Sangre de Cristo Mountains, employing Monte Carlo analysis to assess the effects of multiple glaciological and climatic variables on the magnitude of glacier length variations introduced by interannual variability, and on the resultant overestimation of mean LGM temperature depression introduced by such variability.

Three-stage-model results indicate that, absent long-term climate variations through a 7500-year-long LGM, interannual variability alone would result in glacier length variations of $\pm 400 - 1210\text{m}$ (2σ). If the outermost ice-marginal position produced in each model run is taken to indicate mean LGM conditions, this would result in overestimation of mean LGM temperature depression by $0.17 - 0.45^\circ\text{C}$ (2σ). If low-magnitude cyclic variations of temperature and precipitation during the LGM are introduced in the model, the magnitude of overestimation of mean LGM temperature depression due to interannual variability decreases, and in a small number of model runs the effect of interannual variability is to cause an *underestimation* of mean LGM temperature depression. If cyclic variations of temperature ($\pm 1.0^\circ\text{C}$) and precipitation ($\pm 10\%$) are introduced, the 2σ error in inferred mean LGM temperature depression ranges from a 0.14°C underestimation to a 0.31°C overestimation.

The Quaternary history of yew (*Taxus baccata*) — an overview from an Irish perspective

Karen Molloy, Michael O'Connell

National University of Ireland Galway, Galway, Ireland

Abstract

The Quaternary history of *Taxus baccata* (yew) is readily traceable in the macrofossil record on the basis of its distinctive fruit and leaves and, at a microscopic level, its wood anatomy. Its pollen on the other hand, though distinctive especially at high magnification, is easily confused with other common pollen types including Cyperaceae (sedges), *Quercus* (oak) and *Juniperus* (juniper). This is particularly so in the case of profiles where *Taxus* pollen occurs with low frequencies and is not abundant.

As a result of the difficulties involved in recognising its pollen, it can be assumed that, in many Irish pollen diagrams up to and including most of the 1980s, its pollen went largely unrecognised. A notable exception is the pollen profile from Gort, Co. Galway which is regarded as the standard profile for the Gortian interglacial (Jessen et al. 1959. *Proc. R. Ir. Acad.* **60B**, 1–77). *Taxus* pollen is dominant or at least important for most of this pollen profile which serves to highlight the importance of yew during the Gortian interglacial (equivalent to the Hoxnian/Saalian and Oxygen Isotope Stage (OIS) 11) at this western Ireland location.

Recent investigations have shown that yew also made substantial contribution to Holocene woodlands in Ireland, locally and also regionally, and especially during a period of low human impact in the late Neolithic (ca. 4900 cal. BP). In this presentation, emphasis will be placed on new data that relate to the post-glacial history of yew in Ireland, and the interactions between climate change and human impact in mediating the exceptional post-glacial history of this conifer.

Intensive dairying in 4th millennium BC Ireland? The Ceide Fields complex, Co. Mayo, northwest Ireland

Jessica Smyth, Graeme Warren, Seamas Caulfield
School of Archaeology, University College Dublin, Dublin, Ireland

Abstract

The Céide complex of drystone co-axial field systems in north Mayo, northwest Ireland, has been extensively mapped and partly excavated over a number of decades and is argued to be the oldest in Europe, emerging in the 4th millennium BC. While recent research has demonstrated dairying is contemporary with the arrival of farming in Ireland, by at least 3800 BC, there is as yet no proven relationship between the sophisticated land management evidenced at Céide and dairying, although soil lipid analyses have indicated arable farming is unlikely. This landscapes/foodscapes relationship will be elucidated through molecular and isotopic analyses of lipid residues preserved in Neolithic pottery sherds recovered from excavations within the field systems, which provide a powerful proxy for animal husbandry and consumption practices. This new evidence will be set alongside detailed analysis of the dating evidence for the Ceide Fields complex, demonstrating unequivocally the Neolithic date of the field systems and rebutting recent suggestions of a later, Bronze Age date for the activity.

Direct Push sensing and geoaerchaeological sounding at Neolithic Pestenacker settlement (Lech catchment, SW Germany)

Anne Köhler¹, Johannes Völlmer¹, Stefanie Berg², Ulrike Werban³, Peter Dietrich³, Christoph Zielhofer¹

¹Leipzig University, Institute of Geography, Leipzig, Germany. ²Bavarian State Department for Cultural Heritage (BLfD), Leipzig, Germany. ³Helmholtz Centre for Environmental Research – UFZ, Department Monitoring & Exploration Technologies, Leipzig, Germany

Abstract

Wetland margins are valuable geoaerchaeological archives due to their preferential settlement conditions in prehistoric time. A high groundwater level usually provides excellent preservation conditions for palaeoecological and geoaerchaeological proxies, as well as for archaeological artefacts. However, this advantage also impairs classical archaeological excavations as a result of the increased groundwater inflow. Alternative percussion drillings offer inaccurate depth data due to the increased compaction rates in organic rich sediments. The direct push sensing technology, rarely used for palaeoenvironmental and geoaerchaeological research, offers the opportunity to overcome this problem. Different probes (soil colour, electrical conductivity, cone penetration testing) provide undisturbed and *in-situ* information with a high resolution in a time-effective manner.

The Neolithic settlement of Pestenacker in the Upper Bavarian Alpine foothills (SW-Germany), represents an exceptionally well-preserved wooden house settlement in a wetland environment. It is located at the *Verlorener Bach* floodplain edge and was dated to the year 3495-3476 BC according to dendrochronological investigations. Its great archaeological and transregional importance led to the inclusion in the UNESCO list of World Heritage Sites in 2011 as a part of the “Prehistoric Pile Dwellings around the Alps”.

The talk combines the first results of the different methods and discusses the floodplain stratigraphy at high vertical resolution and the stratigraphic coupling with the Neolithic settlement layers. By using the direct push technology in combination with classical percussion drilling and sediment analysis, we detect a significant change in the Holocene floodplain lithostratigraphy that correspond with the occurrence of Neolithic Pestenacker settlement. Human impact might induced a significant change in catchment hydro-sedimentary dynamics.

Between the peat layers - evaluating wetland archaeological sites through multi-proxy studies in Ireland's Midlands

Ellen O'Carroll¹, Tim Coughlan², Susan Lyons³, Eileen Reilly⁴

¹Trinity College, Dublin, Ireland. ²Archaeological Development Services Limited, Dublin, Ireland. ³University College Cork, Cork, Ireland. ⁴University College Dublin, Dublin, Ireland

Abstract

Archaeological excavations undertaken in a wetland environment in Ireland's midlands have uncovered a multitude of well-preserved archaeological sites over the last 5 decades. In particular, areas of dense archaeological activity have been recorded on the peatlands during the Bronze Age/ Iron Age transition. Several well-constructed and interconnecting trackways and wooden platforms are shown to extend out into the bog during this transitional period. Many theories abound as to why these sites were constructed particularly during this time period. The Late Bronze Age climatic downturn, social occasions, ritual beliefs, an unstable society and/or economic resources have all been debated in relation to the construction and use of these sites. The evidence from this transitional period indicates that people were moving around and within bogs as opposed to across them and there are relatively few longer trackway structures. Can we determine patterns of construction and use in relation to other environmental factors (e.g. vegetation change - local and regional)? This paper will discuss pollen analysis undertaken in tandem with plant macro, wood and insect analysis as important proxies in sourcing motives for wetland archaeological site construction as well as anthropogenic landscape change throughout the Bronze and Iron Age in Ireland's Midlands.

O-2026

Agricultural management practices in Bronze Age Ireland: insights from archaeobotany

Meriel McClatchie

University College Dublin, Dublin, Ireland

Abstract

In common with much of Europe, resource management during the Bronze Age in Ireland (2500–700 cal BC) has largely been considered in terms of metal production. The role of agricultural production has received less attention, even though plant macro-remains and pollen records indicate significant levels of crop cultivation during this period.

Although agriculture was introduced into Europe at the beginning of the Neolithic period (4000 cal BC in Ireland), archaeological studies often suggest that intensive systems of agricultural production were not practiced until the Bronze Age. In the case of Ireland and Britain, the increased appearance of archaeologically identifiable fields and farmsteads during the Bronze Age is often understood to represent agricultural intensification. The intensification of agriculture in Bronze Age Europe is considered to be a precursor to increasing social stratification, with the creation of a strong agricultural economic base enabling the development of hierarchies that controlled the means of production and distribution of produce.

This model of increasing intensity over time will be challenged in this paper through detailed consideration of agricultural terminology and archaeological evidence for intensification, with a focus on archaeobotany. As well as ‘traditional’ methods of archaeobotanical analysis, the paper will show how isotope analysis of charred cereal grains is enabling an exciting new approach to understanding agricultural management in prehistoric Ireland. It will be shown that intensification represents just one of many agricultural strategies available to prehistoric farmers in Europe and cautions against an over-focus on this mode of production.

Splitting the stones! Examining the occurrence and societal impact of drought events in mid- to Late Holocene Ireland

Gill Plunkett¹, David M. Brown¹, Graeme T. Swindles²

¹Queen's University Belfast, Belfast, United Kingdom. ²University of Leeds, Leeds, United Kingdom

Abstract

The maritime climate of Ireland has no doubt had a bearing on Irish identity, encapsulated by the national colour and the island's poetic epithet, the "Emerald Isle", both of which reflect the lush, green pastures that characterise much of the landscape. The weather – specifically, the persistent rain – is a long-standing topic of conversation and humour across the island, and spells of "good weather" (i.e., warm sunshine) are cherished for their relative rarity. But have past populations in Ireland always experienced the same conditions? Discussions of climate impact on prehistoric and early Medieval societies in Ireland have tended to consider how shifts to wetter and/or colder conditions will have negatively impacted the subsistence economy, leading perhaps even to social turmoil and demographic catastrophes (e.g. Turney et al. 2006). Dendrochronological, peatland proxy and early literary evidence demonstrate, however, that Ireland has at times experienced extended (decadal to centennial) phases of drier conditions (Kerr et al. 2009; Swindles et al. 2010; 2012; Torbenson et al. 2012), and documentary evidence highlights the detrimental impact short-term drought has sometimes had on societies. Here we review the palaeoenvironmental evidence for warmer and/or drier periods on the island over the last 9,000 years. With reference to the archaeological and palynological records, we consider the possible socio-economic repercussions of these phases and evaluate whether or not such events played any role in cultural transformations.

Mining activities in the Bernese Alps from the geochemical analysis of alluvial sediments

Filipe Carvalho, Lothar Schulte
University of Barcelona, Barcelona, Spain

Abstract

Mining and smelting activities can release large amounts of metals into the atmosphere, hydrosphere, sediments and soils. Despite the current pollution levels, this contamination is not exclusive of modern industrialisation. For instance, various studies have identified large-scale metal pollution during the Roman and Medieval Periods. The aim of this study centres on the detection of such contamination periods during the last 2500 years, inferred from sedimentary records of the Hasli-Aare delta plain, at the Bernese Alps. The identification of the metal contamination signal is achieved by the analysis of the geochemical responses of four chemical elements: iron (Fe), copper (Cu), zinc (Zn) and lead (Pb). This analysis was performed primarily by X-ray fluorescence (XRF), but results were also compared with conventional XRF, from the analysis of 82 pearl samples. To detect the metal pollution signal, chemical element peak anomalies were selected from values higher or equal to $\bar{X}+SD$ of the entire record. Additionally, we use archaeological and historical sources to corroborate our findings and establish an index of mining activities.

Results from the analysis of the three sedimentary records facilitated identification of the most significant trends of Fe, Pb, Zn and Cu contamination, which correlate with periods of mining activity in the Upper Aare catchment. Considering the positive anomalies of the metal concentration index, four major clusters of higher metal concentrations can be identified. The first major cluster occurs during the prehistoric period, at the end of the Iron Age, between 160 and 100 BCE; the second major cluster occurs at the end of the Roman Period and the beginning of the Early Medieval Period, between 250 and 590 CE; the third major cluster occurs in the Late Medieval Period between 1100 and 1250 CE; and the fourth major cluster occurs at the end of the Late Medieval Period and continues throughout the Modern Period.

The high metal concentration during the prehistoric period is associated with the middle/end of the La Tène culture, which made extensive use of metal and were considerably advanced in their metal-working. The contamination cluster during the Roman Period and beginning of the Early Medieval Period is in accordance with the importance of metal in the roman economy and is also largely corroborated by other sedimentary records that show similar anomalies. The pollution signal from the end of the Late Medieval Period until the Modern Period is supported by various historical records and a few archaeological remains.

Periods of lower metal concentrations and shifts in contamination trends correspond quite accurately with social and economic changes in Central Europe, regional migratory events within Switzerland and significant demographic fluctuations.

Abstract

Pollen data is often used to characterise past vegetation composition and diversity. To improve the interpretation of sedimentary pollen data, it is essential to understand the relationship between pollen and plant richness in contemporary landscapes. This study presents a regional-scale comparison of pollen and plant diversity from northern Europe and evaluates the importance of environmental variables on both pollen and plant diversity. We use a pollen dataset of 511 lake-surface pollen samples ranging through temperate, boreal, and tundra biomes. To characterise plant diversity, we use a dataset formulated from the two largest plant atlases available in Europe. We compare richness estimates and functional diversity estimates based on plant and pollen data.

Pollen richness is significantly positively correlated with plant richness ($r=0.53$). The highest correlation is found between pollen and plant richness of trees and shrubs ($r=0.83$) suggesting that these are the best measures of broad-scale plant richness over several thousands of square kilometres. Data of trees and shrubs is therefore used to test how well pollen data can reflect functional diversity. Community weighted mean values of seven quantitative traits (seed weight, leaf area etc.) are all significantly ($p<0.05$) positively correlated in pollen and plant data of trees and shrubs. The highest correlations are found for seed weight ($r=0.75$) and leaf area ($r=0.68$). For functional diversity (the standardised effect size of mean pairwise distance), the correlations between pollen and plant data are significantly positive for seed weight, leaf weight and leaf area.

Our results confirm that pollen data can provide insights into past plant diversity changes in northern Europe. Reconstructions of mean trait values and functional diversity of chosen traits allow to investigate trends in functional vegetation diversity over long timescales and under changing climatic and habitat conditions.

O-2030

Are communities unsaturated? A millennial scale palaeoecological approach

Sergi Pla-Rabes, Jordi Catalan
CREAF, Bellaterra, Spain

Abstract

Over the last 540 million years, the diversity of life on Earth has increased despite the occurrence of five catastrophic mass extinctions events. Under the current global change, habitat destruction and the introduction of exotic species are the main causes of a worldwide species extinction. However, beyond the global speciation and extinction events, at ecological time scales local diversity is currently increasing in many assemblages. Assuming that communities are saturated, the observed increase in richness could be due to an extinction debt, a transient phenomenon between two ecological states. However, several theoretical developments and empirical data showed that there is no reason to assume an upper bound (other than space) for local and regional richness. Hence, under an open community scenario richness could increase over time. To improve conservation policies is necessary to solve the saturation debate, at least at ecological time scales. Actually, predictive biodiversity models for species composition and richness are mainly considering that there is a limit in the number of species that can coexist in a community. Hence, there is a need for long-term data to include long-term processes and slow variables to understand community assembly and saturation. Here we show a Holocene lake sediment record of benthic and planktonic protist assemblages indicating that communities still unsaturated after 10.000 years (Fig. 1). We observed an early establishment of core functional species that are responding to long-term changes in Holocene climate and lake biogeochemistry. Protist productivity and the abundance of core species declined during north hemispheric cold spells, which lead to a transient increase in rare species. However, after these cold spells species gains was always higher than species losses, which results in the observed increasing trend in richness all through the Holocene. These results points on the relevance of disturbances to maintain and increase local diversity. However, at this stage, we do not know if the local increase on richness is related to a transference of diversity from b-diversity to a-diversity, which would cause a long-term regional biotic homogenization.

Using species indicator values to characterize late-glacial and early Holocene environments and biomes at Kråkenes, western Norway

Vivian A. Felde, Hilary H. Birks

Department of Biological Sciences, University of Bergen, Bergen, Norway

Abstract

Environment and climate control plant distributions. Each species has a tolerance range, which can be characterised by species indicator-values. Several species indicator-values exist for many plants and they have been extensively used in ecological studies to assess environmental changes and ecosystem quality along gradients. However, these values are also valuable tools for reconstructing environment from palaeoecological data.

We used species indicator-values to reconstruct environment and past biomes from detailed plant-macrofossil data from Kråkenes, Norway, covering the late-glacial and the rapid warming into the early Holocene (ca. 14-9.0 ka). We use the well-known Ellenberg values and a newer set of attributes for species geographical distribution along north to south and east to west gradients. This offers a new and simple approach to reconstructing past biomes.

The results show that a stable arctic-montane biome during the late-glacial shifted at the start of the Holocene around 11.5 ka successively into a wide temperate biome ca. 9.0 ka (approximately 2500 years). At the same time, eastern and circumboreal elements characteristic of the late glacial decreased consistently indicating a change from Eurosiberian to European and towards Suboceanic environments.

Mean July and January temperatures are inferred from the modern distributions of the macrofossil species. They show similar patterns to the chironomid-inferred mean July temperature trends at Kråkenes, but these have larger fluctuations and interesting differences in timing. This may be due to different aquatic and terrestrial conditions. Air and lake-water warm quickly, whereas terrestrial substrates warm more slowly as ice melts and species' colonisation lags the temperature development.

Changes in light demand (L), soil moisture (F), productivity (N) and soil reaction (R) show different, but complementary responses. Light demand decreased in time. Soil moisture was relatively stable until it increased during organic soil development during the Early Holocene. Soil nitrogen (a proxy for productivity) also increased during the early Holocene. Soil reaction (pH) increased during the Younger Dryas due to soil disturbance by frost activity. It decreased markedly at the start of the Holocene, reaching low but stable values in the Early Holocene.

Results of our study support earlier interpretations of the vegetational and environmental history at Kråkenes. However, they represent a new and simple way to summarise complex palaeoecological data using similar metrics to those used in modern ecological studies. The responses to past climate warming may help predict what can be expected under present and future climate warming in arctic and alpine regions.

Abstract

In the Mediterranean Basin, long-lasting human activities have largely resulted in forest degradation. Consequently, conservation efforts aimed at preserving and restoring Mediterranean forests often lack well-defined targets when using current forest composition as a reference. In the mountainous areas of central Iberia, land-use has heavily affected woodlands for centuries and even millennia. To assess future developments and as a baseline for planning, environmental managers are interested in understanding the origins of today's landscapes, what were the composition and structure of the 'original' ecosystems and their range of variability. With this main goal, we have been conducting palaeoecological research activities in the Sierra de Guadarrama ('Guadarrama') and Cabañeros ('Cabañeros') National Parks of central Spain during the last years, with a strong focus on conservation and restoration. We have relied on a multi-site (three sites in Guadarrama, two in Cabañeros) and multi-proxy (pollen, stomata, macrofossils, dung fungal spores, charcoal) approach supported by robust chronologies based on the radiocarbon dating of terrestrial plant macrofossils and peat.

Our results show that management history has a strong legacy in current woodland composition and structure. For instance, *Pinus sylvestris* forests have been very stable in Guadarrama for millennia because of the high value of its timber in the past, only declining for short intervals following enhanced grazing and fire occurrence. Contrarily, *Quercus pyrenaica* woodlands appear rather degraded nowadays after centuries of intense coppicing to produce firewood and charcoal, and heavy grazing. In Cabañeros, our data also show a remarkable ecological and engineering resilience of the dominant tree species, deciduous and evergreen *Quercus*, to changing disturbance regimes (e.g. fire, farming), but also a significant decline in the rear-edge populations of *Betula* as a consequence of enhanced grazing activities during the Middle Ages. Our dung fungal spore records indicate that herbivore densities during the last decades are truly unprecedented in Guadarrama and Cabañeros in the context of the last millennia and this may compromise the future persistence of *Quercus pyrenaica* and *Betula*, given the sensitivity to grazing they have shown in the long term.

In summary, our palaeoecological data have allowed: (i) to assure the natural status of pine forests at mid-elevations in Guadarrama; (ii) to prove that birches were more abundant in the past in Cabañeros; (iii) to disclose the existence of significant legacies on the structure of oak woodlands; and (iv) to highlight the sensitivity of birches and deciduous oaks to overgrazing, and the subsequent need for controlling ungulate densities in protected areas and for protecting relict birch populations from browsing by wild ungulates. Finally, we would like to stress the importance of the close and direct contact with the staff of the National Parks to ensure the use of the palaeoecological data in practice.

An analysis of what ecological shortfalls paleoecological data is most suited to address: the case of ancient DNA of plants

Kelsey Lorberau, Kari Anne Bråthen
UiT - The Arctic University of Norway, Tromsø, Norway

Abstract

Ecological shortfalls beset all modern ecological studies: we have incomplete information about species identities, distributions, evolutionary history, functional roles, population dynamics, abiotic tolerances, and ecological interactions. A limiting aspect of many ecological studies to properly address these gaps in our knowledge is the short timeframe, they are rarely longer than a decade, and often inferences are made from only a few years-worth of data. Paleoecological proxies, including pollen, DNA and macrofossils, can remedy this lack of temporal breadth, providing information about distributions, population dynamics, abiotic tolerances and evolutionary history back in time. Functional roles and ecological interactions of plants in the past can be inferred based on our knowledge from today, along with the assumption of the principle of uniformity of nature. Yet, addressing shortfalls, particularly population dynamics, depends on reliable abundance information, while others are dependent on relevant spatiotemporal and taxonomic resolutions which can be challenging to acquire with paleoecological data.

In this study, we look into which ecological shortfalls paleoecological studies are most suited to resolve, exemplified by ancient DNA of plants. Detection of plants from ancient DNA (aDNA) is a proxy that can provide good taxonomic depth and breadth, particularly as databases and laboratory procedures improve. We address the typical spatiotemporal and taxonomic resolutions of both plant community aDNA research and modern ecological vegetation research, with emphasis on study design, and discuss the implications in the context of addressing ecological shortfalls. A careful consideration of these knowledge gaps opens up opportunities for integration between paleo- and modern ecology.

Environmental controls on pollen chemistry variation and implications for palaeoecological research.

Florian Muthreich¹, Boris Zimmermann², Alistair Seddon¹

¹University of Bergen, BERGEN, Norway. ²Norwegian University of Life Sciences, Ås, Norway

Abstract

Quaternary palynologists are heavily reliant on the use of morphological analysis of sub-fossilised pollen grains to document compositional assemblage changes through time. However, traditional methods for pollen identification based on morphology are time consuming and limited by taxonomic precision. Predictions of future ecosystem dynamics rely on our knowledge to identify ecosystems and the species they are comprised of. The ecological information obtained from fossil records is constrained by taxonomic difficulties for some taxa, preventing identification to species level. Infrared spectroscopy has been proposed as a promising alternative approach, which uses the information on chemical composition of pollen by characteristic spectral bands and features, using specific signals from lipids, carbohydrates, sporopollenin and other cell-wall biopolymers that can be used to fingerprint species. Exploring the chemical variation of pollen in modern samples is an important step to apply these methods in palaeoecological research.

This study aims to apply two IR pollen-chemistry methods on *Quercus* and *Eucalyptus* pollen sampled from wild populations in Australia and Portugal, and environmental gradients. *Quercus* and *Eucalyptus* are useful models to test this method, because of large numbers of species in both taxa, which are hard to identify using traditional light microscopy methods. Both genera are interesting objects of study: *Quercus* inhabits a large ecological range and is an integral part of woodlands all over the world, while *Eucalyptus* and its unique fire dynamics through time remain unclear.

Fourier Transformed Infrared Spectroscopy (FTIR) is used to explore the variation in lipid, carbohydrate and protein content, while the composition of sporopollenin is investigated using Raman Infrared Spectroscopy. Here, we present work which investigates whether: (i) taxonomic signals in chemical spectra of *Quercus* and *Eucalyptus* groups can be identified down to species level, (ii) environmental signals are stored in chemical spectra of *Quercus*, (iii) variation in pollen chemistry on population level. These results represent an important stepping-stone for applying pollen-chemistry techniques to fossil samples. Improved taxonomic resolution would improve our understanding of *Quercus* expansions and contractions in response to climate changes during the Quaternary, as well as fire-vegetation dynamics in *Eucalyptus* dominated systems. These methods could be applied to other genera as well and in combination with traditional light microscopy improve the information we can obtain from fossil samples. In addition to increased taxonomic resolution compared to light microscopy, these methods have the potential to uncover differences in chemical composition based on environmental influences or population differences in sporopollenin chemistry. Environmental and population information obtained from fossil records could improve our ability to explain current and future ecological dynamics with palaeoecological research.

Understanding forest responses to climate change in sub-arctic Canada: integrated palaeoecological and ecological records from the Northwest Territories

Helen Roe¹, Rachel Patterson¹, Paul Trainor¹, Jesse Vermaire², Tim Patterson³, Stephen Wolfe⁴

¹Queen's University Belfast, Belfast, United Kingdom. ²Carleton University, Ottawa, Canada. ³Carleton University, Ottawa, Canada. ⁴Geological Survey of Canada, Ottawa, Canada

Abstract

High boreal environments are particularly susceptible to predicted temperature increases, where ecosystem interactions are both spatially variable and driven by episodic natural disturbances. Palaeolimnological studies from sites above the modern treeline in the Northwest Territories have revealed the dynamic nature of the response of the boreal ecozone to inferred climate warming during the mid-Holocene. However, knowledge of the character and timing of landscape evolution in the first few millennia after deglaciation remain poorly understood. This period was characterised by complex environmental changes as glacial meltwaters drained from the region and boreal forest communities migrated northwards in response to climate amelioration. This paper will draw upon peatland and lake sediment records from a transect of sites (n=9) that extends from the central Great Slave Lowlands to the tundra ecozone ca. 200 km to the northeast to (i) provide new insights into rates of peatland initiation, vegetation colonisation and treeline mobility in the early to mid Holocene; and (ii) appraise the utility of a range of proxies (pollen, stomata, chironomids, diatoms and charcoal) for understanding climate-environment interactions during this interval. Such insights have the potential to provide important context for understanding the impacts of future climate change in the region. Quantitative temperature reconstructions will be presented that are derived from fossil chironomid assemblages from three lakes (Matthews Lake, Horseshoe Lake and Frame Lake). These show that during the early Holocene (prior to ca. 8000 cal yr BP) temperatures exceeded present conditions by ca. 1-2 °C, whilst palynological data, particularly evidence from fossil stomata, reveal a more dynamic treeline in the mid-Holocene than previously documented. Pollen data from a transect of modern lakes (n=57) from the same region helps to better contextualise some of the inferred changes in Holocene forest dynamics, but also highlights some of the difficulties of using arboreal pollen data to reconstruct treeline position. Together the records provide a basis for further re-assessment of the character, timing and impacts of regional climate fluctuations in this sensitive northern region, and underline the benefits of integrating long-term palaeoecological data with an understanding of modern ecological processes.

Simulations of Quaternary glacial cycles with complex and simple models

Andrey Ganopolski, Matteo Willeit
PIK, Potsdam, Germany

Abstract

Significant progress has been achieved in recent decades in the understanding of Quaternary climate dynamics. A number of complex and conceptual models which can reproduce the major features of glacial cycles have been proposed. In particular, using the Earth system model of intermediate complexity CLIMBER-2, we were able to simulate the entire sequence of Quaternary glacial cycles. The CLIMBER-2 model incorporates all major components of the Earth system – atmosphere, ocean, land surface, northern hemisphere ice sheets, terrestrial biota and soil carbon, aeolian dust and marine biogeochemistry. Using this model we performed a set of simulations covering the last 3 million years using as the only forcing variations in the Earth's orbital parameters and gradually evolving in time land-ocean distribution and terrestrial sediment cover. We found that gradual removal of the terrestrial sediments from the Northern Hemisphere continent by glacial processes is sufficient to explain the transition from 40-kyr to 100-kyr worlds. Using the result of CLIMBER-2 simulations we also developed a simple model which is able to reproduce the behaviour of the complex model. Results of simulations with both complex and simple models shed light on the fundamentals of Quaternary climate dynamics and strongly support the notion that Quaternary glacial cycles are externally forced and deterministic.

O-2037

A low-latitude driver for Northern Hemispheric ice-sheet build up during the Mid-Pleistocene Transition

Maria Carolina A. Catunda, André Bahr, Oliver Friedrich
Heidelberg University, Heidelberg, Germany

Abstract

The Mid-Pleistocene Transition (MPT, 1.2–0.6 Ma), characterized by the still elusive switch from a 41 kyr to 100 kyr glacial-interglacial cyclicity, constitutes one of the most prominent changes of climate modes throughout the Cenozoic^{1,2}. The massive expansion of glacial ice sheets commencing between Marine Isotope Stages (MIS) 24–22 is thought to be instrumental for this switch, as it prolonged the response time of the climate system to orbital forcing. This ice-sheet expansion also coincides with the so-called “900 kyr event”, a time when the Atlantic Meridional Overturning Circulation (AMOC) critically weakened resulting in prolonged cold sea-surface temperature (SST) conditions in the North Atlantic^{3,4}. Although these cold background conditions favor the sustainability of large ice sheets, they also decrease the atmospheric moisture saturation level, raising a question about the pathways of moisture that would have fed extensive glacier growth in the Northern Hemisphere during that time. Here, we use Mg/Ca-derived mid-latitude Atlantic deep-thermocline temperatures, covering the MPT, to show that decreased thermocline stratification between 40 °N and 60 °N allowed accumulated subsurface heat to reach the surface of the subpolar North Atlantic, particularly during MIS 22. These relatively warm high-latitude SST would have provided a potent moisture source for glacier growth. Our data further indicate that mid-latitude stratification in the North Atlantic is predominantly driven by low-latitude processes, and might therefore act as a mediator for imposing low-latitude climate pacing onto high-latitude glacial ice-sheet dynamics. The combination of this precession-paced low-latitude mechanism for subsurface heat transport into the North Atlantic with the pre-existing obliquity modulation of ice-sheets may have contributed to the emergence of the 100 kyr beat during the MPT^{5,6}.

¹LSCE, Gif-sur-Yvette, France. ²IFREMER, Plouzané, France. ³University of Bordeaux, Pessac, France. ⁴EPHE, Pessac, France. ⁵Vrije Universiteit Amsterdam, Amsterdam, Netherlands

Abstract

Interglacials before the Mid-Bruhnes Event (around 430 kyrs BP) were characterized by colder temperature in Antarctica, lower sea level and lower atmospheric CO₂ compared to the more recent interglacials. Climate simulations have shown that the climate of the interglacials before and after the MBE can only be reproduced when taking into account changes in orbital parameters and atmospheric CO₂ concentrations (Yin and Berger, 2010; Yin and Berger, 2012). Indeed, interglacial atmospheric CO₂ concentrations were ~250 ppm and ~280 ppm prior and after the MBE, respectively. Yet, the cause for this change in atmospheric CO₂ remains mainly unknown. Climate simulations suggest that oceanic circulation was different during the interglacials due to the different background climate states (Yin, 2013). The changes of oceanic circulation could have modified the carbon cycle: a more sluggish circulation would lead to greater carbon sequestration in the deep ocean and, subsequently, a decrease of atmospheric CO₂. However, the possibility of changes of ocean circulation during the pre-MBE interglacials compared to post-MBE interglacials has not yet been assessed using proxy data.

Here we present a new global compilation of benthic foraminifera carbon isotopic ($\delta^{13}\text{C}$) records from 31 marine sediment cores covering the last 800 ka to evaluate possible changes on interglacial circulation across the MBE. We show that the Atlantic $\delta^{13}\text{C}$ distributions obtained from marine sediment cores vary among interglacials, but that all of them differ largely from a glacial state. A small systematic difference between pre and post MBE interglacial $\delta^{13}\text{C}$ is observed, which could be linked to small changes of oceanic circulation. We also use the intermediate complexity model iLOVECLIM (Goosse et al., 2010 ; Bouttes et al., 2015), which simulates carbon isotopes, to evaluate the $\delta^{13}\text{C}$ changes than can be obtained with different circulation changes.

$\delta^{18}\text{O}_{\text{atm}}$ variations at orbital scale and comparison with coupled climate model equipped with oxygen isotopes

Thomas Extier¹, Didier Roche^{1,2}, Louis François³, Amaelle Landais¹, Lucie Bazin¹

¹LSCE, Gif-sur-Yvette, France. ²Vrije Universiteit Amsterdam, Amsterdam, Netherlands. ³University of Liège, Liège, Belgium

Abstract

Glacial-interglacial cycles are recorded in various climatic archives from high to low latitudes over the Quaternary. The EPICA Dome C (EDC) ice core provides a high-resolution record of $\delta^{18}\text{O}_{\text{atm}}$ (i.e. $\delta^{18}\text{O}$ of atmospheric O_2) which combines past variations of the low latitude water cycle and of the biosphere productivity. Over the last 800 ka, the $\delta^{18}\text{O}_{\text{atm}}$ presents similar orbital variability to the summer insolation at 65°N . However, the uncertainty associated with the $\delta^{18}\text{O}_{\text{atm}}$ / insolation relationship for building ice core chronology is high (6 ka) and limits the interpretation of ice core records in terms of past climate dynamics. Based on comparisons between the $\delta^{18}\text{O}_{\text{atm}}$, $\delta\text{O}_2/\text{N}_2$ and their respective orbital targets as well as with the $\delta^{18}\text{O}_{\text{calcite}}$ from low latitude speleothems, we propose a new EDC chronology with reduced uncertainties using a new dating strategy based on the synchronism between $\delta^{18}\text{O}_{\text{atm}}$ and $\delta^{18}\text{O}_{\text{calcite}}$.

To address the lack of quantitative interpretation of the $\delta^{18}\text{O}_{\text{atm}}$ and check our assumption of synchronicity between $\delta^{18}\text{O}_{\text{atm}}$ and $\delta^{18}\text{O}_{\text{calcite}}$, we use a modelling approach to simulate precise estimates of past oxygen fluxes over several glacial-interglacial cycles. This approach combines (1) the coupling between the intermediate complexity climate model iLOVECLIM and the vegetation model CARAIB, (2) an estimation of the oxygen fluxes associated with photosynthesis and respiration processes, (3) an estimation of the isotopic composition of the oxygen in leaf water ($\delta^{18}\text{O}_{\text{leaf}}$) and (4) an estimation of the oxygen fractionation during oxygen uptake. This method associates the climatic parameters and water isotopes simulated by iLOVECLIM with the changes in vegetation distribution and terrestrial biosphere productivity obtained by CARAIB for 26 PFTs (Plant Functional Types) instead of the 2 PFTs previously used in iLOVECLIM.

We present here the results of this new coupled model over several glacial-interglacial cycles. We discuss the spatial distribution of the $\delta^{18}\text{O}_{\text{leaf}}$ as well as the oxygen fluxes linked to the continental biosphere productivity. The $\delta^{18}\text{O}_{\text{leaf}}$ corresponding to the terrestrial contribution of the $\delta^{18}\text{O}_{\text{atm}}$, our results can be compared, as a first approximation, to the isotopic $\delta^{18}\text{O}_{\text{atm}}$ data measured in EDC ice core and to the simulated $\delta^{18}\text{O}_{\text{calcite}}$ of low latitudes speleothems.

Modeling the evolution of the Northern Hemisphere ice sheets around Marine Isotope Stage 19

Jorge Alvarez-Solas¹, María Fernanda Sánchez-Goñi², Alexander Robinson¹, Marisa Montoya¹

¹Universidad Complutense de Madrid, Madrid, Spain. ²EPOC | Université de Bordeaux, Bordeaux, France

Abstract

The Marine Isotope Stage 19c (MIS19c) interglacial period (~777,000 years ago) is a good orbital analog to the Holocene and thus it can be contemplated as the current climate system in the absence of any anthropogenic influence. We here run an ice-sheet model forced by the simulated climate of MIS19 from a recent realisation of a general circulation climate model. We show that different ice sheets likely existed at this period. The most extended and thick of this ice masses develops west of Greenland, gathering Baffin and Ellesmere Islands together with the Canadian Archipelago, at the same time as smaller ice sheets are found in Alaska, Northeastern Siberia and the Barents-Kara region. Transient simulations are also carried out in which, by perturbing the former MIS19 climate, we investigate the following glacial inception. Particularly, we focus on the effects that the recorded abrupt changes in humidity advection in Southwest Europe may have had on the evolution of the Eurasian ice sheets.

Abstract

Understanding the dynamics of the climate system during past climatic extremes under diverse boundary conditions is one of the major challenges in paleoclimate research. Only few direct sea-land comparison records exist for past glacials, and none is available for the most severe glacials occurring after the middle Pleistocene transition such as the Marine Isotopic Stages (MIS) 16 (621–676 ka) and MIS 12 (424–478 ka). Both glacials are characterised by increasing ice volume since the glacial onset until the beginning of deglaciations and are marked by major instabilities of Northern Hemisphere ice sheets during the glaciation onset, before the peak glacials and during deglaciation. Those Northern Hemisphere ice sheets instabilities are however stronger after the peak glacial as revealed by maxima of ice-rafted detritus deposition in the North Atlantic. The major difference between the two interglacials is associated with the meridional SST patterns in the North Atlantic region which has been attributed to a more northern position of the Arctic front during MIS 16 when compared to MIS 12.

We present the first high-resolution direct sea-land comparison (including pollen, alkenone derived SST, % C37:4 and benthic $d^{18}O$) of IODP site U1385 from the SW Iberian margin, encompassing the MIS 16 and MIS 12. Our data show that dry conditions over western Iberian Peninsula are synchronous with major freshwater pulses in the North Atlantic during both glacial periods. However, the driest conditions were attained during the onset of MIS 16 and prior to MIS 12 peak glacial rather than during episodes of maxima IRD deposition (deglaciations) in the North Atlantic region. Here we will discuss about the possible drivers of such unexpected signal within each glacial period.

Last Interglacial $\delta^{13}\text{C}$ variability in the North Atlantic - a model study

Augustin Kessler¹, Nathaëlle Bouttes², Didier Roche², Jerry Tjiputra¹

¹NORCE Norwegian Research Centre, Bergen, Norway. ²Laboratoire de Sciences du Climat et de l'Environnement Gif-sur-Yvette (LSCE), Gif-sur-Yvette, France

Abstract

The variability of $\delta^{13}\text{C}$ in watermass can be used to infer changes in ocean circulation, watermass ventilation and changes in biological carbon pump, among others. New high resolution proxy reconstructions reveal that during the Last Interglacial (125-115ka) the variation of $\delta^{13}\text{C}$ in the North Atlantic is not homogeneous both in space and time. Previous studies revealed that during this period the reconstructed $\delta^{13}\text{C}$ trend was different from one sediment core site to the other (Gardar Drift IODP site U1304 vs Eirik's drift MD03-2664) highlighting the sensitivity of the watermass in these locations to modifications in the ocean circulation, ventilation, or biogeochemistry. In addition, abrupt changes of $\delta^{13}\text{C}$ have also been clearly shown, suggesting deep and fast changes of these watermass properties over short time window. In this study, using an Earth System Model of intermediate complexity (iLOVECLIM), we analyze the changes in $\delta^{13}\text{C}$ at these two sediment core sites by performing a set of transient simulations, with varying external forcings that could contribute to watermass property changes in the region. Under the preindustrial climate, the model reproduces fairly well the observed $\delta^{13}\text{C}$ distribution. In our last interglacial simulations, we vary the fresh water input, which is presumed to impact the ocean circulation and ventilation, and therefore the $\delta^{13}\text{C}$. The fresh water is introduced in different regions for each experiment: (1) the Labrador Sea and (2) at the Ruddiman belt over the Eemian period (125ka-115ka). In addition, abrupt and fast change of fresh water input will also be tested by performing an 8.2 event scenario.

Abstract

Located in the eastern desert of Jordan, the resource-rich ecosystem of the Azraq wetland has been a magnet for humans and human ancestors for at least the past 400,000 years. Lower, Middle, Upper, and Epipaleolithic occupations have been discovered throughout the endorheic Azraq basin, and recent work in the central wetland indicates that, at particular times in the past, the spring-fed Azraq oasis area functioned as a desert refugium for inhabitants of the basin during dry regional conditions. These dry period occupations were separated by extended wet periods—spanning tens of thousands of years—when the central Azraq basin filled with a large, shallow lake. Such fluctuations in the extent and distribution of freshwater resources played an important role in the lives of Azraq's Pleistocene inhabitants, and we argue that regional settlement patterns between 400,000-30,000 years ago reflect hunter-gatherer mobility and adaptation to regional palaeoclimatic conditions.

Here we present the results of stratigraphic and site formation analysis at the 270,000-year-old Shishan Marsh 1 (SM1) excavation site, combined with a deposit model of the surrounding Shishan Marsh landscape using sedimentological data from ten additional stratigraphic sections. Drawing on a series of optically stimulated luminescence, uranium-series, and radiocarbon dates, the newly developed deposit model for the Shishan Marsh is integrated with previous work in the area to reconstruct the late Middle and Late Pleistocene palaeolandscape of the greater Azraq oasis area. Together with geomorphic and stratigraphic data from outside the central Azraq basin, the palaeolandscape model indicates a complex pattern of settlement dynamics that is intertwined with fluctuations in the extent and distribution of freshwater resources over the past 400,000 years. These palaeoenvironmental fluctuations had dramatic effects on Pleistocene vegetation and faunal variability, which in addition to geomorphic changes have impacted the modern visibility and distribution of archaeological remains. Deciphering this complex settlement history and identifying specific hunter-gatherer adaptations to fluctuating freshwater resources in the Azraq basin has important implications for early human dispersal across arid southwest Asia.

Abstract

A significant issue for palaeoecologists and archaeologists working with long sequences is the degree to which they retain a complete reflection of past environments, climates and human activity. This is particularly the case in caves, where sedimentation is sometimes discontinuous. Here we reassess the chronology and present a first detailed assessment of the upper part of the Haa Fteah Cave in the Gebel Akhdar in Northeast Libya; an important biogeographic refugium where continuity of human settlement was perhaps possible during the last glacial period.

In the 1950s, excavations of the Haa Fteah uncovered a lengthy Late Quaternary sequence of human activity with an iconic lithic sequence. Subsequent research on the prehistory of North Africa has used these discoveries as a yardstick. However, the chronology of the cave stratigraphy and archaeological sequence was based on a small number of age determinations made very early in the history of radiocarbon dating. Modern chronostratigraphic techniques were used in a recent reassessment of the age of the sequence, but considerable uncertainties have remained.

This paper presents the high resolution chronostratigraphy for the last ~50ka years of the Haa Fteah cave-fill using 241 AMS radiocarbon dates on charcoal, seeds and shells along with tephrochronology and OSL dating which have been integrated with climatic patterns deduced from molluscan assemblages and $\delta^{18}\text{O}$ stable isotopes. Integral to this has been the ability to reliably radiocarbon date the stratigraphically ubiquitous terrestrial gastropod *Helix melanostoma*, which has a consistent ^{14}C shell reservoir offset of 476 ± 48 ^{14}C yr.

The very high resolution of the dating of the Haa stratigraphy reveals a complex sedimentary sequence with multiple short depositional hiatuses; significantly improving our understanding of the chronology of the archaeological sequence and the processes underlying sedimentation in long-sequence cave sedimentary deposits of this type. It also shows the difficulties in developing age-depth chronologies in caves without very high-resolution dating. The ability to reliably ^{14}C date terrestrial shells throughout the sequence also means we can now tie climatic and stratigraphic information to evidence for anthropogenic activity reliably throughout the studied sequence.

This tightly linked framework of fine-scale geomorphology and fine scale dating, has enabled us to demonstrate with sufficient clarity that the atypical climate of the Gebel Akhdar during the Late Quaternary was a clear factor in the ability of early people to occupy the region continually; thus remaining a refugium when much of the rest of Northeast Africa was uninhabitable through extreme aridity. The success of this approach, on a sequence as complex as the Haa Fteah, emphasises the need for high resolution multiple dating allied with sophisticated geoarchaeology in we are to use humanly occupied caves in addressing these 'big questions' about humans and climate change.

Human-environment interaction in the Upper Palaeolithic of the Southern Levant

Hannah Parow-Souchon

CRC 806 - Our Way to Europe, University of Cologne, Cologne, Germany

Abstract

Human adaptation to the environment and the resulting settlement patterns are a major point in the understanding of hunter-gatherer economy and subsistence, and rarely more so, than in environments including different ecotones as the Southern Levant. For the timeframe of the Upper Palaeolithic the results of a geoarchaeological study are presented investigating these processes on two different scale levels. A dataset of 129 inventories of published Upper Palaeolithic sites from the Southern Levant is used to model the settlement patterns. As an essential source-critical step an evaluation of the preservational conditions for Late Pleistocene sites is conducted through the analysis of geomorphological maps. Geomorphological and climatic results are used to reconstruct the Late Pleistocene Levantine environment, which presents itself as dominated by rising water tables and abundant fluvial sedimentation. The spatial distribution of the sites is mapped in relation to the major resources (water and raw material) to understand guiding factors in site locality choice. The Late Pleistocene Levantine environment is thus argued to be characterised by a mosaic landscape of patches with high resource availability and areas with resource depletion. Multivariate statistical evaluation is used to test the explanatory value of different environmental factors on the variability in the archaeological dataset. Particularities in site locality choice for the different cultural units are highlighted. The settlement patterns of Pleistocene hunter-gatherers are reconstructed and evaluated through an assessment of the different inventories in terms of the representation of the operational chains, the diversity of the tool assemblages, the working time invested in the production of the lithic assemblages, the caloric yield of the faunal inventories and tool curation. In general, the Upper Palaeolithic of the Levant is characterised by a stable residential mobility system adapted to the patchy but abundant distribution of resources.

Holocene paleoclimatic changes, land use and landscape dynamics in the central Mediterranean. A comparison of archaeological and natural soils

Fabio Scarciglia

Dipartimento di Biologia, Ecologia e Scienze della Terra (DiBEST), Università della Calabria, Arcavacata di Rende (CS), Italy

Abstract

A wide literature exists on paleoclimatic and paleoenvironmental reconstructions in Mediterranean sites using traditional continental and marine proxies (sedimentary successions, fossils, stable isotopes, pollens, plant macroremains, dendrochronology, archaeological findings, historical documents). Paleosols are also used as paleoclimatic archives, but papers focused on the Mediterranean mostly investigate pre-Holocene times. An overview on the response of soils and paleosols from archaeological and natural sites of central and southern Italy to Holocene paleoclimate, land use changes and geomorphic dynamics is proposed here. An emphasis is given to different methods and ancillary techniques applied to interpret the pedostratigraphic record, trying to disentangle the role of natural versus anthropogenic factors on paleoenvironmental changes.

A number of soils/paleosols from coastal and inland areas showed a varying volcanic ash input, sourced as proximal or distal products of Pleistocene and Holocene eruptions, often hidden as micrometric cryptotephra. The volcanic material allowed the development of andic features which contributed to make them fertile. The development to different extent of andic properties, related to short-range order minerals derived from the weathering of volcanic glass, versus dominant phyllosilicate clay minerals, is successfully used as an indicator of prolonged soil moisture availability against a pronounced seasonal contrast, which marked major climate shifts from the post-glacial amelioration to the Holocene climatic optimum and the late Holocene. Varying moisture conditions during soil formation during the Holocene are confirmed by other pedogenic features (illuvial clay coatings and iron oxyhydroxides), developed in soil profiles from several Italian volcanic and non-volcanic environments. At some sites, soil charcoal data evidence a major phase of geomorphological stability with a paleovegetation dominated by deciduous oak forest during Neolithic times, coupled with abundant humus accumulation in the paleosols. A sharp environmental change is widely recorded at the macro- and microscale around 5-3 ka BP in many sites. Paleosol truncation, colluvial processes or burial by younger aeolian, alluvial and slope deposits (and associated soils) indicate stages of landscape instability with increased erosion/sedimentation processes. This important paleoenvironmental change can be a consequence of one or more aridity phases (in places marked by stable isotopes in pedogenic carbonates), possibly superimposed (or alternatively controlled) by increased anthropogenic activities since the late Neolithic to the Bronze age and Roman times. Settlement remains, pole pits, ceramic artefacts, charcoals, bone fragments, plow furrows etc. document human occupation. Forest clearance and a drastic transformation of the vegetation cover from oak woodland to pine forest is recorded by soil charcoal data in some inland mountain sites, where agricultural practices increased over historical times. Recent erosion during the last 50-60 years as a response to deforestation, agricultural exploitation/abandonment and land degradation is documented in some soils by fallout radionuclide tracers (^{137}Cs and $^{239+240}\text{Pu}$) derived from nuclear weapon tests.

Abstract

The research of interaction between humans and surrounding environments during Holocene becomes one of the hot research problems in recent years. Here we presented a synthesis evolutionary series based on available information from stratigraphic profiles and prehistoric archaeological discoveries in the Mu Us Desert, China. Results showed that the earliest Human appearance commenced in Mu Us Desert region during Holocene when the Yangshao Culture began to expand and reached this remote area of northwestern China around 7.0ka BP. In the eyes of number and magnitude of available 541 archaeological sites, the culture exhibited a status of prosperity at Late Yangshao (5.5-5.0ka BP) and Longshan Culture (4.6-3.9ka BP) period, while it showed depression in the latter Bronze Age. Actually, the rise and fall of cultures was also determined by subsistence strategies, which reflected in the different types of artifact stone implements and indicated the possible subsistence behaviors including agriculture, animal husbandry, hunting, fishing and so on. In addition, combined with the soil micromorphological features of palaeosol layers, we considered that 5.5-3.9ka BP was the highly possible veritable Climate Optimum period in the Mu Us Desert, based on the comprehensive evidence derived from natural and human records. The above study may offer insights in comprehending how climate change could have affected human societies and the potential feedbacks from prehistoric humans in long-term scale.

Early to Middle Holocene human-environment interactions: a multi-scalar geoarchaeological investigation of continental aeolian deposits in SE Iberia.

Ana Polo-Díaz¹, Rosa María Poch², Carlos Ferrer³, Magdalena Gómez Puche¹, Javier Fernández López de Pablo^{1,4}
¹IPHES- Institut Català de Paleoecologia Humana i Evolució Social., Tarragona, Spain. ²Departament de Medi Ambient i Ciències de Sol. ETSEA. Universitat de Lleida., Lleida, Spain. ³Museu de Prehistòria i Servei d'Investigació Prehistòrica de la Diputació Provincial de València., València, Spain. ⁴Àrea de Prehistòria, Universitat Rovira i Virgili., Tarragona, Spain

Abstract

Early to Middle Holocene archaeological sites located in sand deposits are crucial for our understanding of subsistence strategies and palaeoclimates of late prehistoric hunter-gatherer and the first farming groups in Europe.

Geoarchaeology, especially if applied at a multi-scalar level, has the potential to contribute relevant new data on anthropic behavior and how climatic fluctuations during the Last Glacial-Early Holocene transition may have shaped cultural responses during this period.

In this context the evidence gathered by our investigations at the sites of El Arenal de la Virgen and Casa Corona (Upper Vinalopó Basin, Alicante, SE Iberia) sheds new light on this issue by providing new geoarchaeological data supported by field and laboratory works.

These two Mesolithic campsites formed in a continental dune system developed at the margins of the Villena paleolake. The archaeological deposits together with their geomorphological setting are currently subject to multi-scalar analyses at intra- and off-site level (stratigraphy, micromorphology, texture and soil chemistry) within the frame of the project PALEODEM -Late Glacial and Postglacial Population History and Cultural Transmission in Iberia (ERC-CoG 2015-ref 683018).

Our investigations at the sites focus on:

1. The sedimentary contextualisation of human occupation events to establish the origin and formation of the continental dune system and associated soils where the sites are located and determine the extension of the settlement area.
2. The identification of traits of anthropic behaviour to allow assessment of its impact in the sediments, characterize occupation surfaces at intra-site level and determine the integrity of the archaeological record.
3. The construction of a reliable chronological framework for the dune system, associated soils and the Mesolithic settlement combining C14 dating of domestic structures and OSL dating of sand deposits. Our aim is to improve our knowledge of the palaeoenvironmental contexts before during and after the Mesolithic occupation and assess the impact of climatic shifts on the settlement pattern of the area of study.

Our results indicate a correlation between soil development and environmental stability and human occupation at the sites during the Mesolithic. This soil formation is embedded between two aeolian sand formations indicating that human occupation was preceded and followed by two climatic periods of increased aridification. They also suggest

that the aeolian sediments overlying the Mesolithic occupation are most likely a local manifestation of the 8.2 cal BP event, which in turn can be directly related to the gap detected in the occupation of the study area.

We found evidence of run-off and colluvial events embedded between the aeolian deposits, indicating that both wind and water-related processes were involved in the formation of the dune system, attesting to environmental fluctuations that framed human activities in the area of study during the transition to the Holocene.

Human-environment interactions during the past 4000 years in Sagalassos and South-Western Turkey

Nils Broothaerts, Maarten Van Loo, Ralf Vandam, Sam Cleymans, Dries Daems, Jeroen Poblome, Gert Verstraeten
KU Leuven, Leuven, Belgium

Abstract

South-Western Anatolia has been an area of intense human occupation since the early Neolithic. However, human pressure on the landscape did not follow a linear trajectory from the Neolithic to the present but is rather characterized by cycles of land cover expansion and contraction, contrary to many temperate environments in NW Europe. Here, we provide a synthesis of human-environment interactions in the region of the antique city of Sagalassos in the Taurus mountain in South-Western Turkey during the past 4000 years. Multivariate statistical analysis of pollen data (cluster analysis and non-metric multidimensional scaling) was used to semi-quantify human impact on the vegetation dynamics. This palynological data in combination with archaeological and geomorphological data and spatial modelling techniques, enabled to reconstruct the relative importance of human disturbance and natural variation on the environment. The sensitivity of the landscape towards anthropogenic disturbance is strongly controlled by the geomorphic setting and feedback mechanisms in the soil system. The first major clearing of the landscape in the Iron Age led to a peak in soil erosion, but also to soil exhaustion limiting erosion rates in subsequent periods. This soil exhausting led in turn to a decrease in crop yield at the hillslopes and to changes in the settlement patterns. Soil erosion and sediment delivery is more limited during the main occupation phases of the Roman Imperial Period. Periods with more favorable climate in the Roman and Mid-Byzantine periods resulted in the occupation of more isolated parts of the territory (i.e. higher altitudes), whilst a decrease in human pressure can be observed during the Early Byzantine and Ottoman periods related to less favorable climate conditions. Such smaller and short-lasting bursts of human occupation did not significantly impact the environment. Only in the last two hundred years, human pressure reached similar high values as those encountered in the classical period.

O-2050

Vulnerability of the global peatland carbon sink: past, present, and future tipping points

Julie Loisel¹, Angela Gallego-Sala²

¹Texas A&M University, College Station, USA. ²University of Exeter, Exeter, United Kingdom

Abstract

The importance of peatland ecosystems has been mostly unrecognized and there is a pressing need for improved management strategies worldwide. Peatland soils are non-renewable, vulnerable to human disturbances, and their capacity to provide Earth System Services needs a comprehensive, informed strategy for their conservation and protection. Peatland ecosystems provide and balance water resources, regulate climate via long-term carbon (C) sequestration and exchange with the atmosphere, mediate nutrient and sediment supply to the oceans, and maintain biodiversity integrity. Peatlands also support human health by providing food, fiber, and fuel to our growing world population, in addition to providing natural barriers against wildfires and floods. From a paleoclimate perspective, it is well known that peatlands play a key role in the global C cycle at the millennial timescale. Likewise, hydrological and biogeochemical analyses have highlighted the importance of peatlands in regulating the quantity and quality of water flow across the land surface across the annual to decadal timescale. Despite the fundamental connections between peatlands, near-surface land processes, the global climate system, and our society, these ecosystems are still omitted from all CMIP5 Earth System Models.

This contribution challenges the current modeling approach in which peatlands are not considered. We identify and locate the drivers of change that can provoke non-linear responses in peatland carbon cycling; tropical and high-latitude peatlands are examined separately. The level of past, present, and future risk (vulnerability vs. likelihood) of rapid peatland carbon loss or gain from natural and anthropogenic disturbance is also explored. Lastly, order-of-magnitude estimates of the change in C stocks and fluxes over time are provided on the basis of expert assessment.

Abstract

Northern peatlands are a globally important carbon (C) store that are predicted to remain a C sink under future warming scenarios. Understanding the drivers and predicting the future trajectory of the peatland C store requires upscaling from cores and sites to regions and continents, alongside a detailed understanding of the mechanisms governing peatland C sequestration. However, recent studies have shown that both within- and between-site variability in individual peatland C accumulation histories is high, driven by factors such as climate, hydrology, (micro)topography and vegetation, creating highly heterogeneous ecosystems. Studies incorporating replication are therefore important to quantify how this variability may affect upscaling from local-scale dynamics to models. In addition, we need to better understand the processes driving observed variability but the interplay between plants, microbes and C cycling in peatlands remains poorly understood. One approach to address both issues is to examine replicated microbiological functional traits within a multi-proxy framework to provide an ecosystem-level perspective on ecological and biogeochemical processes. Peatland testate amoebae (TA) are a functionally important group of protists well-suited to such an approach.

Here, we compare four key TA functional traits (mixotrophy, aperture size and position, biovolume) to C accumulation, palaeohydrological and vegetation changes in 12 post-Little Ice Age peat cores from high-boreal and low-subarctic regions in northwestern Québec, Canada in an experimental design that includes internal and external replication at both site and regional scales. Correspondence between C accumulation, palaeohydrology and functional traits varies, but recent changes mixotrophy and aperture size, which may effect peatland C sequestration potential and microbial food web structure respectively, show tentative links to recent C accumulation increases. Analysing TA functional traits provides an opportunity to examine processes that may effect key peatland ecosystem services. Detailed replication, coupled with future spatial classification, should allow the effect of ecosystem and landscape heterogeneity on upscaling to be quantified.

Global peatlands and the carbon cycle during the last millennium

Anne Quillet¹, Angela Gallego-Sala¹, Dan Charman¹, Renato Spahni², Benjamin Stocker³

¹University of Exeter, Exeter, United Kingdom. ²Universität Bern, Bern, Switzerland. ³Universitat Autònoma de Barcelona, Barcelona, Spain

Abstract

Coupled climate carbon cycle models point to a positive climate-carbon feedback, whereby climate change results in a larger fraction of anthropogenic CO₂ emissions remaining in the atmosphere, further warming the climate. However, the strength of this feedback is highly uncertain and the terrestrial carbon cycle feedback is the least well quantified. Furthermore, models have completely ignored the potential contribution of peatlands, even though they contain 530-694 GtC, i.e. almost as much as the total amount of carbon in the atmosphere. Even the sign of the contribution of peatlands to the global carbon cycle feedback is poorly known. The assessment of this feedback is limited by the available the spatial coverage of carbon accumulation data from peatlands, especially away from northern latitudes.

Efforts have been made to widen our understanding of the potential of different peatlands to accumulate carbon. This synthesis effort has led to a compilation of a dataset of carbon accumulation rates for most latitudes and regions during the last millennium (850-1850 AD).

Benefiting from this data, this study takes into account a range of peatland types and novel regions (tropics, China, etc), where carbon accumulation can be very high. The aim of this study is to assess the contribution of peatlands to the global carbon cycle over the last millennium, in order to provide a basis for projections of future peatland-climate feedbacks and to enable inclusion of these effects in climate models. First, the spatial extent and the carbon fluxes of peatlands simulated with the LPX model are evaluated against the newly available dataset. Second, the simulated carbon fluxes are used to assess the sign and magnitude of the feedback of peatlands on climate.

It is expected that the feedback effects included in LPX, e.g. between peatlands and hydrology or nitrogen availability, play an important role in the response of the model to changes in climate.

O-2053

Investigating the evolution of peatland area and peat carbon accumulation since the LGM using a dynamic global vegetation model

Jurek Müller^{1,2}, Fortunat Joos^{1,2}

¹University of Bern, Bern, Switzerland. ²Oeschger Center for Climate Change Research, Bern, Switzerland

Abstract

Results from process based models offer an independent perspective on the transient evolution of global peatlands and peat carbon stocks, complementing data-based reconstructions of global peatland expansion and carbon accumulation (Loisel et al. 2017). Our goal is to investigate the global dynamics of peatland area change and carbon accumulation since the Last Glacial Maximum (LGM) using the LPX-Bern Dynamic Global Vegetation Model. The model includes formulations for peatland establishment and expansion based on a TOPMODEL approach (Stocker et al. 2014) and simulates vegetation, acro- and catotelm dynamics, and carbon, nitrogen, and greenhouse gas fluxes (Spahni et al., 2013). Model parameters are calibrated towards modern data (Lienert and Joos, 2018) and climate forcing fields are constructed by combining a modern observation-based climatology with anomalies from climate model simulations.

First, we assess uncertainties stemming from the choice of climatic boundary conditions. Precipitation and temperature anomalies for LGM conditions are taken from eight different climate models used in the Paleo Model Intercomparison Project. Simulated peatland area is then in the range of 3 to 5 Mkm² for LGM conditions. This demonstrates a high uncertainty in modelled past peatland extent due to uncertain past climate forcing.

Next, we quantify peatland area change and carbon accumulation since LGM and identify the dominant climatic and environmental drivers. Transient simulations over the past 22,000 years are performed in standard and factorial model setups. The model simulates a 40% increase in global peat area from LGM until today, resulting from a combination of the expansion of new peatlands, mostly in the north, and the loss of old peatlands mostly in the tropics and North-American subtropics. These changes are driven by rising sea level, flooding peatlands on continental shelves, and the retreat of the ice shields, exposing new land for peatland establishment, as well as by nonlinear and local interactions between temperature precipitation and atmospheric CO₂. The results suggest that all these different physical and environmental drivers contributed significantly to the overall peat evolution. Here we present the model results, compare to proxy-based reconstructions, and discuss strenghts and shortcomings.

Wetland Assessment and Monitoring Tool: establishing baseline conditions for New Zealand's wetlands

Michelle M McKeown¹, Jamie R Wood¹, Sarah J Richardson¹, Olivia R Burge¹, Edward A D Mitchell^{2,3}, Alex Fergus¹, Janet M Wilmshurst^{1,4}

¹Manaaki Whenua - Landcare research, Lincoln, New Zealand. ²University of Neuchâtel, Neuchâtel, Switzerland.

³Jardin Botanique de Neuchâtel, Neuchâtel, Switzerland. ⁴The University of Auckland, Auckland, New Zealand

Abstract

Peatlands have been heavily exploited for human activities across the globe. It is estimated that 10% of the New Zealand mainland was covered by wetlands before human arrival around 750 cal. yr BP. Today over 90% of New Zealand's wetlands have been lost. Although the early indigenous Māori settlers caused extensive deforestation of dryland forests by burning, wetland extent was minimally affected until after European arrival (1800s), when loss accelerated rapidly for development and agriculture. Remaining wetlands are therefore of high conservation priority; restoration of degraded wetlands is also a priority.

Little is known about the microorganism communities in New Zealand and recent evidence from European peatlands suggests that testate amoebae (a polyphyletic assemblage of free-living single-celled shelled eukaryotes) can provide more accurate information on environmental change than vegetation. However, most of the work on peatland testate amoebae has been undertaken on Northern Hemisphere *Sphagnum*. In New Zealand, the main peat formers are the restiads *Empodisma minus* and *E. robustum* in the North Island; and graminoids, *E. minus*, and *Sphagnum* spp. in the South Island. Little is known about testate amoebae communities in these peatlands as they remain less studied in the Southern Hemisphere.

In this study, we evaluate if testate amoebae can be used as reliable indicators for determining wetland conditions through time in New Zealand. Eighteen wetlands were selected for this study from the West Coast and Southland regions of New Zealand, including six bog systems that were highly impacted, six bogs that were moderately impacted, and six that were relatively non-impacted. Vegetation surveys were carried out at each site using four randomly located 5 x 5 m plots. Environmental variables were measured at each sampling site and the surface testate amoeba community patterns and community-environment relationships compared. Our preliminary data support the potential use of testate amoebae as indicators of ecological integrity of New Zealand bogs.

Contrasting carbon sink and source activities in Amazonian and Arctic peatlands under a changing climate

Qianlai Zhuang¹, Sirui Wang¹, Outi Lähteenoja², Frederick Draper², Zicheng Yu³, Scott Bridgham⁴, Jason Keller⁵, Hinsby Cadillo-Quiroz²

¹Purdue University, West Lafayette, USA. ²Arizona State University, Tempe, USA. ³Lehigh University, Bethlehem, USA. ⁴University of Oregon, Eugene, USA. ⁵Chapman University, Orange, USA

Abstract

We use a process-based peatland biogeochemistry model to quantify the carbon accumulation in the Pastaza-Marañon foreland basin (PMFB) in the Peruvian Amazon from 12,000 years before present to 2100 AD. We found that, under warmer and presumably wetter conditions over the 21st century, SOC accumulation rate in the PMFB slows down to 7.9 (4.3~12.2) from the current rate of 16.1 (9.1~23.7) and the region may turn into a carbon source to the atmosphere at -53.3 (-66.8~-41.2) (negative indicates source), depending on the level of warming. Soils in the PMFB may lose up to 0.4 (0.32~0.52) Pg C by 2100 AD with the largest loss from palm swamp. The carbon-dense Amazonian peatland may switch from a current carbon sink into a source in the 21st century. We also simulate the SOC accumulation in Alaskan terrestrial ecosystems over the last 15,000 years using the model. The simulated average rate of peat C accumulation was 2.3 Tg C with a peak value of 5.1 Tg C during the Holocene Thermal Maximum (HTM) in the early Holocene, four folds higher than the average rate of 1.4 Tg C over the rest of the Holocene. The SOC accumulation slowed down, or even ceased, during the neoglacial climate cooling after the mid-Holocene, but increased again in the 20th century. We found that warmer summer temperature and stronger radiation seasonality, along with higher precipitation in the HTM and the 20th century might have resulted in the extensive peatland expansion and carbon accumulation. Currently, we are evaluating the fate of Arctic peatland carbon during this century.

O-2057

Exploring lake ecosystem resilience in a warming (sub)arctic through ecosystem structural changes

Roseanna Mayfield, Peter Langdon, John Dearing , Patrick Doncaster
University of Southampton, Southampton, United Kingdom

Abstract

Ecosystem resilience is the ability of a system to absorb disturbance and is fundamental for the continuation of ecosystem productivity, functionality and diversity. But understanding how resilience is affected by environmental stress is a major research challenge. This study aims to investigate how changes in ecosystem structure, used as a proxy for resilience, are related to increased temperature stress in (sub)arctic lake ecosystems. These ecosystems are at risk from rising global temperatures, with warmer temperatures already recorded and predicted to continue rising in high latitude areas. Increased temperatures create stress on ecologically sensitive environments where many organisms are adapted to cold temperatures. Temperature-sensitive organisms, such as chironomids (non-biting midge), provide useful datasets for investigating ecosystem structures in relation to climate change.

Three sets of analyses - beta diversity, compositional disorder, and network skewness - are applied to near-modern chironomid communities along temperature gradients in arctic and subarctic North America, Norway and Russia. Breakpoint analyses indicate significant shifts in the Norwegian chironomid communities between the Svalbard and Mainland Norwegian lakes, and between the arctic and subarctic lakes in the North American and Russian community compositions. Comparable results for beta diversity, compositional disorder and network skewness analyses suggest a strong temperature control on community composition in all three regions.

Community structural response to warming in the three regions is also assessed through time, from the beginning of the 20th century. Results indicate that the majority of the lakes have undergone warming since 1901-1950, both within arctic and subarctic zones. Associations between relative temperature change and the beta diversity, compositional disorder and network skewness results are less clear. This suggests that the chironomid response to warming, and hence the climate resilience of high latitude lake ecosystems, is mediated by local conditions, but also raises questions about the measurement of ecosystem structures.

O-2058

Quantifying climate-induced changes in ecosystem resilience using remote sensing and modelling

David I. Armstrong McKay^{1,2}, Joshua Buxton³, Chris A. Boulton³, Timothy M. Lenton³

¹Stockholm Resilience Centre, Stockholm University, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ³Earth System Science Group, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom

Abstract

Anthropogenic climate change is expected to impact heavily on global ecosystems, for example by triggering range shifts, food web disruptions, and changes in water availability. Greater climate variability is also expected on top of these trends, which may in turn be integrated by ecosystems and lead to an increase in ecosystem variability. Together, these changes could degrade ecosystem resilience – the rate at which ecosystems recover from perturbations – leading to a greater risk of triggering large-scale ecological regime shifts. Various ecosystems are hypothesised to feature tipping points beyond which regime shifts would occur, especially if they are characterised by bistability. Dynamical systems theory suggests these tipping points are often preceded by indicators such as critical slowing down (indicated by e.g. increasing autocorrelation) and greater variability. These indicators can be used as resilience metrics, with increases indicating reduced resilience due to a weakening of stabilising negative feedbacks. However, despite recent advances in quantifying ecosystem resilience, many studies remain spatially or temporally limited.

Here we present preliminary results from two different approaches to quantify climate-induced changes in ecosystem resilience on a global scale. Firstly, we utilise remote sensing data available for recent decades via integrated online platforms, such as Google Earth Engine, to perform a comprehensive scan of short-term changes in spatiotemporal autocorrelation and variance in proxies of ecosystem productivity. Secondly, we simulate the decadal-to-centennial timescale impact of climate change and climate variability on global ecosystem structure and resilience over historical-to-future scenarios using the Madingley general ecosystem model, and compare how the spatiotemporal variability of the simulated ecosystems corresponds to increasing variability of the climate.

O-2059

Spatial and temporal indicators of resilience loss in networks of paleoecological records

M. Allison Stegner, Zak Ratajczak, John W. Williams
University of Wisconsin, Madison, Madison, USA

Abstract

Many ecosystems have abruptly changed in the past and may again in future, yet prediction and inference of causal mechanisms remains challenging. Critical transitions are one such mechanism, occurring when systems with alternative states cross a non-reversible threshold. These shifts between alternative states can be associated with a gradual loss of resilience, often signaled by increasing variance over time and space. Paleoecological time series have potential to reveal changes in resilience at broad scales by documenting past critical transitions, measuring whether variance increases before abrupt changes, and linking driver and state variables to reveal underlying processes. However, a key challenge is the transformation of resilience signals by sedimentological time-averaging and subsampling. The prairie-forest ecotone in midcontinental North America is considered an example of a system with alternative states, capable of critical transitions between prairie and forest when water availability crosses thresholds. Prior work has shown that the prairie-forest ecotone was highly mobile during the Holocene, shifting in response to changes in precipitation and fire frequency. We explore indicators of resilience loss in sites that remain prairie throughout the mid- to late Holocene, versus sites that transition from prairie to forest.

Using high-resolution, well-dated pollen records from midcontinental North America from the Neotoma database, we first investigated whether temporal variance was higher for sites that transitioned from prairie to forest, compared to sites that remained prairie. For each site, we created a Generalized Additive Model for Location and Scale (GAMLS), which models both mean and variance through time, and compared modeled variance through time for sites that remained prairie to sites that transitioned from prairie to forest. We incorporated estimates of temporal uncertainty by creating Bayesian age models for each site, then resampling the model posteriors and creating a new GAMLS for each iteration. Preliminary results indicate no significant differences in temporal variance between groups. Second, we investigated whether spatial variance was higher for clusters of sites that transitioned from prairie to forest than for clusters that remained prairie. Because spatial heterogeneity influences how vegetation at a site responds to a climatic driver, the susceptibility of an individual site to a critical transition can vary even among nearby sites. Increasing differences among sites during the transient phase between vegetation states are indicative of resilience loss, which is measured as variance across sites, through time. We measured spatial variance in 250-year time bins for two clusters of sites, finding that the cluster that transitioned from prairie to forest had higher spatial variance than the cluster that remained prairie. These initial findings suggest that shifts in the prairie-forest ecotone were caused by climatic drivers that changed too quickly for resilience loss to occur, or that the system is not characterized by alternative states.

Identifying lake ecological resilience across the tropical Andes

Xavier Benito¹, Tobias Schneider², Sherilyn C. Fritz³, Gavin Simpson⁴, Albert Ruhi⁵

¹National Socio-Environmental Synthesis Center (SESYNC), University of Maryland, Annapolis, USA. ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ³University of Nebraska, Lincoln, NE, USA.

⁴University of Regina, Regina, Canada. ⁵University of California, Berkeley, Berkeley, USA

Abstract

Climate change has been identified as a main driver of ecological change in Andean lakes. However, evidence linking environmental variation to regime shifts is often restricted to small spatio-temporal scales. Here we test the hypothesis that if climate variability controls lake ecosystem transitions, historical climate fluctuations should have already induced shifts in the past; and should have done so in a synchronized manner across large geographic areas (Moran effect). We analyzed four lake records spanning the last 2,000 years across the tropical Andes (Yahuarcocha and Llaviucu in Ecuador, Umayo and Titicaca in Peru), and we modeled diatom community variance as an indicator of critical transitions via Generalized Additive Models (GAMs). In addition, we tested for potential spatial synchrony in regime shifts and in historical floristic trajectories by plotting fossil diatom samples passively, against a contemporary database of tropical South American diatoms (8°N–30°S and 58–79°W). Our results suggest that Andean lakes have undergone different states, as indicated by diatom community clusters or ‘basins of attraction’. Shifts in diatom community composition showed spatial synchrony in the two Ecuadorean lakes at 60-80 and 1000-1100 cal yr BP. However, the investigated lakes showed distinct floristic trajectories over time, with different environmental drivers influencing their dynamics. GAMs showed marked and cumulative increase in compositional variance in a variable fashion across the four Andean lakes, suggesting the existence of external and internal drivers following latitude-related controls. Our research will provide a better understanding of long-term ecological resilience by connecting paleoecological and contemporary data across a large spatial scale. This improved understanding may help inform sustainable management of lake ecosystems that provide critical water resources to the Andean and Amazonian nations.

O-2061

Estimating continuous measures of ecological resilience from palaeoecological time series

Gavin Simpson, Stefano Mezzini
University of Regina, Regina, Canada

Abstract

Ecosystems are highly variable across time and space and the consequences of this variation have been widely studied. Interest in ecological resilience has recently increased as we now appreciate the role environmental variability plays in maintaining biodiversity and in the identification and early detection of regime shifts. Frustratingly, quantifying resilience from palaeoecological time series is difficult because samples are irregularly spaced in time, sample ages are uncertain, and older samples are compacted and represent greater amounts of time. One of the most widely-used methods for estimating resilience time series involves calculating indicators over moving windows. Critically, statistical evaluation of resilience time series is complicated for four reasons. First, the resilience indicator time series violates the independence assumption of Kendall's τ . Second, using surrogate time series to assess the significance of τ requires fitting a time series model to the original data, which is problematic given the irregular observations. Thirdly, moving windows yield truncated resilience indicator time series; up to half the number of observations in the original series may be lost. Fourth, the moving window approach involves several *ad hoc* decisions; the size of window, how the original data are detrended, and the detail of the time series model fitted for the surrogate time series all affect the results.

We present a novel approach to the estimation of resilience indicators based on generalized additive models (GAMs), which resolves the problems described above. GAMs have previously been used to model trends in palaeoecological time series, assuming that other properties of the series are constant. Distributional GAMs relax this and allow the simultaneous estimation of mean, variance, and other parameters of the data, whilst maintaining the flexibility and simplicity of GAMs. We illustrate our approach by generating continuous estimates of key resilience indicators for time series of algal pigments from a sediment core from Lake 227 (Ontario, Canada), which has been experimentally manipulated to induce eutrophication. We show that our distributional GAM approach is capable of reproducing previous results (Cottingham et al 2000, *Ecology Letters*) that identified an increase in the variance of phytoplankton populations in the lake post disturbance whilst also providing a continuous estimate of the variance for the entire time series where previously only a single estimate was available for periods before and after manipulation. Furthermore, skewness, another key resilience indicator, can also be estimated, uncertainty is fully quantified, and we can accommodate age uncertainty, effects due to sediment compaction, and censored observations that are below detection limits. Our results show that distributional GAMs provide robust, continuous estimation of time series of ecological resilience, which may be used to reliably identify patterns of stability and resilience and to test key predictions of resilience theory using long-term ecological records.

Using species distribution modelling and palaeoecology to understand what determines resilience to fire in a critically endangered rain forest community

Michael-Shawn Fletcher¹, Michela Mariani^{1,2}, Haidee Cadd³, David Bowman⁴, Simon Haberle⁵, Hahjung Chin⁵
¹University of Melbourne, Carlton, Australia. ²University of Nottingham, Nottingham, United Kingdom. ³University of Adelaide, Adelaide, Australia. ⁴University of Tasmania, Hobart, Australia. ⁵Australian National University, Canberra, Australia

Abstract

Recent catastrophic wildfires in the Tasmanian highlands herald a significant threat to the future endangered fire-sensitive ecosystems. One such ecosystem is the montane rain forest community dominated by *Athrotaxis* spp. (Cupressaceae) and *Nothofagus gunnii* (syn *Fuscospora gunnii*; Nothofagaceae) in Tasmania, Australia. This endemic and hyper fire sensitive rain forest community has floral affinities with the temperate rain forests that dominated the super-continent Gondwana. Today, it is restricted to upper-montane areas of this topographically complex island. Wildfires following the British invasion of Tasmania in the late 1700s have reduced the distribution of montane rain forest by around 50%, and there is little evidence for post-fire recovery of these systems. Here, we use palaeoecology, species distribution modelling and remote sensing to unpack the various factors governing the resilience of this community to fire. We contend that both landscape heterogeneity in complex topographic landscapes and flammable species invasion can over-ride the effects of regional climate on ecosystem resilience to fire in this region. We provide evidence that long-term climatic change acts to decrease the rate of recovery of rain forest from disturbance by fire, thus, bringing these ecosystems closer to points of critical transition (so-called tipping points of collapse) - i.e. a critical slowing down. Whether a critical transition occurs is, at least in part, dependent on the presence or absence of species that can initiate a positive feedback switch that can shift the ecosystem to an alternate state. We conclude with a provocation: should we say goodbye to Gondwana in Australia or should we use this data to focus our efforts in areas of greatest reward for effort?

O-2064

Spatial distribution of Palaeolithic sites in relation to raw material sources in the central Narmada valley, India

Vivek Singh

Indian Institute of Science Education & Research, Mohali, India

Abstract

The spatial distribution of archaeological sites in a particular area represents the land use patterns of hominin population adaptations in accordance to raw material and water resources. Understanding these distribution patterns also suggests their adaptations to different conditions which provide insights on understanding their behaviour. Landscape adaptation in central India is quite exceptional as more than 300 Lower Palaeolithic sites/occurrences have been reported in different contexts. The present work specifically deals with these assemblages and associated raw material sources in the central Narmada valley. The central Narmada valley is rich in various rock types (sedimentary, metamorphic, igneous and volcanic) which also served as raw material for various Pleistocene hominin populations. The Narmada River divides the region into northern and southern parts. In the northern part of Narmada Valley, there are mainly the Vindhyan Supergroup (sedimentary and metamorphic rocks) and Deccan Trap (volcanic rocks), whereas in the southern part of Narmada Valley, there are mainly the Gondwana Supergroup (sedimentary rocks), Deccan Trap and the Mahakoshal Group. Along the river, there are a few exposures of the Vindhyan Supergroup and thick deposits of Quaternary alluvium. Due to this varied geology, the quartzite and sandstone from the Vindhyan Supergroup are prominently utilized, whereas, in the south of Narmada, the main raw materials came from quartzite of the Mahakoshal Group in the form of pebbles, cobbles and boulders, and chert from Gondwana Supergroup in the form of *in situ* exposures. Acheulean sites are mostly found along the foothills of Vindhyans as well as along the banks of the Narmada River and its tributaries. As pebbles and cobbles dominate the southern parts of the valley, the majority of the Palaeolithic assemblages there comprise flake and chopper industries, which makes it difficult to assign them to a particular lithic cultural phase. For now, no sites have been reported or found on basalt (Deccan Trap) although stray artefacts have been observed. In this paper, the author has tried to link these raw material sources with the occurrences of Palaeolithic sites to have a better understanding of past hominin land use patterns and ecological adaptations.

Absence does not mean absence: Modern day land-use and the visibility of the archaeological record (Kibbanahalli Palaeolithic Complex, southern India)

Akash Srinivas

Department of Humanities and Social Sciences, Indian Institute of Science Education and Research (IISER), Mohali, India

Abstract

Kibbanahalli is an important Lower Palaeolithic site-complex in southern Karnataka, a state in the southern region of Peninsular India. This region is important as it is somewhat centrally located between regions to the north, east and south, where decades of systematic Palaeolithic research has led to the establishment of firm cultural stratigraphy(s), and even, in cases, of chronology(s). However, in stark contrast to these regions, southern Karnataka is often ignored in prehistoric research. Over 90 years of (intermittent) Palaeolithic investigations at this site-complex have set the foundation of our understanding of the Palaeolithic occupation of this vital region. It is of utmost importance to continue Palaeolithic research in this area as it is one of the fastest industrialising and urbanising zones of the world, with large population centres such as Bangalore (Bengaluru), Mysore (Mysuru) and others located here. Documenting the rich Palaeolithic heritage in this region, before its eventual surrender to the forces of 'development' is thus a priority. Further, it is also necessary, if possible, to qualify and quantify the impact of these developmental processes on the visibility and preservation of the archaeological record, in general, and the Palaeolithic record, in particular, which might serve as a model for future research in other similar regions. It is with this objective that the present author has initiated field investigations into the rich Palaeolithic record of this region. These recent investigations have led to a secure identification of the technological attribution of the lithic assemblages here, as well as the identification of many new Palaeolithic localities. The presence of a uniform stratigraphical association of the archaeological horizon and similarities in the lithic assemblages have led to the reclassification of the many sites/localities at Kibbanahalli and its vicinity, into a site-complex. This paper reports on a series of field observations and remotely-sensed data collected to understand the distribution pattern of the various Palaeolithic localities of this site-complex. Results of this study highlight the important role played by modern day land-use patterns in the region on the observed distribution of the archaeological record as well as on the visibility of the archaeological record itself. This challenges previous interpretations regarding the settlement patterns and strategies suggested for the Palaeolithic occupation of this region. Further, this study draws attention to the need and necessity to understand the role of various site formation processes, especially modern day land-use activities, on the observed and observable patterns in the archaeological record as well as the visibility, or lack thereof, of the archaeological record.

O-2066

Stretching Boundaries: A geo-archaeological re-examination of District Damoh and adjacent areas of Madhya Pradesh, from river channels to peripheral landforms.

Yezad Pardiwalla

Indian Institute of Science Education and Research, Mohali, India

Abstract

Since the publication of R.V. Joshi's work over half a century ago on the Palaeolithic record of Damoh, this area of Madhya Pradesh in central India has received little interest compared to its neighbours, the Narmada Basin in the south and the Son Valley to the northeast. This is not surprising since a well-developed Quaternary stratigraphy is preserved along the Narmada and Son. Though R.V. Joshi speaks about two tool-bearing gravel horizons and Sali (1990) puts forth a general stratigraphy for the area, in comparison, the Sonar and Bearma, and their tributaries, flowing through the district of Damoh and adjacent areas have far less extensive river sections with Quaternary deposits, with the underlying Vindhyan bedrock exposed at regular intervals. However this Vindhyan geology, made up primarily of shale and sandstone with quartzite outcrops, and dominating the lithology of these basins, offers an opportunity to understand the development of cultural surfaces/horizons, not limited to the outcome of fluvial processes. A recent pilot survey in the area was undertaken with the objective to better understand the landscape by expanding the focus to include the pediments and escarpments on the northwest and east of the district while also surveying the various river and stream channels. Several geomorphic processes including deposition by river action but also erosion, in-situ weathering of bedrock and mass wasting seemed to have contributed uniquely to the distribution and exposure of Palaeolithic sites across the region. The variety of available raw materials which was seen to increase towards the fringes of the Sonar-Bearma basins warranted widening the survey area to include parts of districts Panna and Satna, and the breccia formations of Chhatarpur and understand any corresponding variability in lithic assemblages. By stretching boundaries beyond fluvial environments, the most commonly worked upon archaeological context in South Asian Palaeolithic studies, the present work aims to fill a lacuna in our understanding of this potentially interesting study area straddled by some of the richest prehistoric sites in the Indian subcontinent. Owing to the preliminary nature of the research currently undertaken, no cultural or chronological categorisation of Palaeolithic sites from the area has been attempted. However by revisiting localities mentioned in the published literature and several previously unexplored ones, the various geomorphological processes and proximity to a range of different fine quality raw material sources seem to have resulted in a rich archaeological record spanning much of the Palaeolithic.

O-2067

Late Pleistocene palaeoenvironments in South Asia and associated palaeoanthropological implications

Shashi Mehra, Parth Chauhan

Indian Institute of Science Education and Research, Mohali, India

Abstract

Climate change is prominently considered as a causal mechanism for hominin dispersals, expansions and technological innovations/transitions in the Old World. Being in the centre of the Old World and ecologically diverse, the Indian subcontinent must have played a prominent role in hominin dispersals and adaptations across Asia during the Late Pleistocene. Despite available palaeoenvironmental proxies and ample archaeological evidence, very few detailed multidisciplinary studies have been carried out to investigate environment-human interactions in prehistoric South Asia. This presentation focuses on the status of younger palaeoenvironmental studies in South Asia and associated debates regarding hominin behaviour and faunal extinctions. It synthesises current palaeoclimatic data and prehistoric evidence at regional levels and proposes testable hypotheses regarding dispersal routes, technological diversity (especially after ~100Ka) and associated adaptive strategies (e.g. Toba issue, seasonal monsoon). Broad inferences are drawn from ~ 100 studies, carried out on individual proxies including carbonates (7), sediments (34), pollen (16), ostrich eggshell fragments (2), fossil enamel/wood/seed (4), speleothem (1) and multi-proxies (30). The records show that the period from 125 – 80 ka is predominantly characterised by humid environments. It was followed by varied results/changes in climatic conditions at 79-70 ka and arid environments at 69-60 ka. Between 59-30 ka, South Asia's environment was again generally humid. The period from 29-20 (LGM) again represent varied results which were later followed by the arid conditions from 19-11 ka. Typo-technological transitions from the Middle Palaeolithic to the early Mesolithic are also addressed, including interpretative issues with the Upper Palaeolithic. Palaeoenvironmental reconstructions carried out thus far have lacunae regarding geographical, temporal and methodological aspects. Finally, this paper highlights the importance of investigating unexplored regions and focused time periods and attempts to link the South Asian palaeoenvironmental records with regional Asian counterparts about hominin adaptations and population movements.

New techno-chronological data on select terminal Pleistocene-late Holocene microlithic occurrences in the central Narmada basin, Madhya Pradesh, India

Nupur Tiwari¹, Morthekai P², K Krishnan³, Parth R. Chauhan¹

¹Indian Institute of Science Education and Research, Mohali, Punjab, India. ²Birbal Sahni Institute of Palaeosciences, Lucknow, Uttar Pradesh, India. ³M. S. University of Baroda, Vadodara, Gujarat, India

Abstract

The earliest occurrences of microliths in South Asia date back to the Late Pleistocene at Mehtakheri in central India (48-45ka), Jwalapuram in southern India (38ka), Batadomba-Lena in Sri Lanka (35-36 ka) and Kana and Mahadebbara in northeastern India (38-35 ka). Microlithic technology is distributed almost across the entire Indian Subcontinent and chronologically continues up to the Iron Age. This paper discusses new data acquired from the author's ongoing doctoral research in the two districts of central Narmada Basin, Madhya Pradesh (Hoshangabad and Sehore) in central India.

The surveys were carried out in the Vindhyan and Gondwana foothills and in the surrounding Narmada floodplains. Over 30 microlithic occurrences were identified and documented through the four seasons of fieldwork (2015-2018). The assemblages were collected to study the technological aspects of the microliths and locational data was recorded to understand land use patterns. Few sites with abundant lithic assemblages in exposed sediments were selected for optical dating, samples for which were processed between 2016-2018. We present here the preliminary dates from key sites namely Pilikarar, Morpani, and Gurla-Sukkarwada. The dates range between 12.4 ka and 2.2 ka. The luminescence measurements were carried out using Risoe TL/OSL Reader at the Birbal Sahni Institute of Palaeosciences, Lucknow. The SAR (single aliquot regeneration) protocol was applied to all the samples. The samples were processed with basic chemical treatments to remove any substantial organic material and carbonates. The fine-grained (4-11 mm) methodology was used to process the samples by preparing fifty aliquots per sample. The ages were calculated from the DRAC using the central age model.

Technology during the terminal Pleistocene and early Holocene transitions from non-geometrical to geometrical shapes, however, the assemblages are still being analysed for a more comprehensive picture. The dates are varied between terminal Pleistocene to Holocene, which can propose a change in the technology of the microlithic production. However, major factors such as continuation of hunter-gatherer populations co-existing with the other technologically developed populations by the proto-Historic and Historical periods cannot be ruled out. This research confirms the existence of hunter-gatherer populations over a prolonged time in the central Narmada basin since at least the late Pleistocene and possibly much earlier, based on published data.

O-2069

Understanding Geo-archaeology in Trans-Himalaya: A Case study based on Lithic assemblages from Dzamathang, Spiti Valley, Himachal Pradesh, India

EKTA SINGH, Raman Patel, Pradeep Saklani
HNB Garhwal University, Srinagar Garhwal, India

Abstract

The Trans- Himalayan region is generally seen as a barrier during prehistoric times due to its topographic and intense climatic features. Spiti Valley is located in the trans-Himalayan terrain of India, from where non-geometric microliths, were recently discovered in this part of Himalaya. While the Siwalik Hills have been subject to extensive prehistoric surveys, this is the first evidence of lithic tools discovered in the trans-Himalayan region of Himachal Pradesh, India. This suggests that this Himalayan zone may have also acted as a corridor instead of a barrier during human migration. In fact, in the adjoining area of western Tibet, other researchers have reported lithics from several sites and assigned to the Middle Palaeolithic. This paper is based on artefacts which were collected from surface contexts. Large numbers of lithics and debitage were found in the Dzamathang area of Spiti Valley. These assemblages consist of assorted artefacts including a unifacial chopper, microlithic core, blade flakes, backed blades, burins and a large amount of debitage. The majority of artefacts are on quartzite or quartzarenite. The quartzite is the most common rock in the Spiti valley, from Neoproterozoic to Permian age. The quartzite is mainly found in the Chandpur, Nagthat, Batal, Katarigali, Chambaghat, Kauriyala formations (Neoproterozoic); Koti, Kunzam La formations (Cambrian); Thango Formation (Ordovician); Muth quartzite Formation (Devonian) and Po Formation (Carboniferous) in Spiti valley. The future surveys will be targeted at recovering primary context sites for excavations and absolute dating.

O-2070

A geo-archaeological study on mounds using multi proxy to reconstruct past climate and drainage affecting Harappan population near Rakhigarhi, India.

Apurva Alok¹, Naresh. C. Pant¹, Hari.S. Saini², Yukiyasu Tsutsumi³, Kaushik Das⁴, Ravish Lal⁵

¹University of Delhi, Delhi, India. ²Ex- director, Geological Survey of India, Noida, India. ³Natural Museum of Nature and Sciences, Tokyo, Japan. ⁴Hiroshima University, Hiroshima, Japan. ⁵IISER, Mohali, India

Abstract

The age old of problem of the demise of Harappan Civilization, is conflicted because of uncertainty related to the existence of a perennial river, also known as the Saraswati River. On the basis of zircon dating, Clift et al. (2012), has suggested that the flow to the river was perennial before 30ka and the river became ephemeral sometimes between around 30 and 15ka. Giosan (2012) observed that the absence of late Painted Grey Ware Harappan sites in the lower reaches of the present day Ghagghar River (former Saraswati River), suggests that Harappans moved out of the area due to lack of perennial source of water or due to weakening of monsoon. However the migration of population, and the drainage disorganization of the river (Clift et al. 2012) do not coincide. Few archaeological sites in Rakhigarhi, when observed from the present proposed course of the river, lie very far away from any perennial river channel (Singh et al. 2010), for any early civilization, hence Mehdi et al. (2016), on the basis of remote sensing, identified two more tributaries which supported the presence of archaeological sites away from the river.

Singh et al., 2010 and 2011, suggested the migration and expansion of Harappan population on the basis of distribution of archaeological sites during different phases of Harappan timeline, whereas Giosan et al. 2012, highlighted the role of climate and rainfall on the societal evolution of the civilization. Numerous studies suggests that earlier river was perennial which turned ephemeral before onset of Harappan Civilization (Singh et al.

Fig: Distribution of archaeological sites representing different phases of Harappan period.

However, our preliminary studies on sediments obtained from multiple archaeological mounds near Rakhigarhi suggests a new story. Presence of burnt charcoal and ash collected from different sedimentary layers within mounds suggests a series of occupation and abandonment of these sites. C-14 ages of charcoal have helped in constraining these activities from early to Mature Harappan phase. The presence of thick massive deposits of mud interlayered with ash deposits suggests that during Harappan period, Rakhigarhi was in the vicinity of an active river which frequently flooded the entire region forcing people to migrate. Similar studies have been conducted on geological

cum archaeological mound in the main paleochannel which also represents age between early and late Harappan phases. At least three events of flood has been recorded and have been analyzed. In this amalgamation of geology and archaeology, we have attempted to create a relatively high resolution climate record and fluvial activities in the region based on multiple proxies which affected the Harappan population to the extent that it forced them to abandon these sites.

O-2071

Multi-proxy records from Plio-Quaternary cave sediments in Slovenia

Nadja Zupan Hajna¹, Petr Pruner², Pavel Bosák², Andrej Mihevc¹

¹ZRC SAZU Karst Research Institute, Postojna, Slovenia. ²Institute of Geology of the CAS, Prague, Czech Republic

Abstract

In karst terrains caves often preserve the only sedimentary record of the latest stages of landscape evolution. Caves trap and accumulate various clastic, chemical and organic sediments brought into caves by sinking rivers, vertical percolation of precipitation or collapse. The dynamics of sedimentation is mainly controlled by climate and hydrology (*e. g.* glaciations, floods, precipitation), by changes in river catchment and by evolution of cave network. Protected in caves sediments are generally well preserved and reveal exceptionally good, multi-proxy record of surface environmental conditions at the time of their deposition. They can cover time span from several million years up to the present.

Systematic research of cave sediments sampled over the last 20 years used different dating methods shows that sediments in Slovenian karst are up to 5 Ma old. Previously it was believed that the cave sediments deposited mostly during Pleistocene and that caves are not much older. The majority of sediments studies has been carried out in SW Slovenia (*i.e.* in the NW part of Dinaric Karst), and at some sites of Alpine karst. More than 4,000 samples were taken and analysed in 42 different sections from active, relict and unroofed caves and surface sediments. Standard paleomagnetic analyses were used (thermal /TD/ and alternating field /AF/ demagnetization, magnetic susceptibility measurements, etc.). All field hand specimens were oriented *in situ* and on some profiles magnetic susceptibility was directly measured. Procedures were selected to allow the separation of the respective components of the RM and the determination of their geological origin. The systematic acquisition of paleomagnetic data within a studied section allowed the construction of a detailed magnetostratigraphic profile with a high resolution. In intervals with polarity change, the frequency of sampling was so high that an almost continuous record of the magnetic and paleomagnetic parameters was obtained. Results from paleomagnetism and magnetostratigraphy were calibrated by U-series, paleontological and geomorphological dating if possible. Age sequences were made of composition of sections with different ages within Cenozoic era. A robust chronology in the spatially and temporally highly discontinuous sediment record preserved in karst was set up. Calibrated data contributed to the reconstruction of speleogenesis, deposition in caves, and indirectly to the evolution of karst surfaces and succession of tectonic movements. The oldest sediments, about 5 Ma, are now situated in relict caves close to the surface or in unroofed caves, which were exposed to surface by karst denudation. Sedimentation in caves has also reflected the evolution of the surrounding landscape; *i.e.* climatic changes with flood events or/and changes of the tectonic regimes during Neogene and Quaternary. Paleomagnetic data obtained from cave sediments were also used to document neotectonic (<5Ma) vertical-axis rotations in the NE corner of the Adria-Eurasia collision zone.

Pliocene-Quaternary landscape evolution based on cave geomorphology: Picos de Europa mountains (Spain)

Daniel Ballesteros¹, Santiago Giralt², Joaquín García-Sansegundo³, Montserrat Jiménez-Sánchez³

¹UMR 6266 IDEES, University of Rouen Normandy-CNRS, Mont Saint-Aignan, France. ²Institut of Earth Sciences Jaume Almera (ICTJA-CSIC), Barcelona, Spain. ³Department of Geology, University of Oviedo, Oviedo, Spain

Abstract

Karst caves preserve morphologies and records, which study reveals data about regional landscape evolution. In the Northern Iberian Peninsula, Picos de Europa mountains are formed by Carboniferous limestone that occupies the majority of their topographic surface. These mountains with more than 420 km of cave conduits represent one of the most important karst areas of the World, including 14% of the deepest caves explored today. This work aims to reconstruct the Pliocene-Quaternary evolution of these high mountains at regional scale, based on geomorphological and geochronological research (U/Th and Al/Be) carried out in four alpine caves. Cave geomorphological mapping showed 12 km of studied caves formed by 47 % vadose canyons and shafts, 45 % phreatic/epiphreatic conduits organised in six cave levels, and 7 % breakdown-modified passages. Cave deposits include perched flowstones that represent ancient pavements, fluvial terrace deposits with allochthonous clasts, slackwater deposits related to cave floods, and debris deposits produced by breakdown. One Al/Be burial age indicated a minimum age of 2.1 ± 0.5 Ma for the caves development, allowing estimation of the mountain uplift at $0.15-0.25$ mm·a⁻¹ since the late Pliocene. Thirty-four U/Th ages allow us to define main sedimentary and erosive periods from MIS 8 to 1. This data provided a landscape evolution model with 6 phases at regional scale. Phase 1: development of cave in the Pliocene, in limestone partially or totally covered by the detrital Permian-Mesozoic cover. Phase 2: river incision, erosion of this cover and occurrence of fluvial captures. Phase 3: cave infill during 220-145 ka, probably caused by the erosion of Stephanian detrital outcrops. Phase 4: erosion of cave infill during 125-45 ka. Phase 5: apparent pause in the speleothem formation during 45-25 ka related to dry and cold regional conditions. Phase 6: reactivation of the speleothem precipitation since 25 ka. Fluvial incision, regional climate, and the ancient presence of detrital rocks that covered limestone would be the main factors that controlled the regional geomorphological evolution since the Pliocene.

O-2073

Speleothems as recorders of centennial- to millennial-scale climate events during the Last Glacial

Frank McDermott¹, Mareike Stahlschmidt²

¹University College Dublin, Dublin, Ireland. ²Max-Planck-Institute for Evolutionary Anthropology, Leipzig, Germany

Abstract

Caves are unique environments that offer physical protection for speleothems and other climate-sensitive archives, particularly during glacials when surficial deposits may be removed or reworked by erosion. Speleothems (calcitic or aragonitic stalagmites, stalactites and flowstones) are ideal materials for U-series dating, permitting the construction of exquisitely detailed chronologies for depositional phases, well beyond the c. 50ka limit of radiocarbon dating. Crucially, speleothem deposition requires that liquid water is available to percolate downwards through soils and bedrocks, and so during glacials, intervals of speleothem deposition indicate episodic absences of permanently frozen ground and the availability of biogenic CO₂. Results of 1-D thermal modelling of heat conduction through soils and bedrock will be presented, along with a discussion of new and published U-series dates from selected European caves, with specific examples from Ireland, the Alps and Georgia to constrain the duration of the onset of climate amelioration during the Dansgaard-Oeschger (DO events). Previously published U-series dates from Crag Cave, SW Ireland (Fankhauser et al., 2016), augmented by additional dates for key speleothems from this site provide evidence for short-lived climate-driven centennial to millennial scale episodes of deposition. These occur during Marine Isotope Stage 5 (MIS-5) through to the Last Glacial Maximum (LGM), into the Late Glacial. New U-series dates will also be presented for stalagmites collected from Solkota Cave in western Georgia during 2016. Stalagmite SKK 16-3 from Solkota Cave exhibits intense but short-lived depositional phases that are contemporaneous with DO events in the Greenland ice cores. In detail, SKK 16-3 shows rapid but intermittent growth around 84 ka, coinciding with climatic amelioration during Marine Isotope Stage (MIS) 5a, and specifically during the short-lived Greenland Interstadial 21.1e (GI-21.1e). Following a long-lived hiatus, a short interval of deposition resumed at 57 ka, coinciding with a warm interval in MIS3, Interstadial GI 16.1, indicating a strong climatic control. Coeval episodes of speleothem deposition are seen at Crag Cave and in the published results from caves in the European Alps. Finally, the new results permit snapshot comparisons of elevation-corrected Last Glacial speleothem longitudinal $\delta^{18}\text{O}$ gradients during selected DO events across Europe, from the Irish Atlantic margin in the west to the Black Sea in the east, with those of the Holocene.

Fankhauser, A., McDermott, F. and Fleitmann, D. (2016) Episodic speleothem deposition tracks the terrestrial impact of millennial-scale last glacial climate variability in SW Ireland. *Quat. Sci. Rev.* 152, 104-117.

Millennial-scale glacial climate variability from a cave record in Southeastern Alaska follows Dansgaard-Oeschger cyclicity

Paul Wilcox^{1,2}, Jeffrey Dorale³, James Baichtal⁴, Christoph Spötl², Sarah Fowell¹, Lawrence Edwards⁵, Johanna Kovarik⁶

¹University of Alaska Fairbanks, Fairbanks, USA. ²University of Innsbruck, Innsbruck, Austria. ³University of Iowa, Iowa City, USA. ⁴Forest Service, Thorne Bay, USA. ⁵University of Minnesota, Minneapolis, USA. ⁶United States Department of Agriculture, Washington D.C., USA

Abstract

Speleothems have the potential to preserve long terrestrial records, with the added benefit of precise dating with U-series dating. These records are therefore sought after for reconstructing climate histories in different parts of the world. However, this approach has seldom been applied in Alaska, with no long, continuous record available. Here, we fill-in this gap and provide the first precisely dated terrestrial paleoclimate record from Alaska covering large parts of the last glacial period. A stalagmite from Prince of Wales Island grew between ~75,000 and ~11,100 yr BP, interrupted by seven hiatuses. Hiatuses correspond to permafrost development and a temperature drop of up to 5°C from modern. Intervals of calcite deposition place tight constraints on the timing of mild climatic episodes in Alaska during the last glacial period, when no permafrost was present, allowing water infiltration into the karst system. These periods of calcite deposition are synchronous, within dating uncertainties, with Greenland Interstadials 1, 10, 11, 12c, 14b-14e, 16.1a, 17.2, and 20c. This speleothem record is the first chronologically well constrained evidence of the impact of Dansgaard-Oeschger events on climate and vegetation in the northeast Pacific realm.

Chronology of a Pleistocene cave ventilation event that impacted speleothem records and their geochemistry

David Domínguez-Villar¹, Kristina Krklec¹, Hai Cheng², R. Lawrence Edwards³

¹University of Zagreb, Zagreb, Croatia. ²Xi'an Jiaotong University, Xian, China. ³University of Minnesota, Minneapolis, USA

Abstract

Speleothems rarely grow continuously for more than some thousand years. However, the composite speleothem record based on multiple samples from the same cave can have tens or even hundred of thousands years in duration. The geological evolution of the cave systems (e.g., re-routing of drip flow, opening/colmatation of conduits affecting ventilation, etc) is often a common cause for changes in speleothem growth. These non-climate change related cave processes can also be recorded in the geochemical and petrological speleothem proxies, causing problems when interpreting paleoclimate from speleothem records. Identification of hydrological or inside-cave climate events unrelated to climate changes in speleothem records is difficult, although the study of the erosive and/or depositional record of caves often provide valuable information.

Here we present a study of an extreme case of condensation corrosion in Eagle Cave (central Spain). Large speleothems were formed in this cave, although a sudden ceiling collapse caused a drastic change in cave ventilation that resulted in a net dissolution of speleothems over the main hall of the cave due to the condensation corrosion process. Speleothems affected by dissolution show blunt morphologies and their internal structure (i.e., layers) is visible on their surface. Cyclic thermal changes related to the new ventilation dynamics, forced the condensation of water droplets on the cave walls and the speleothems. The droplets had an acidic pH as a result of cave atmosphere CO₂ diffusion in the solution, causing the corrosion of carbonates where the drops were standing or flowing. The dissolution of speleothems by this event is recorded through the cave, although the magnitude of the process varies locally. Based on the morphology of speleothems, the thickness of carbonate lost by dissolution was in the order of tens of centimetres for most speleothems.

Progressively, the collapse sinkhole that enabled the large thermal variability in the cave was filled with gravitational sediments and the ventilation regime became once more stable enough for speleothems to have net accumulation. Thus, a distinctive series of speleothems overgrew the dissolved speleothems. Dating of several speleothems before and after the dissolution event framed the condensation corrosion event between 60 and 55 ka BP, suggesting that dissolution rates might have been as high as 100 μm/yr. Petrology and geochemistry of speleothems differed before and after the dissolution event as the result of ventilation dynamic differing from the previous stage of speleothem formation. This research highlights the potential of speleothem proxies to record non-climate change related processes.

Speleothem rubble as a new low-impact tool for Quaternary palaeoclimate studies: insights from a cave model

Rieneke Weij¹, John Hellstrom¹, Kale Sniderman¹, Liz Reed², Russell Drysdale³, Jay Gordon³, Jon Woodhead¹

¹School of Earth Science, The University of Melbourne, Melbourne, Australia. ²School of Physical Sciences, The University of Adelaide, Adelaide, Australia. ³School of Geography, The University of Melbourne, Melbourne, Australia

Abstract

As speleothems become increasingly valued for their scientific importance and aesthetics, the pressure on cave environments grows. Several recent scientific studies have stressed the necessity of low-impact sampling strategies such as pre-screening, mini-coring and re-installation of samples after use to reduce unnecessary damage. The great abundance of speleothem 'rubble' in caves, however, suggests another highly-promising tool for low-impact scientific study. Here this concept is first explored in a model, and then applied to the World Heritage Naracoorte caves in South Australia.

To construct the model, we assume that the age frequency distribution of randomly sampled rubble from a family of caves will reflect periods of enhanced and reduced effective precipitation. Speleothem U-Th age frequency distributions were then synthetically generated based on an assumed climatic forcing; Monte-Carlo simulations then help us to understand any potential biases when using the rubble approach. Since any interpretation from an age frequency distribution is strongly dependent on the precision and accuracy of the timing of peaks and troughs within it, we also studied factors that affect the curve shape, such as the type of probability density function, sampling method and sample size. To produce the frequency distribution, a Kernel Density Estimator (KDE) was used rather than the typically employed Probability Density Function (PDF), because the latter rewards ages with small uncertainties producing spiky peaks. In addition, absolute age-uncertainties vary with age for the U-Th method which also introduces bias into a PDF. Our model shows that peaks in the KDE can be reliably identified up to 300-350 ka. After 350 ka, the intensity and timing of the peaks become more difficult to interpret and should be treated with care. The model also confirms the ideal minimum sample size of 120 – 150 mentioned in previous studies.

In our real-world example 137 individual rubble samples (stalagmites, stalactites and flowstones) were collected from thirteen caves in the Naracoorte region, and dated with U-Th techniques. We observe no correlation between sample size (diameter of stalagmites and stalactites) and age, suggesting that there is little if any bias related to rubble form/preservation. The exponential relationship in the natural decay of speleothem material (i.e. a decrease in the number of old stalagmites) reported in recent work was not observed for the Naracoorte region. Based on our model, we suggest that under-sampling and non-random sampling may cause spurious trends in speleothem age frequency distributions, and that their influence should be thoroughly assessed before interrogation of the proxy record. The rubble sampling method offers great promise for palaeoprecipitation studies but can also provide valuable information on the timescales of karst processes and, when combined with other proxy methods (e.g. speleothem palynology), offers a novel, low impact method of palaeo-environmental reconstruction.

O-2077

The view from the cave: vertebrate responses to abrupt climate change over the last 60ka in Britain

Danielle Schreve

Royal Holloway University of London, Egham, United Kingdom

Abstract

The rapid climatic fluctuations of the Last Cold Stage and particularly the Last Glacial-Interglacial transition produced a major re-ordering of the vertebrate (chiefly mammalian and avian) faunas of northwestern Europe, resulting in aggregations of extinct and extant taxa that have often been referred to as 'disharmonious', by comparison to their present day biogeography. Previously, the combined problems of poor resolution and chronology have made it hard to establish whether the apparent patterns of vertebrate turnover observed are really synchronous with the climate changes recorded in long terrestrial records such as the Greenland ice cores and whether the apparent co-existence of species that are not sympatric today is genuine, or a taphonomic artefact of a low-resolution record. This has hampered our understanding of (i) the mode and tempo of faunal movement, (ii) regional extinction chronologies in this complex period and (iii) baseline evidence for establishing what is a native species. Cave sequences, especially those from Britain - at the margins of the North Atlantic - offer some of the best archives for addressing these questions, where extensive vertebrate assemblages can be extracted from (semi)continuous sequences. Using new evidence from British cave assemblages, this presentation will examine the different responses of mammalian and avian taxa to withstand abrupt climate change during this period and evaluate the role of cryptic northern (micro)refugia at the very margins of the North Atlantic.

Abstract

The Northern Isles of Scotland extend northward into the North Atlantic (~59°N) and are ideally located to reconstruct the interactions between the ocean-atmosphere-terrestrial systems during the Last Glacial-Interglacial Transition (LGIT). The climate of this region is strongly influenced by the North Polar Front and the North Atlantic thermohaline circulation (Barker et al., 2009). Currently, the INTIMATE Greenland stratotype sequence is the best highly resolved archive for understanding climate changes across the North Atlantic region (Rasmussen et al., 2014). However, this assumes that climate and environmental changes are synchronous across the North Atlantic. Presently, temperature oscillations for the wider North Atlantic region are not well understood and have been largely inferred through computer modelling.

Outwith the Greenland ice sheet, environmental changes in the ocean-atmosphere system can be reconstructed from a range of proxies, for example pollen, diatoms and speleothems. However, each proxy is not without its problems and few are directly sensitive to single climate variables, particularly temperature. Palaeo-temperature records have been inferred from coleopteran beetle assemblages but these tend to lack sufficient temporal resolution. Chironomids, on the other hand are found in large concentrations, within small quantities of sediment and provide high resolution records of climate change - within sub-centennial scales (Brooks et al., 2016).

Here, we present the first high-resolution chironomid inferred mean July summer temperature record from the Northern Isles of Scotland. Three continuous cores were sampled from lake basins in Caithness (Northern mainland Scotland), the Isle of Orkney and the Isle of Shetland. The cores are constrained by a robust age-depth model based on AMS dating and supported by tephrochronology. While the three chironomid inferred temperature records show broadly similar climatic shifts to the Greenland Ice Core records they differ in magnitude. Also, based on the bayesian age-depth models, there appears to be significant differences between the timing of temperature changes in the Northern Isles of Scotland and the Greenland Ice Core records during the LGIT.

Abstract

Snowfall is an important component of Earth's climate system; however, long, continuous high-resolution records of global snowfall are lacking because of the absence of suitable proxies. In this study, diatom record from the sediments of Yunlong Lake, in the southeastern Tibetan Plateau, was used to reconstruct snowfall during the Younger Dryas. Variations in the abundance of low-light-tolerant diatoms and diatom flux indicate that the duration of lake ice-cover during the YD was significantly longer than during the colder Heinrich event 1; this suggests that heavy snowfall, rather than temperatures, was responsible for the greater duration of lake ice-cover during the YD. Thus, we conclude that prolonged, heavy snowfall occurred in the southeastern Tibetan Plateau during the YD. In addition, this conclusion is supported by the results of a climate model simulation that also suggest that heavy snowfall occurred at high latitude in the Northern Hemisphere during the YD. We propose that the heavy snowfall intensified cooling in Northern Hemisphere by increasing the albedo; and that it increased hydrological variability at low latitudes by increasing the duration of the southward migration of the Intertropical Convergence Zone, and by delaying the onset of the Asian summer monsoon. The snowfall would have been a source of continuous freshwater that acted as a positive feedback and resulted in a prolonged weakened state of the Atlantic meridional overturning circulation which lasted for more than 1000 years. Overall, our results emphasize the amplification and positive feedback function of heavy snowfall in triggering abrupt climate change.

The sensitivity of decadal resolved *n*-alkane hydrogen isotope records of two adjacent lakes in northern Poland during the Younger Dryas

Theresa Grunwald¹, Bernhard Aichner², Florian Ott¹, Oliver Rach¹, Michał Słowiński³, Achim Brauer¹, Dirk Sachse¹
¹GFZ Potsdam, Potsdam, Germany. ²University of Potsdam, Potsdam, Germany. ³Polish Academy of Sciences, Warsaw, Poland

Abstract

Lipid biomarkers, preserved in sedimentary archives, have become important tools to reconstruct past climate change. Particularly *n*-alkanes, produced by aquatic and terrestrial organisms, are employed due to their ubiquity and stability. Compound specific hydrogen isotope ratios ($\delta^2\text{H}$) are used to reconstruct hydrological changes on local and regional scales. With increasing analytical sensitivity and automated extraction techniques it is now possible to work on a sub-decadal sample resolution in annually laminated lacustrine archives, potentially reconstructing changes related to weather rather than climate. Here we test the sensitivity of *n*-alkane concentrations, compound distributions and $\delta^2\text{H}$ values by comparing two adjacent paleoclimate records in northern Poland (Trezchowski Paleolake TRZ, Czechowskie Lake JC) that shared the same catchment (TRZ is included in the larger JC catchment), were exposed to the same climate and were surrounded by the same vegetation. The precise age models for both lakes, based on varve counting and tephrochronology made it possible to compare them at a resolution of exactly the same ten year steps in a varved section shared by both lakes between 13,000 and 12,679 yrs BP and in high temporal resolution (~ 10 years/sample) between 12,679 to 10,500 yrs BP which includes the abrupt onset and the termination of the Younger Dryas (YD) cold period. Within the varved section we observed significant differences in the response of the individual biomarkers. Average offsets in $\delta^2\text{H}$ values of *n*-alkanes between both lakes for the $n\text{C}_{23}$, $n\text{C}_{25}$, $n\text{C}_{27}$, $n\text{C}_{29}$ and $n\text{C}_{31}$ were 14‰, 8‰, 4‰, 5‰ and 4‰ respectively. At the transition into the YD similar responses showed in both lakes, with lower *n*-alkane concentrations and a coeval decrease of *n*-alkane $\delta^2\text{H}$ values (19-15‰TRZ and 10-5‰JC). Offsets in $\delta^2\text{H}$ values between both lakes for the mainly aquatic derived $n\text{C}_{23}$ and mixed aquatic-terrestrially $n\text{C}_{25}$ were larger than the average analytical uncertainty of 1-2‰, implying differences in the source of $n\text{C}_{23}$ and $n\text{C}_{25}$. During the YD JC showed a significantly lower Average Chain Length (ACL) index, also suggesting increased aquatic macrophyte derived $n\text{C}_{23}$ and $n\text{C}_{25}$ input compared to TRZ. As such we suggest, that $n\text{C}_{23}$ and $n\text{C}_{25}$ in JC were more of aquatic origin during the YD compared to TRZ. The smaller TRZ showed a significantly higher variance (15‰-25‰) of $\delta^2\text{H}$ values compared to JC (6‰-13‰), except for $n\text{C}_{23}$ (47‰JC, 34‰TRZ). These results suggest that in smaller lakes the mainly aquatic sourced $n\text{C}_{23}$ and the mixed aquatic/terrestrially sourced $n\text{C}_{25}$ concentration and $\delta^2\text{H}$ values are prone to be affected by changes in the aquatic ecosystem, such as available aquatic growth area. Terrestrial long-chain *n*-alkanes showed smaller offsets (4-5‰) and less dissimilarity between both lakes, probably due to concurrent change in the common catchment, indicating a more robust representation of local hydrological change.

Holocene temperatures from the Mutual Ostracod Temperature Range method in Northern Estonia

Kadri Sohar

Institute of Ecology and Earth Sciences, University of Tartu, Tartu, Estonia

Abstract

Continental archives like lakes help to understand and test climate models for the Quaternary. Reconstructions using fossils, e.g. calcareous ostracod shells, pollen or chironomids, express quantitative palaeotemperature excursions for interglacials. The Mutual Ostracod Temperature Range (MOTR) method (Horne 2007) reconstructs the mean monthly air temperature ranges for January and July and MOTR based annual mean temperatures range.

Here is offered a MOTR example from Estonia, northern Baltic, where the method is used for Holocene continental sequence from Lake Äntu Sinijärv. The lake is unique due to its continuous calcareous sedimentation throughout the Holocene and the lake marl gives opportunity to study and test different approaches (fossils, chemical composition of lake sediments etc) to detect any abrupt changes. Ostracod-based study relies on a new age model for the lake (Street-Perrott et al 2018).

Ostracods occupied the lake at ca 10500 yrs BP and their fossil data covers the entire Holocene period and expresses different freshwater ostracod assemblages. This gives a good background for applying MOTR method. Results suggest temperature around +18° to +19°C for July and -2° to 0 C for January and the mean annual temperature (MAT) range from +7° to +9° C in the Early-Holocene (10 500-9200 yrs BP). This is a little higher than modern temperatures. MOTR method suggest an abrupt cooling around 10 000 yrs BP when MAT was ca +3.5° C.

At 9200-3900 yrs BP the MOTR July temperatures varied around +17° C and January temperatures were ca -3° C, MAT values ca +5° C. Sudden MAT drops occurred at ca 9000 yrs BP and 8500 yrs BP where the MATs were around +3° C, and at 6550 yrs BP when MAT values dropped lower than -6° C.

The MOTR suggest for the Late-Holocene rather cool period. July temperature range was from +15° to +17° C and MAT was ca -4° to -2° C. Temperatures started to increase at ca 1500 yrs BP, where temperature for July was ca +18°C and for January ca 0°C, MAT values around + 9° C.

In perspective, the Holocene temperatures derived from ostracod assemblage structure can be tested in combination with different proxy methods and refine any regional reconstructions.

The groundwater recharge lake evolution in arid region, a case from Badain Jaran Desert, Northwestern China

Ning Kai^{1,2}, Yang Zhenjing¹

¹Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences, Shijiazhuang, China. ²Lanzhou University, Lanzhou, China

Abstract

Vertical water transport plays an important role in the development and maintenance of lakes in arid zones. However, previous study of this phenomenon has focused mainly on the effects of regional precipitation, rather than effects of groundwater recharge, on arid-zone environmental change. We selected a core from a seasonal lake basin located in the hinterland of the Badain Jaran Desert, northwestern China, to assess the Holocene environmental evolution of this region and its response to climate change.

Our results show that peat deposition from 11 to 10ka indicates humidification after YD, the lake sediment, lower EM2 and lower PCA-1 scores indicates relative more humid environment from 10 to 7.8ka, the lake sediment and higher EM2 and higher PCA-1 scores indicates most humid environment from 7.8 to 5.8ka, the transition from lacustrine facies to limnetic facies and increasing salinity indicates drying trend from 5.8 to 2.5ka, and the aeolian sand sediment, lowest EM2 and lowest PCA-1 scores indicates driest environment from 2.5 to 0.8ka, lacustrine facies and finest grain size indicates relative humid environment during the Little Ice Age period. The environment was relative humid in early Holocene, most Humid in mid-Holocene and dry in mid-late Holocene. The moisture pattern in the hinterland of the Badain Jaran Desert was synchronous with that in the northeastern of Tibetan Plateau, imply that the groundwater recharge lake was dominated by the intensity of groundwater recharge from monsoon margin area, especially the northeastern of Tibetan Plateau. As a record from groundwater recharge lake without runoff, our study provides the groundwater output quantity record from northeastern of Tibetan Plateau and would benefit the environment change research and regional water resources allocation around the Tibetan Plateau.

By analyzing the peak of the short term (non - millennial scale) of the main proxy of sedimentary profile, ten environmental events were identified including the wet events of 10.3 ka, 7.4 ka, 6.3 ka, 4.2 ka, and 0.4 ka and drought events of 9.4 ka, 8.2 ka, 5.4 ka, 2.8 ka and 1.4 ka. And these events, except for events of 6.3 ka and 5.4 ka, are consistent with the North Atlantic cold event as a response to global climate change. It is a perfect record about the North Atlantic cold event in the groundwater recharge lake from arid land of China.

Millennial and centennial climatic influences on productivity and sediment composition in two boreal lakes

Sofia Ninnes¹, Carsten Meyer-Jacob^{1,2}, Julie Tolu^{1,3}, Richard Bindler¹, Antonio Martínez-Cortizas⁴

¹Department of Ecology and Environmental Science, Umeå University, Umeå, Sweden. ²Paleoecological Environmental Assessment and Research Laboratory (PEARL), Department of Biology, Queen's University, Kingston, Canada. ³Department of Water Resources and Drinking Water, Eawag – Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland. ⁴Departamento de Edafología e Química Agrícola, Universidade de Santiago de Compostela, Santiago de Compostela, Spain

Abstract

In arctic and high alpine lake ecosystems climate often has a direct influence on the lakes, through changes in mixing regime, lake depth and ionic concentration, while in boreal and temperate systems climate often has a more indirect, catchment-mediated influence. The latter includes complex processes linked to catchment size, geology, soils, vegetation and elevation, and can effectively filter and distort climatic signals, as well as introduce lags in response. One particularly important filter in the cool and humid boreal region is catchment and near-shore wetland dynamics, because of the influence that the extent and configuration of wetlands have on hydrological flow paths, the production of dissolved organic carbon and aquatic habitat availability. Our paired boreal headwater lakes in central Sweden are governed by strong lake-wetland dynamics and provide the opportunity to examine how climate forcing over millennial and centennial timescales are registered in the paleolimnological records of these systems. In addition to paleoecological data (pollen, diatoms), we apply principal component analysis to Fourier-transform infrared spectroscopy and inorganic and organic geochemistry data from two 10,400 cal. y BP sediment records with the aim to link climatic forcing with long-term and short-term excursions in lake productivity and sediment composition. Our results indicate that solar irradiance is important for millennial-scale trends in lake productivity, but that indirect, catchment-mediated processes through lake-wetland interactions dominate sediment dynamics in these boreal lakes. Near-shore wetlands effectively both mute and reinforce climatic signals, but over different timescales. One example is the wetland expansion at ~2000 cal. y BP, which substantially altered the organic matter composition and the diatom community assemblages in both lakes. Additionally, human land use, also linked to the presence of wetlands, may have had important influence on sediment composition over the last 1000 years. For these lakes, wetland dynamics emerge as key to understanding the effects of future climatic changes on these lake ecosystems.

The 4.2 ka BP event: multi-proxy records from Hulun Lake in the northern margin of the East Asian summer monsoon

Jule Xiao^{1,2}, Shengrui Zhang³, Jiawei Fan¹, Ruilin Wen¹, Dayou Zhai⁴, Zhiping Tian⁵, Dabang Jiang⁵

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²College of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, China. ³College of Resources and Environment, Hebei Normal University, Shijiazhuang, China. ⁴School of Resources, Environment and Geosciences, Yunnan University, Kunming, China. ⁵Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

Abstract

The 4.2 ka BP event has been widely investigated since it was suggested to be a possible cause for the collapse of ancient civilizations. With the growth of proxy records for decades, however, both its nature and its spatial pattern have become controversial. Here we examined multi-proxy data of the grain-size distribution, ostracode assemblage, pollen assemblage and the pollen-reconstructed mean annual precipitation from a sediment core at Hulun Lake in northeastern Inner Mongolia spanning the period between 5000 and 3000 cal. yr BP to identify the nature and the associated mechanism of the 4.2 ka BP event occurring in the monsoonal region of eastern Asia. Higher sand fraction contents, littoral ostracode abundances and Chenopodiaceae pollen percentages together with lower mean annual precipitation reveal a significant dry event at the interval of 4210–3840 cal. yr BP that could be a regional manifestation of the 4.2 ka BP event in the northern margin of the East Asian summer monsoon (EASM). We suggest that the drought would be caused by a decline in the intensity of the EASM on millennial-to-centennial scales that could be physically related to persistent cooling of surface waters in the western tropical Pacific and the North Atlantic. The cooling of western tropical Pacific surface waters could reduce moisture production over the source area of the EASM, while the cooling of North Atlantic surface waters could suppress northward migrations of the EASM rainbelt, both leading to a weakened EASM and thus decreased rainfall in the northern margin of the EASM.

O-2085

Application of seismic geomorphology in reconstructing the Quaternary evolution of Australia's Northwest Shelf

Michael O'Leary, Victorien Paumard
The University of Western Australia, Perth, Australia

Abstract

An ongoing acoustic seabed mapping program by Geoscience Australia has revealed extensive palaeoshorelines features and drowned reefs along the West Australian continental margin. These features constitute one of the most detailed and unique palaeoclimate archives documenting reef and coastline evolution in response to climate and sea level change during the Quaternary.

Acoustic multibeam mapping of the seabed has been effective in defining the geomorphology of submerged shorelines and other coastal sedimentary environments where the primary morphology has been preserved. However, a more typical scenario is the significant reworking or burial of palaeoshorelines particularly during sea level transgression, masking or eroding the original landform and limiting palaeoenvironmental reconstructions.

Over the last decades, the petroleum industry has been collecting extensive 3D seismic data over Australia's Northwest Shelf. Here we investigate their utility for imaging the paleoshorelines of the Quaternary by processing the first few milliseconds of return data (~upper 50 m of seabed) with *PalaeoScan*TM software. This type of data analysis not only reveals the internal architecture of submerged landforms but captures a temporal and spatial record of the shoreline evolution in response to stable and oscillating sea levels.

A total of ~15,000 km² of 3D seismic data sets located in the Barrow Sub-basin to the west of Barrow Island were analysed, revealing an extremely detailed and complex relic submerged coastal landscape encompassing a range of landforms including channels, coastal barriers, barrier spits and islands, tombolo's and coral patch reefs. These mature landforms are uniformly located in water depths of around -70 m which would suggest a significant sea level still stand at this elevation.

3D seismic data provide the opportunity to create multiple DEM's each representing a single seismic reflector thus enabling for the analysis of coastal landform evolution under a variety of climate and sea level scenarios. These results might provide useful analogues for understanding future coastline response under changing sea levels and climates.

O-2086

Sea-Level Change and Preservation of Submerged Terrestrial Landscapes in the Western Gulf of Maine

Joseph Kelley

University of Maine, Orono, USA

Abstract

For more than 30 years I have mapped the seafloor from the western Gulf of Maine (USA) out to 60 m depth, collecting approximately 6,000 km of boomer and 3.5 kHz seismic reflection as well as side scan sonar observations and about 1000 km of multibeam bathymetric records. With students and colleagues, I have more than 50 vibracores and many hours of submersible and ROV observations to groundtruth remotely sensed records. In all of this effort, we have found terrestrial landscapes in only a few locations that depend on local temporal and spatial conditions. Sea-level change offers a strong constraint on landscape preservation. Following a late glacial highstand in Maine around 15 ka, sl fell rapidly to a lowstand at 60 m depth by 12.5 ka. It then rose rapidly until 7.5 ka and entered what we have termed a "slowstand" when sl rose only a few meters between 11 ka and 8 ka. Since then sl rose quickly and then ever-more slowly to the present. The early sl regression was rapid and few traces remain offshore. The lowstand was a time of uncertain length during which isostatic and eustatic sl changes were in equilibrium. Exposed sandy paleodeltas graded to 60 m depth were places of sediment accumulation, but the subsequent transgression wiped out most early traces. Off muddy paleodeltas natural gas obscures the sediment from acoustic tools. Landward from the lowstand, the regressive unconformity was mostly eroded by the subsequent transgression. The transgressive unconformity is widely seen offshore from the lowstand to the coast. Immediately above it one commonly finds *in situ* shellfish and wood fragments that have provided many dates for the local sl record. Sea level rose rapidly from lowstand, passing over glacial landforms with minimal erosion since there was little time or sediment freed up to construct new coastal landforms. The slowstand interval between 11 and 8 ka and 15-25 m depth, is where most paleo-landscapes are found. The slow rise of sl eroded glacial landforms but provided time for large amounts of sediment to accumulate. We have cored an intact salt marsh from 22 m depth and recognized lake basins, terrestrial wetlands and intertidal shellfish *in situ* with associated human artifacts between 15-22 m. Potential lakes were recognized as basins with a connection to the sea, but all cores in these locations lacked lake sediment presumably due to erosion as they drowned. A rapid rise in sl after this preserved this record well. Since 5 ka, slow sl rise has allowed marshes and barrier beaches to grow, and excellent marsh peats are cored off all large beaches, but no artifacts were recovered.

Visualising a unique marine cultural '*terra incognita*', James Price Point, southern Kimberley

Ingrid Ward¹, Piers Larcombe^{2,1}, Thomas Whitley³

¹University of Western Australia, Perth, Australia. ²RPS Metocean, Perth, Australia. ³Sonoma University, California, United States Minor Outlying Islands

Abstract

The ancient landscapes of Australia's NW shelf that were drowned by Post-Glacial sea-level rise represent an unexplored frontier – an archaeological *terra incognita* – home to thousands of years of past Australian lives, culture and memory. At James Price Point, in the southern Kimberley region, high-resolution bathymetric imagery reveals a series of astonishingly well-preserved drowned shoreline sequences at depths of ~15 m and ~8 m, with relief of up to 5 m above the surrounding seabed (Figure 1). These linear palaeoshorelines likely date to the early Holocene (last ~9000 years) and border a now-infilled palaeo-lagoon and associated fossil intertidal flats, and are rich in material able to inform reconstructions of past sea level, salinity, temperature and other environmental information. Further, these geological units have high archaeological potential (Ward et al. 2016), which, coupled with many well-documented archaeological sites at the coast, mean that they probably constitute Australia's best prospect of finding its first fully marine archaeological sites. Supported by oceanographic measurements, we use the 3D visualization tools of Terragen 4.0 (Planetside Software, 2017) to develop experimental simulations of shoreline morphology (e.g. <https://www.youtube.com/watch?v=lKqzahMOBrA>) and archaeological site preservation potential through the Holocene, which can be tested through ground-truthing.

Figure 1. Surface topography and nearshore bathymetric image off James Price Point, showing series of parallel N-S lineations of the -15 m and -8 m shorelines (sourced from DSD 2010, Fig.1–8).

Late Quaternary sea-level change and evolution of Belfast Lough, Northern Ireland: new offshore evidence and implications for regional sea-level models.

Ruth Plets¹, S. Louise Callard², Andrew Cooper¹, Joseph Kelley³, Antony Long², Daniel Belknap³, Robin Edwards⁴, Rory Quinn¹, Derek Jackson¹

Abstract

The Irish Sea region has one of the most complex deglacial sea-level histories on earth, with glacio-isostatic adjustment (GIA) models displaying great variability across the region. Field data needed to calibrate these GIA models are often sparse for areas across Britain and Ireland where past sea level was lower than present and where sea-level indicators are now buried in offshore sediments.

This contribution presents the analysis of marine geophysical data, 39 vibrocores and 24 radiocarbon dates acquired in the marine embayment of Belfast Lough (east coast Northern Ireland). Results show a typical sequence of till, glacial marine and Holocene sediments, as well as a distinct Younger Dryas deposit. All data were used to evaluate existing models as well as to develop a new relative sea-level (RSL) model for the region. Our data provide constraints on the direction and timing of RSL change since c. 15ka cal BP. Furthermore, by applying the concept of a 'Depth of Closure', a sea-level position with associated error term has been calculated.

The proposed RSL reconstruction shows two lowstands (max. -40m) at c.13.5 and 11.5ka cal BP. These are both preceded by rapid transgression, in turn followed by a period of RSL stability. This first transgression can temporally be linked to the final stage of meltwater pulse 1A, with the stable sea level coinciding with the Younger Dryas period. The second stillstand is dated to 10.3-11.5ka cal BP. The timings of events and lowstand depths differ from the GIA models but validate some previously published data.

Whilst marine limiting data, such as obtained through this project, are often disregarded by GIA modellers, this presentation will highlight their importance for the construction of ground-truthed RSL reconstructions and the re-evaluation of the eustatic and/or isostatic components used in the regional models.

Drowned barriers, gravel spits and beaches from the southern Namibian shelf: a story of antecedent controls on shoreline preservation

Andrew Green¹, Lynette Kirkpatrick^{1,2}, Nombuso Maduna¹

¹University of KwaZulu-Natal, Durban, South Africa. ²Namdeb Diamond Corporation (Pty) Ltd, Oranjemund, Namibia

Abstract

Multiple drowned gravel spits and beaches are preserved along the southern Namibian coastline. A dense grid of seismic profiles reveals an ~ 300 km long, buried set of ridge features at elevations of -70 to -50 m. Ridges may be compound or simple, with internal geometries that vary from bimodal, onshore-offshore dipping planar strata, to steeply seaward dipping strata. These are identical to the gravel barrier spits and beaches of the contemporary coast. The submerged shoreline features vary in along-strike character, with barrier spits prevalent to the south in a palaeo-embayment, merging into beaches outside of the sheltered zone. With increasing drift alignment, the shorelines increase in volume. The largest barriers are found in the antecedent shelter of old embayments and low points formed by incised valleys. These form large (> 15 m thick) features with complex internal structures and evidence of partial cementation in the form of dislocated blocks. The formation of these features is ascribed to the development of planform equilibrium shorelines during a still stand, fed by strong littoral sediment supply. Given their depth co-occurrence with similar features on the SE African margin, we consider these to have formed during a still stand at the same time. Their preservation is linked to antecedent conditioning, together with rapid increases in the rate of sea level rise associated with melt water pulse 1B.

Abstract

Stratigraphic records provided by offshore surveys have greatly improved understanding about dynamic evolution of sedimentary system associated with the Quaternary sea-level changes. There are many studies about sediments on coastal shelves especially those of the Late Pleistocene to the Holocene based on high-resolution seismic surveys, whereas fewer studies about succession on shelf slopes. At active marginal zones, shelves tend to be narrow and sediments should be efficiently delivered to offshore through the narrow shelves during the lowstand stages. Therefore, sediments of the lowstand stages could be archived as shelf slope sediment at active marginal zones. As a part of offshore active-fault survey, we conducted multi-channel seismic survey with a small watergun (15 in³) source to obtain high-resolution profiles including shelf slopes at off the Yufutsu Plain, Hokkaido, Japan. The study area develops narrow shelf of 25 km wide and 130 m depth. The shelf slope is 500 m height and basin floor is > 600 m depth. The seismic profiles figured out sedimentary structure up to 500 m under sea-bottom surface. At the shelf slope and basin floor, we can recognize at least 4 sedimentary packages based on seismic facies. The sedimentary packages are bounded by downlap surfaces, and downlap structures are clearly formed at the toes of shelf slopes. Repetition of downlapping sedimentation suggest cyclic change of sedimentary flux on the shelf slope and basin floor. Sea-level changes in the late Quaternary should have strongly controlled coast-line migration and sedimentary budget stored on the shelf. Therefore, the regression of coast line would increase sedimentary flux outside of the shelf and the transgression would starve the sedimentary flux. Consequently, downlapping sedimentary bodies should be sediments of falling and lowstand stages, and downlap surfaces should be formed during transgressive and highstand stages. Based on the assumption, the sedimentary packages are correlated with sequence of MIS 5-2, MIS 7-6 MIS 9-8, MIS 11-10, in descending order. This interpretation is concordant with chronology of existing marine geological map (Tuzino and Inoue, 2012). Our result demonstrated that lowstand sequences since the Middle Pleistocene were successively stacked on shelf slope of active marginal zone. Sequence boundaries recognized in high-resolution seismic profiles can be used as chronological scale of 100 ka order and are also useful especially for evaluations of active-fault activities. Comparison among the lowstand sequences would contribute to verify magnitude and duration of the lowstands since the Middle Pleistocene.

Antecedent topography controls preservation of late Quaternary transgression record and Cliniform geometry: the São Francisco delta (Eastern Brazil)

Adriane Rangel, José Dominguez
Federal University of Bahia, Salvador, Brazil

Abstract

The shallow (<60m) and narrow (<40km) shelf off east-northeast Brazil makes it difficult to investigate the effects of the last eustatic sea-level rise in the development of the Brazilian deltas. In addition, high wave energy results in greater shear stress at the bottom, precluding the development of deltaic cliniforms exhibiting a classical sigmoidal geometry. Notwithstanding, because of very peculiar characteristics, a complete record of the last sea-level rise is present at the wave-dominated São Francisco delta. This delta was built in a topographically low region of the shelf, associated with the head of the homonymous canyon. This resulted in the creation of an additional accommodation space of several tens of meters. This peculiarity, in addition to favoring the development of a thick muddy cliniform, allowed us to investigate the influence of sea level rise on the architecture and stratigraphic evolution of the delta since the LGM. Five isostratigraphic units were identified in shallow seismic records. The lowermost units (U1, U2 and U3) accumulated around the canyon head in an estuarine environment. U1 was possibly drowned by Meltwater Pulse 1A. U2 and U3 accumulated in the subsequent period characterized by decreasing rates in sea-level rise, which culminated in the Younger Dryas period. The top of U3 passes laterally (along strike) to a wave-cut terrace sculpted in the side walls of the bathymetric depression. This terrace is located approximately 60m below present sea level, and marks the shoreline position at the YD. U3 was drowned by MWP1B as indicated by a wedge of sediments that buries its lateral terminations. U4 deposition began after the MWP1B, from 8.8 to 8.3 ka, based on lateral correlation and radiocarbon dating of samples recovered from boreholes drilled at the deltaic plain. U4 was also drowned after the 8.2 ka event, after which the modern day cliniform (U5) started prograding over U4. U5 muddy cliniform has a typical sigmoidal geometry that dips gently (0.4°) towards the ocean. Its thickness does not exceed 40 meters in the most proximal portion of the delta, decreasing progressively offshore, where it reaches just 2 meters. Currently, the cliniform has prograded over half of the shelf, reaching the canyon head. Muddy sigmoidal cliniforms usually develop on extensive low wave-energy shelves. The development of the São Francisco sigmoidal cliniform in a narrow shelf with high wave-energy was favored by the existence of an antecedent bathymetric low, where the modern delta prograded. The present work shows how variations in sea-level rise rates coupled with local antecedent morphology helped in creating a continuous sedimentary record of the Holocene transgression, also allowing the development of the modern sigmoidal deltaic cliniform of the São Francisco river.

O-2092

Dating Younger Dryas icefield retreat in Scotland using glaciolacustrine varves and tephrochronology.

Adrian Palmer¹, Alison MacLeod², John Lowe¹, Ian Matthews¹, Rhia Grant¹

¹Royal Holloway, University of London, Egham, United Kingdom. ²University of Reading, Reading, United Kingdom

Abstract

A major debate has developed concerning the timing of Loch Lomond Readvance (LLR) ice cap retreat in the Scottish Highlands and the forcing mechanisms responsible. Bromley *et al.* (2014) dated organic remains that accumulated in small basins within one of the main centres of ice dispersal (the Rannoch plateau) and proposed a minimum date for deglaciation of this area by ~ 12.2 ka BP. However, Small and Fabel (2016) argue on the basis of CRN dates obtained from boulders located in the same sector of the ice cap that deglaciation was not initiated until $\sim 11.5 \pm 0.6$ ka. The latter view supports the findings of MacLeod *et al.* (2011) and Palmer *et al.* (2010), based on radiocarbon, tephra and varve chronologies obtained from deposits in ice-dammed lake systems at the terminal zones of two ice lobes fed by the icefield, in the Loch Lomond and Glen Roy/Glen Spean catchments. Consequently, for these opposing views to be resolved additional and more stringent chronological information is required.

A key location for establishing the timing and nature of ice cap demise lies north of the Rannoch plateau, within the Glen Spean-Glen Roy catchment. Glaciers fed from mountains at the plateau margins contributed to the ice barrier that dammed the lakes, which temporarily occupied these valleys. Varved deposits accumulated in the lakes and episodes of ice advance and retreat, which led to changes in the lake levels, are reflected in variations in the thickness of the varve layers. Analysis of the varve records provided an initial estimate of the overall duration of the lakes of 515 years, termed the Lochaber Master Varve Chronology (LMVC), the first robust quantification of this time period for the UK (Palmer *et al.*, 2010). Here we will present new data obtained from a network of sites within the Glen Roy basin that, when combined with recent tephrochronological studies, allow the LMVC to be refined and estimates of the precise timing of initial ice retreat in this valley to be revised on an absolute timescale.

These new data provide more robust age estimates supporting the timing of the deglaciation onset in Glen Spean-Glen Roy catchment close to the end of the GS-1 interval, although glacial ice probably persisted into the early Holocene. They also provide insight into the challenges to be met when developing varve chronologies and integrating results with tephrochronology to generate robust absolute chronologies for dating glacier advance and retreat. The evidence, nevertheless, casts doubt on the Bromley *et al.* (2014) hypothesis and provides insight into the response of the LLR ice cap to climatic forcing, which may have been triggered by enhanced atmospheric warming driven by oceanic changes during the latter stages of the GS-1.

Timing the Little Ice Age Advance and Fluctuations of a Glacier in the Eastern Alps - a multi-proxy Lake Sediment Study

Abstract

In order to investigate the variation of glacier extent during the Little Ice Age (LIA) and Holocene in the Eastern Alps, we studied a multi-proxy sediment record from a small high alpine lake spanning over 10 kyr. The lake is located at 2790 m a.s.l. in Southern Tyrol, Italy, in a terrain with active glaciers. Proxies include organic carbon and nitrogen content, dry-weight and wet-density; sediment geochemistry at 1 cm resolution measured on ground dry samples with ED-XRFA, and at 1 mm resolution on core halves with ITRAX-XRF core-scanner; P-wave velocity, gamma density, and magnetic susceptibility measured at 1 mm resolution with a GEOTEK Multi-Sensor Core Logger; biological microfossils. With the Bayesian age-depth modelling software Bacon, we established an age-depth model based on 15 radiocarbon dates using plant macrofossils, and ²¹⁰Pb and ¹³⁷Cs dating of the top sediment layers. Due to turbidites and visible changes in sediment accumulation rate, establishing a robust chronology remained challenging. In the age-depth model we considered turbidites >1 cm thickness and a boundary layer caused by the shift in sediment properties due to glacier reconnection.

While the lake has currently lost its fluvial connection to the local glaciers, the periods of glacier meltwater input are evident in the sediment record. Before 10 000 cal. yr BP the lake first lost its connection to the glaciers; around 9500 ± 500 cal. yrs BP the lake shifted from a turbid to a clear water lake, and sediment layers became very homogenous and dominated by organic sedimentation for the major part of the Holocene. After 1100 ± 220 cal. AD, we observed another clear system shift; distinct changes in sediment organic content, density, turbidites, and geochemical composition separated several periods with glacier meltwater input of variable intensity and frequency and thus marked the onset of the LIA in this region, and the subsequent fluctuations in glacier extent. Around 1880 ± 20 cal. AD the glaciers started to retreat, and by 1950 ± 7 cal. AD the lake again became a clear water lake without direct glacier meltwater inflow, thus indicating a major retreat of the glacier that is currently still ongoing.

Despite highly variable meltwater input and connectivity to the local glaciers, the lake's sediment record itself was not disturbed or repositioned by glacier movements during the LIA. However, during LIA glacial maxima, the catchment area increased almost eightfold. The resulting vast water volume caused lake outbursts recorded in chronicles from a village in the lower valley which was affected by floodings and landslides. The unique position of the lake at the fringe of a glacier during LIA maximum glacier extent makes this lake's sediment a sentinel for glacier fluctuations and climate variations, especially during the Little Ice Age.

Abstract

Steffen Glacier (47°S) is the southernmost outlet glacier of the Northern Patagonian Icefield. Although it has been retreating since the Little Ice Age (LIA), the first aerial images of the glacier in 1944 show a frontal retreat of only 200 m between 1945 and its most likely LIA position approximately 70 years earlier. Since then the glacier has retreated over 5 km, of which 3 km during the last two decades. The ice front retreat resulted in the formation of proglacial Steffen Lake between the glacier and the LIA moraine, through which most of the water and sediment flow before reaching Steffen Fjord via Huemules River. Proglacial lakes are well known to have a filtering (coarse sediments are filtered out) and trapping (decreased downstream sediment yield) effect on the sediment output. Here, we aim to investigate the sedimentary signature of the recent retreat of Steffen Glacier in downstream fjord sediments at exceptionally high temporal resolution. During a field expedition in 2017, four gravity sediment cores were collected along a proximal-to-distal transect in Steffen Fjord. An age-depth model was constructed for the most distal core based on varve thickness and ¹³⁷Cs concentrations, which reveals very high sediment accumulation rates during the last 60 years (2–4 cm/yr). Lithostratigraphic correlations between the four fjord sediment cores based on magnetic susceptibility (MS) and grain-size results indicate that sediment accumulation rates decrease by a factor of two over a distance of 10 km. Results from the different sediment cores demonstrate that sediment accumulation in the fjord increases through time with accelerating glacier retreat, in contrast with the many studies that indicate that the formation of a proglacial lake generally results in a decrease in sediment yield. This implies that, in the case of Steffen Fjord, the increase in sediment delivery due to accelerating loss in ice volume exceeds the sediment trapping effect of the growing proglacial lake. The fjord sediments also show a slight fining-upward accompanied by a decrease of the flood-induced MS, grain-size, and to a lesser extent Zr peaks, most likely due to the increasing filtering effect of the developing proglacial lake. However, our findings show that the filtering effect of the proglacial lake reached a maximum when the lake attained a length of approximately 2 km in 1998. The last 3 km of the glacier retreat during the last 20 years does not seem to have had any additional impact on downstream sedimentation. This study confirms that proglacial lakes do have a sediment filtering and trapping effect but that (1) the trapping effect can be outpaced by the accelerating glacier retreat and (2) the filtering effect becomes stable once the lake attains a certain critical size.

Abstract

Presently a strong correlation exists between southern westerly wind (SWW) strength and precipitation west of the Patagonian Andes ($r=0.8$; Garreaud *et al.*, 2013). As a result glacier chronologies west of the Andean divide are capable of recording local to hemispheric palaeoclimatic shifts during the late Quaternary better than their eastern counterparts. The aim of the #ChileFjords18 project is to develop a detailed understanding of glacier expansion and manner of recession of intermittently marine terminating outlet glaciers to unravel the interplay between glaciological, climatic and oceanographic forcing during the last glacial-deglacial phase in south-western Patagonia. To reach this aim, we conducted a field-expedition in November 2018, where we combined geomorphic mapping techniques (terrestrial and marine) and geochronological methods to constrain glacier geometry changes of two major outlet glaciers (Icy and Xaltegua) between the Gran Campo Nevado and Pacific Ocean (52°S, 72-74°W). High-resolution terrestrial and marine geomorphic mapping is integrated to understand sub- and marginal glacier dynamics. Cosmogenic surface exposure dating of bedrock and erratics is used to establish vertical and horizontal retreat rates of the former Icy and Xaltegua outlet glaciers. Given the hyper-humid setting in the south-western fjords of Chile (Kilian & Lamy, 2012), we also apply a novel approach to determine sample-specific weathering rates by combining cosmogenic and optically stimulated luminescence techniques (Sohbati *et al.*, 2012; Lehmann *et al.*, 2018). The latter is relevant to assess impact of weathering rates on final cosmogenic surface exposure ages. By using a multi-method approach we hope to provide high-resolution empirical data for integration and testing of regional to global glacier-climate models spanning the last glacier termination.

³⁶Cl exposure-age chronology of Late Pleistocene glaciations on Mount Tymphi, Pindus Mountains, northwest Greece

James Allard¹, Philip Hughes¹, Jamie Woodward¹, David Fink², Krista Simon², Klaus Wilcken²

¹The University of Manchester, Manchester, United Kingdom. ²Australian Nuclear Science and Technology Organisation, Sydney, Australia

Abstract

The mountains of Greece and the wider Balkans were glaciated during the Pleistocene. The most extensive glaciations occurred during the Middle Pleistocene when large ice caps and glaciers formed in several ranges including the Dinaric Alps and the Pindus Mountains. The Late Pleistocene in the Balkans, however, was characterised by smaller ice masses with glaciers restricted to the highest mountains. Nevertheless, these glaciers were important in shaping much of the high mountain landscapes that we see today and they supplied many rivers with outwash sediments. Here we present preliminary results from ³⁶Cl terrestrial cosmogenic nuclide analyses. From samples collected in summer 2017, we have calculated exposure ages from moraine boulders and glaciated bedrock in the uppermost valleys and cirques of Mount Tymphi massif (2497 m) in northwest Greece. We address both a significant geographical gap in Mediterranean glacial chronologies and the temporal gap in the glacial history of this region by targeting the previously undated Late Pleistocene glacial record. Coupled with published U-series ages from lower elevation moraines, this is the first glacial chronology in the east-central Mediterranean based on multiple dating methods.

On the southwest side of the massif, 18 exposure ages obtained from 3 moraines in the cirque and mouth of the Laccos Megalon Litharion valley and the mouth of the western cirque of Tsiumako (2155 m), indicate moraine formation between 1700 m and 2050 m a.s.l. during the Late Pleistocene. This complements previous U-series ages obtained from secondary calcites in glacial sediments below 1700 m (and elsewhere in the Balkans), which demonstrate more extensive glaciations dating to the Middle Pleistocene. At ~1430 m a.s.l. in the Laccos cirque on the northeast side of the massif, 6 exposure ages (5 boulders, 1 bedrock) from a pair of end moraines represent the first dates from this side of Mount Tymphi. They suggest small cirque glaciers persisted until at least the end of the Late Pleistocene, facilitated by avalanching snow and shading from the cliffs of Goura (2467 m). Understanding where, when and why glaciers reached their maxima during the last glacial cycle is not only important for understanding the dynamics of the glacial climate in this region, but also for the timing of sediment and meltwater delivery to river systems; the dynamics of Mediterranean refugia; and has implications for understanding the environmental context of nearby Middle and Upper Palaeolithic archaeological records.

Rapid retreat of the western Laurentide Ice Sheet driven by Bølling-Allerød warming

Sophie Norris¹, Martin Margold², Duane Froese¹

¹University of Alberta, Edmonton, Canada. ²Charles University, Prague, Czech Republic

Abstract

The last deglaciation of the Laurentide Ice Sheet (LIS) dominated Late Pleistocene sea level rise and its retreat serves as an analogue for understanding the dynamics of modern ice sheet change. Accurate reconstruction of the timing and mechanisms of LIS retreat are important to our understanding of the sensitivity of ice sheets to climate forcings. Within western Canada, knowledge of Laurentide Ice Sheet deglaciation is also an important constraint on the migration of flora and fauna (including early humans) between Beringia and the region south of the North American ice sheets. Furthermore, ice sheet configuration also controls the evolution of large glacial lakes and the development of meltwater drainage routes to the Arctic Ocean. Despite its importance, much of the ice sheet retreat history of the southwestern LIS is still poorly constrained by minimum limiting ¹⁴C data. Here, we present a database of ¹⁰Be surface exposure ages from glacial erratics spanning southwestern Alberta to northwestern Saskatchewan. We combine these data with regional geomorphic mapping to provide an updated chronology for the retreat of the southwestern LIS. Our dataset suggests that the retreat of the southwestern LIS began at ~14.9 ka BP, concurrent with, or possibly somewhat before the abrupt warming at the onset of the Bølling-Allerød, and retreated >1200 km to its Younger Dryas position in ~2000 years or less. This new chronology implies the southwestern sector of the LIS was highly dynamic, retreating earlier and at an accelerated rate than portrayed in radiocarbon derived deglaciation models.

¹Bates College, Lewiston, USA. ²Dartmouth College, Hanover, USA. ³Brown University, Providence, USA. ⁴Victoria University of Wellington, Wellington, New Zealand. ⁵Makerere University, Kampala, Uganda. ⁶Rice University, Houston, USA

Abstract

Mountain glaciers and their moraine records are vital to interpreting the timing and magnitude of past climate changes. Equilibrium line altitude (ELA) reconstructions, however, typically relate to moraines with no or poor age control, and the interpreted changes in climate usually focus on temperature without accounting for precipitation. Here, we use a 2-D ice-flow and mass-balance model to simulate continuous glacier extents and ELAs in the Rwenzori Mountains in East Africa since 31,000 years ago (31 ka), including the Last Glacial Maximum (LGM), Late Glacial period, and the Holocene Epoch. The model uses branched glycerol dialkyl glycerol tetraether (brGDGT) temperature reconstructions from alpine lakes on Mt. Kenya, and the LGM precipitation change is set to -10 and +30% from modern conditions in separate runs. Our results show strong agreement between the brGDGT temperature reconstructions, the timing and magnitude of modeled glacier extents, and mapped and dated moraines in the Rwenzori. Rwenzori alpine regions require a $>6^{\circ}\text{C}$ cooling with a -10% precipitation change to simulate glaciers that reach moraines dated to the LGM.

The earliest Acheulean-Middle Stone Age transition highland site in Kenya

Christine Ogola¹, Veronica Waweru², Job Kibii¹

¹National Museums of Kenya, Nairobi, Kenya. ²Yale University, New Haven, USA

Abstract

The human family tree likely dates back to ~7million years ago. With the exception of our own species *Homo sapiens*, many hominins have appeared and gone extinct. There is great interest in when *H. sapiens* first appeared, the manner of this speciation, and the diversity of behavioral and technological adaptations at the dawn of our species. The Middle Stone Age (MSA) period is widely acknowledged as the period that provides the behavioral context for *H. sapiens*, whose earliest fossils date to at least 200ka. The MSA is also a watershed of behavior that is considered modern. Few archaeological sites document this transition technologically or with fossil remains of early modern *H. sapiens*. Emerging research documents MSA technology sites, including Yiapan, that predate 300ka suggesting that the appearance of *H. sapiens* is earlier than known or that there existed contemporaneous MSA tools-making variants of archaic *H. sapiens* in the Mid- Pleistocene. The Yiapan site is newly discovered in Mau Narok, Kenya and is one of very few highland sites dating to the Mid- Pleistocene. The site documents archaeological remains that are associated with the appearance of our own species *Homo sapiens*. Preliminary investigations indicate that Yiapan site is stratified and has stone tool assemblages that range from Late Acheulean/Early Middle Stone Age (EMSA), Middle Stone Age (MSA) and the Neolithic. The site therefore potentially represents the first time that stone tools of such antiquity have been reported at such high altitude, and indicate previously undocumented hominin adaptation to highlands in Kenya. Rift Valley basinal sites comprise the bulk of archaeological assemblages known to researchers in Eastern Africa and consequently may result in a skewed understanding of hominin behavioral variability. This paper presents results of preliminary research conducted at this site that has the potential to contribute to the understanding of technological and environmental adaptations of hominins in East Africa at the dawn of our species *H. sapiens*.

Abstract

The Southern Caucasus is a rugged and environmentally diverse landscape characterized by a mosaic of distinct ecological niches and large temperature gradients with strong seasonal fluctuations across different elevations ranging from 400 to more than 5000 masl. This posed major challenges and opportunities for hunter-gatherer populations. Seasonally fluctuating environmental conditions and differential resource availability along topographic gradients most likely prompted Pleistocene hominin groups to adapt through adjusting their mobility strategies. However, the role that relatively higher elevation landscapes played in hunter-gatherer settlement systems during the Late Pleistocene (Middle Palaeolithic [MP]) remains poorly understood.

The MP site of Kalavan 2 (Armenia), on the northern slopes of the Areguni Mountains, is currently the only open-air locality in the Southern Caucasus with a stratified sequence that preserves faunal remains and lithic artifacts in association. The site is situated in the Kura River catchment on the northern slopes of the Areguni Mountains north of Lake Sevan. At 1640 masl on a parched river terrace near the confluence of the Barepat River and one of its tributaries, the site is ideally positioned for testing hypotheses on elevation-dependent seasonal mobility and subsistence strategies over repeated occupations of a single locale. Initial excavations exposed at least four meters of stratified fluvial-alluvial deposits with MP stone artifacts and animal bones. In 2017 – 2018, excavations were resumed at Kalavan 2 by our Armenian – Monrepos (Germany) research group. This lecture presents the initial results of the latest excavations, highlighting chronologically and environmentally contextualized archaeological data that shed light upon Pleistocene hunter-gatherer subsistence, mobility, and land-use behaviors in a higher elevation landscape of the Southern Caucasus.

Late Paleolithic vegetation and climate changes in Yunnan province, SW China

Wei-Ming Wang¹, Ji-Xiao Zhang², Feng Gao³

¹Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China. ²University of Science and Technology of China, Hefei, China. ³Yunnan Provincial Institute of Cultural Relics and Archaeology, Kunming, China

Abstract

During the past decade, many Late Paleolithic sites were excavated in Yunnan Province, SW China, which gives us opportunity to reconstruct vegetation and climate background for the early human beings before the occurrence of agriculture. Case studies are carried out at two sites, including Xiangbidong site and Naminan Site. The Xiangbidong site is located in Hengduan Mountains, the first cave relic found in Jianchuan County. The Naminan Site is located in the west of Luoguo Mountain, Xishuangbanna Dai Autonomous Prefecture.

Pollen study on seven archaeological layers with two different stages at the Xiangbidong Site recovers abundant palynomorphs, indicating a change process of vegetation and climate. It reveals that the Xiangbidong Site during 100-75 Ka BP was under a warm and humid climate condition represented by abundant *Nyssa* and *Pinus* at first, and followed with a short dry period indicated by a distinct occurrence of *Chenopodiaceae*. The warm and humid climate condition mostly recognizable by *Nyssa* and *Fagus* was then resumed again. It is consistent with the climate condition in the last interglacial period (MIS 5). At about 11 Ka BP, *Nyssa* and *Fagus* became the maximum which is accompanied by *Cyclobalanopsis*, representing a much warmer climate condition in the postglacial period.

The Naminan Site is located in a karst cave, and pollen are not well preserved. Instead, rich phytoliths were found from six archaeological layers with six recognizable phytolith zones. According to the warm index and humid index of the phytoliths, it infers that the Naminan Site experienced a process of climate changes with warm and humid at first, and followed by cold and dry, cool and humid, cool and dry, cold and dry, and warm and humid conditions during 23 Ka BP -10 Ka BP, which is more or less comparable with the global changes.

Taking into the account of high woody pollen value on the whole at the Xiangbidong Site, the signal for human activities during the two separated stages was still weak. Meanwhile, both sites show no evidence for cultivated plant in the fossil assemblages, gathering, hunting and fishing are considered as the human being's main approaches for living at that time. Palm-type phytoliths are very rich in most of the phytolith assemblages which might indicate an enhanced human activity at the Naminan Site.

A general exploration of other Late Paleolithic sites in the Yunnan Province is given for future study. This work was supported by National Science Foundation of China (No. 41771219) and the Strategic Priority Research Program of Chinese Academy of Sciences (No. XDB26000000).

Late Pleistocene hunter-gatherer occupation of the high-altitude afro-alpine ecosystem in the Bale Mountains, South Ethiopia

Götz Ossendorf¹, Minassie Girma Tekelemariam¹, Joséphine Lesur², Alexander Groos³, Tobias Bromm⁴, Bruno Glaser⁴, Ralf Vogelsang¹

¹Institute of Prehistoric Archaeology, University of Cologne, Cologne, Germany. ²MNHN / CNRS - UMR 7209 Archaeozoology, Archaeobotany laboratory, Paris, France. ³Institute of Geography, University of Bern, Bern, Switzerland. ⁴Department of Soil Biogeochemistry, Martin-Luther-University Halle-Wittenberg, Halle, Germany

Abstract

Long-held views of high-altitudes as natural ecosystems characterized by late anthropogenic transformation processes have recently been challenged by studies carried out on the world's high plateaus. This is all the more relevant in light of the demanding question where prehistoric populations retreated to, especially during arid intervals, when lowlands may have become uninhabitable.

In this presentation we introduce an interdisciplinary approach for the reconstruction of Quaternary abiotic, biotic and cultural changes in African model highland environments of southern Ethiopia. The Bale Mountains represent the largest afro-alpine ecosystem of the continent. They are characterized by a very high biodiversity including a large number of endemic species and they host relevant archives to reconstruct the coupled landscape and human history. First results of a joint Ethio-European research unit ("The Mountain Exile Hypothesis", funded by the Deutsche Forschungsgemeinschaft) summarized here, comprise archeological, archeozoological, soil biogeochemical and glacial chronological studies and concentrate on the earliest human occupation and persistent use of the available resources.

The Bale Mountains feature the oldest evidence for humans in African high elevations. Late Pleistocene hunter-gatherers must have been very familiar with the then glaciated environment. In immediate vicinity to valley glaciers, high-quality obsidian was regularly and repeatedly extracted from primary outcrops located above 4200 m asl, the highest known occurrences in Ethiopia. Settlement and subsistence activities concentrated on the ice-free areas with access to melt-water. Prehistoric foragers were moreover capable of developing unique subsistence strategies for sustainable and continuous survival and to satisfy the higher caloric demands of living in these altitudes. The associated Middle Stone Age material culture shows the existence of networks to lowlands, but at the same time exhibit the development of distinctive and independent technological traditions.

Bone collagen stable isotope analysis of a Bronze-Age-Site of Liushugou in arid Northwest China and its implication for subsistence strategy

Weimiao Dong

Department of Cultural Heritage and Museology, Fudan University, Shanghai, China. key Laboratory of Western China's Environmental Systems (Ministry of Education), Lanzhou University, Lanzhou, China

Abstract

Liushugou site is located at one of the southern mouths of Eastern Tianshan Mts., Xinjiang, China. Our investigation of Liushugou, a Bronze Age agropastoral community that consist of both semi-sedentary residential space and burial areas (3.5-2.9 cal ka BP), focused on bone carbon and nitrogen stable isotopic analysis of both the human and faunal assemblage. By virtue of macrobotanical result, attempting to understand how these people responded to the harsh environment and thus resource scarcity, and eventually overcame all and made a living in a valley for several centuries. Stable isotopic results revealed that the inhabitants of this site have high animal protein in diet with mean $\delta^{13}\text{C}$ value of $-18.1 \pm 0.4\text{‰}$ and mean $\delta^{15}\text{N}$ value of $13.1 \pm 1.5\text{‰}$ ($n = 46$). Sheep/goats served as their dominating livestock and also the primary food source which produce a mean $\delta^{13}\text{C}$ value of $-17.8 \pm 1.2\text{‰}$ and a mean $\delta^{15}\text{N}$ value of $8.3 \pm 1.7\text{‰}$ ($n = 37$). Cattle was the second favorite in number output a mean $\delta^{13}\text{C}$ value of $-19 \pm 0.6\text{‰}$ and mean $\delta^{15}\text{N}$ value of $8.9 \pm 1.8\text{‰}$ ($n = 11$). Wild animals like boars, deer, antelope, goral and hare were also explored as protein sources (See left). Test flotation result demonstrated that if there was no other cereals, at least barley was grown there, implying they were no pure pastoralists. Comparing the isotopic composition of Liushugou with published data of other sites from this region with result showing right. It's revealed that the food structure can be divided into two clusters, with one likely consumed more C4 food and the other more C3 food, also the former group may have had more animal protein in their diet compared to the later one, besides, the isotopic signal were more diversified in the first cluster. It's highly likely that Liushugou people lived a life far away from their contemporary Tianshanbeilu occupants from Hami Basin, instead they were more like the later ones from north. Basically, the occupants of Liushugou site were pastoralists like their neighbors from north of Tianshan Mts., with high proportion of animal food mainly mutton and chevon intake, and barley as a nutritional supplementary, lived in a primitively structured society. May have been resulted from the harsh environment and consequently source shortage, except for animal breeding near the site and long-distance herding to maximize pasture, hunting to supplement food diversity, swapping goods to increase income, to survive this community could never have been a peace-loving population, drastic competition even killing and cannibalism should have been expected, which explains how the human thoracic vertebrae ended up on the residential floor.

Late Holocene subsistence change in North America's highest residential villages: Alpine archaeobotany in the White Mountains, California, USA

David Rhode¹, Robert Bettinger²

¹Desert Research Institute, Reno, NV, USA. ²University of California at Davis, Davis, CA, USA

Abstract

The White Mountains of eastern California, USA, contain the highest-elevation prehistoric residential occupations known from North America, with villages composed of several house foundations and dense occupational middens ranging from ~3000 to as high as 3850 m. The White Mountains alpine archaeological record documents striking late Holocene shifts in settlement and subsistence patterns, predominantly focused on hunting mammals ranging from ground squirrels to marmots to mountain sheep. Equally striking are shifts in the use of plant foods, the subject of this report. Plant materials from 12 sites were retrieved from sediment samples from firehearth, storage pits and other features, and from more general contexts within the sites. These sites date to four main time periods designated by archaeological phase names: Little Lake (4450-3150 BP), Newberry (3150-1350 BP), Haiwee (1350-650 BP), and Marana (650-100 BP). During the Little Lake and Newberry phases, limited evidence of plant usage incorporated a mix of lowland, montane, and alpine resources, mainly seeds of subalpine pine (*Pinus flexilis*, *P. longaeva*) and goosefoot (*Chenopodium*). During the ensuing Haiwee phase, when residential village occupation began to intensify, the abundance of plant remains increased, and taxonomic diversity also increased substantially. Remains of root crops – bitterroot (*Lewisia pygmaea*), biscuitroot (*Lomatium*) and spikerush (*Eleocharis quinquefolia*) – as well as nuts from the montane pinyon pine (*Pinus monophylla*) and grass seeds became important resources. Montane and alpine plant foods dominate, while valley-based plants diminish in abundance. During the ensuing Marana phase, when residential village occupation became firmly established, plant food use increased once again, dominated almost exclusively by montane rather than alpine crops. The results suggest that when family-based residential village occupation commenced in the White Mountains alpine zone, inhabitants experimented widely with a variety of food-getting strategies, making use of plant foods from several habitats and exploiting both high-cost as well as high-value resources. Once the alpine residential mode became better established and better integrated with other seasonal food-gathering strategies, the roster of plant foods declined in variety, increased dramatically in abundance, and focused heavily on economically most valuable plant foods from nearby montane habitats, rather than from the alpine zone itself.

O-2105

Late holocene glacier and archaeological history of the Miyar Basin, Lahaul Himalaya

Rakesh Saini¹, Milap Chand Sharma²

¹Dr HARISINGH GOUR CENTRAL UNIVERSITY, SAGAR, India. ²JAWAHARLAL NEHRU UNIVERSITY, NEW DELHI, India

Abstract

The glacial-archaeological history of the last millennium is not known in parts of the Himalayas. Various studies made attempt to reconstruct the glacier fluctuations of the period but have a number of limitations. Observation suggests that glacial chronology of the period in the region is largely dominated by relative dating and in areas where the absolute dating has been applied; it has a low frequency of dates. Areas (such as Gangotri and Mount Everest) which have been historically accessible dominate on part of the available glacial chronology of the region. Reconstruction based on the archaeological records in the glacier end moraine complex gives the direct guide to understand the climatic variation, glacier fluctuations and people's survival in the region. We report the glacier archaeological history of the Tharang glacier, Lahaul Himalaya, India which lasts for almost of a Millennium. Three high altitude villages (*Tharang*, *Phundang* and *Patam*) thrived in the end moraine complex of the glacier with around 100 settlements, associated agriculture fields and irrigations systems. Radiocarbon dating suggests that these villages survived in the glacier end moraine complex between 980-1840AD, encompassing the period of the Medieval Warm Period (800-1300) and the peak of the Little Ice Age (1300-1600), elsewhere. Inference based on the chronology of the ruins, geomorphology of the basin and available historical maps and dendrochronological of the region suggests that during the span of these ruins glaciers in the region were constrained even it was the period of the peak of LIA, elsewhere. Glacier could only advance by the late 18th or early 19th century in the region. The advance resulted in 1-2 kilometres length change in all the glaciers of the basin from their present terminus position.

Relevance of high-resolution records for understanding the past and future ecology of tropical ecosystems in a warmer world

Daniele Colombaroli

Royal Holloway University of London, Egham, United Kingdom

Abstract

The history and diversification of tropical ecosystems result from complex interactions between climate, ecological succession and disturbance regimes on multiple time scales ranging from inter-annual to multi-millennial. Regional and global reconstructions of biomass burning suggest that large uncertainties still exist for tropical regions, due to the lack of continuous and spatially-representative records, but also due to the endemically complex nature of climate-vegetation-fire relationships (and relative feedbacks) in the tropical domain. Over the last few decades, multi-proxy and high-resolution, continuous records from extra-tropical regions greatly advanced our understanding of past ecosystem dynamics, the historical legacy of past human impact, and the relevance of past records for biodiversity conservation and ecosystem management under future climate and land use changes. This full potential is yet to be uncovered for most tropical regions. Continuous and well-dated palaeorecords, especially when located at key ecotonal positions or near biogeographical boundaries, can reveal how fire and associated ecological processes mediated climate control on the savanna/forest boundary, the legacy of prehistoric human impact on tropical ecosystems, and the extent to which tropical ecosystems may be adapted (or not) to future changes. Also, continuous records of tropical climate and environmental history at high temporal resolution can be integrated and compared with time series from other natural archives that display seasonal to multi-annual resolution. Recent advancements in stable-isotope research show that tree rings from tropical species may contribute to century-long reconstructions of rainfall variability, or provide spatially detailed disturbance histories and stand-scale dynamics, with annual resolution. Methodological approaches integrating these different temporal scales are relevant for tropical palaeoecology because they can improve existing regional-scale syntheses of climate and ecosystem history (vegetation and fire dynamics) at a greater temporal resolution and precision. Such framework may then inform landscape management aiming at the conservation of endangered tropical tree species, such as the African teak (*Pericopsis elata*) in the Congo Basin.

Coherence from complexity? Maya lowland records of hydroclimate and human impact.

Sarah Metcalfe¹, Adam Bermingham², Mark Brenner³, Jonathan Holmes⁴, Matthew Jones¹, Haydar Martinez Izquierdo¹, Roger Medina Gonzalez⁵, Kees Nooren⁶, Nicholas Primmer¹

¹University of Nottingham, Nottingham, United Kingdom. ²Northumbria University, Newcastle, United Kingdom.

³University of Florida, Gainesville, USA. ⁴University College London, London, United Kingdom. ⁵Universidad Autonoma de Yucatan, Merida, Mexico. ⁶Utrecht University, Utrecht, Netherlands

Abstract

Syntheses of North American/Neotropical palaeoclimates have tended to include only a small fraction of published records from the lowland Maya area (modern Guatemala, Belize and Mexico) due to poor dating control, the relatively short periods covered by some records, or a lack of clarity about the primary driver of the signal contained. The interpretation of climatic records from the Maya lowlands is made more difficult by the complexity of the region's climatology lying between the main zones of influence of the ITCZ and the Mexican (North American) Monsoon, mediated by drivers from the Atlantic (AMO) and Pacific (ENSO). Interactions between climate and human activity have also long been of interest in this region, with ongoing debates about the impact of climate (especially drought) on the sustainability of human occupation and likewise the extent to which human activity caused significant changes in natural ecosystems, resulting in environmental degradation. Studies of different archives and different proxies have tended to provide insights into either hydroclimate (primarily based on $\delta^{18}\text{O}$) or vegetation change (pollen, charcoal), with relatively few adopting a multi-proxy approach that might allow a more robust discrimination of these two elements. Here we present recent results from Lake Tuspan (Guatemala), beach ridges associated with the mouth of the Usmacinta River (Mexico), Cenote Yaal Chac and Laguna Esmeralda (Mexico) which provide continuous records covering up to 8,800 years. Today the sites experience very different rainfall amounts (from > 2000 mm to < 1000 mm yr⁻¹) and represent different hydrological settings. They also cover a range of known intensities of Maya occupation, with Tuspan lying close to a number of major sites, while Esmeralda appears to have been in an area with rather sparse occupation during the Maya period. All sites have been analysed using a variety of proxies which record both regional and local signals. Sedimentological, geochemical, isotopic and diatom data provide records of changes in water balance and periods of catchment disturbance, while charcoal data can be related to both natural fires and deliberate vegetation clearance at different times. Results are broadly consistent with established patterns of NH tropical climate response to insolation forcing during the Holocene, but also reflect variability at shorter timescales (e.g. centennial) which must be related to other drivers. Factors such as sea level change and changes in seasonality also come in to play. Comparison with other records from the lowlands, primarily from other lakes and speleothems, highlight periods of coherence in behaviour, but also illustrate the complexity of individual system response. Different hydroclimatic settings also influence whether wetter or drier conditions are conducive to agricultural intensification and the potential vulnerability of Maya communities to drought.

Developing annual tree-ring chronologies and climate reconstructions from moisture sensitive *Araucariaceae* trees in tropical and subtropical Australia

Heather A Haines¹, Nathan B English², Quan Hua³, Jon M Olley¹, Patricia S Gadd³, Jonathan G Palmer⁴, Justine Kemp¹
¹Griffith University, Brisbane, Australia. ²Central Queensland University, Townsville, Australia. ³Australian Nuclear Sciences and Technology Organisation, Sydney, Australia. ⁴University of New South Wales, Sydney, Australia

Abstract

Many parts of tropical and subtropical Australia lack both annually-resolved long-term instrumental climate data and proxy climate records. This limits our understanding of past climate patterns and impacts. There are however, remnant forest stands where dendroclimatology could be applied to extend the climate record. Early studies into tropical Australian tree species suggested difficulty in dating these records due to the fact they are compromised by numerous ring anomalies. This has led to such species being understudied with little known about their tree growth to climate relationships and paleoclimate potential. Recent research of trees in the *Araucariaceae* family has attempted to address these issues in order to develop annual, chronologically precise, long-term climate reconstructions across tropical and subtropical Australia.

Araucariaceae trees are commonly found across northern and eastern Australia and are longer lived than many other local non-temperate species. They are known to produce growth rings that are mostly annual and their growth appears sensitive to climate, specifically to moisture conditions. Three *Araucariaceae* species, hoop pine (*Araucaria cunninghamii*), bunya pine (*Araucaria bidwillii*) and purple kauri pine (*Agathis atropurpurea*) have been studied at five locations within the rainforests of eastern Queensland. Ring anomalies including false, faint, locally absent, and pinching or wedging rings, were identified. This was done by applying bomb-pulse radiocarbon dating, radiographic analysis, and density pattern assessment to hoop pine trees from subtropical Lamington and D'Aguilar National Parks. Additionally, dendrometers were installed on trees of all three species so that the annual nature of growth could be proven and the climate variables influencing seasonal growth identified. This analysis verified annual growth for all three species and proved that dating can be confirmed using a multi-technique approach. This demonstrates the suitability for dendrochronology in tropical and subtropical Australia to be applied for high-resolution climate reconstruction. Examination of growth-climate relationships indicated that moisture conditions are driving tree growth in these species so long-term reconstructions of rainfall and drought can be established. Following this, a 164-year drought reconstruction for Southeast Queensland was developed using hoop pine trees from the subtropical rainforest of Lamington National Park and a record extending back to 1400 has been developed for tropical Queensland. Additional work is continuing using this approach to further develop a network of long-term Queensland, Australia tree-ring climate records.

DeepCHALLA – a 250,000 year record of hydroclimate from equatorial East Africa using diatom and organic isotope data

Philip Barker¹, Melanie Leng², Heather Moorhouse¹, Jack Lacey², Christian Wolff¹, Maarten Van Daele³, Thijs Van der Meeren³, Christine Lane⁴, Dirk Verschuren³

¹Lancaster University, Lancaster, United Kingdom. ²British Geological Survey, Nottingham, United Kingdom. ³Ghent University, Ghent, Belgium. ⁴Cambridge University, Cambridge, United Kingdom

Abstract

Long-term variability of rainfall in equatorial East Africa is thought to be associated with Hominin evolution and ecology. At the millennial scale, rainfall patterns have been quite well constrained for the last 25,000 years but earlier records are more fragmentary hindering consideration of the role of climate in the evolution of our species. Here, we provide information on past hydrological changes using oxygen and carbon isotopes in fossil diatom frustules ($\delta^{18}\text{O}_{\text{diatom}}$) and sedimentary organic matter ($\delta^{13}\text{C}_{\text{org}}$) from the ~214-metre long ICDP DeepCHALLA sediment record retrieved from Lake Chala ($3^{\circ} 19'S$, $37 42'E$), a freshwater crater lake (92 m deep) situated on the lower eastern flank of Mt. Killimanjaro. Provisional chronologies suggest this record extends to MIS 8, and the consistent laminated structure imply few discontinuities. Lake Chala's hydrology is driven by evaporation exceeding local precipitation and surface inflows, and lake level being maintained by groundwater inflow and outflow. Precipitation and shallow groundwater inputs deliver water with low oxygen isotope ratios to Chala's surface water ($\delta^{18}\text{O}_{\text{lake}}$) where it is subjected to evaporation. Sedimentary $\delta^{18}\text{O}_{\text{diatom}}$ signatures are thus a measure of local insolation and relative humidity, skewed towards the diatom growth season (Southern Hemisphere winter when conditions are dry and windy) over inter-annual timescales. Sedimentary $\delta^{13}\text{C}_{\text{org}}$ signatures are driven by variation in autochthonous productivity and terrestrial inwash. Seasonal and long-term variation in East African rainfall reflects shifts in the latitudinal position of the tropical rain belt linked to the Intertropical Convergence Zone (ITCZ), which migrates meridionally in response to changes in interhemispheric heat distribution. However, the intensity and movement of the ITCZ itself is driven largely by variation in Indian Ocean Sea Surface Temperatures (SSTs), which in turn determine the strength of monsoonal dynamics delivering rainfall to eastern Africa. The diatom-isotope data from Lake Chala reflect major hydroclimate variability in equatorial East Africa through the last glacial cycles, superimposed on a long-term hydrochemical evolution of the lake basin.

The contribution of Lynch's Crater to the history of local, regional and global environmental change

Peter Kershaw¹, Chris Turney², Susan Rule³, Patrick Moss⁴, Nick Branch⁵, Keith Fifield³, Zoe Thomas²

¹Monash University, Melbourne, Australia. ²University of New South Wales, Sydney, Australia. ³Australian National University, Canberra, Australia. ⁴University of Queensland, Brisbane, Australia. ⁵University of Reading, Reading, United Kingdom

Abstract

It is 50 years since the iconic site of Lynch's Crater was 'discovered'. It has provided and continues to provide insights into patterns and causes of environmental change through the latter part of the Quaternary on the volcanic Atherton Tableland and the broader region of tropical north-eastern Australia with implications for the environmental history of the Australian continent and the globe as a whole. In relation to vegetation, the record demonstrated, contrary to a then widespread belief in the stability of tropical rainforest, that lowland tropical rainforest expanded to replace sclerophyll vegetation on the Tableland after the last glacial period and changed progressively in composition since that time. Further back in time the record revealed the importance of a moist rainforest type that was dominant during recent glacial periods but now largely confined to subtropical latitudes, as well as documenting several regional plant extirpations, and the total extinction of a species or even genus - an event rarely recorded during this late Quaternary period. Additionally, the last known record of a tropical swamp forest in Australia was detected in the early Holocene from a combination of pollen and plant macrofossil evidence. Climate variation, operating at various scales, from orbital to millennial, has been identified as exercising a major control over changes in vegetation and associated sediment stratigraphic features with the recognition of southern and northern hemisphere and tropical forcing, as well as some novel and significant interactions between them. However, the cause of the major and sustained transformation of the vegetation with the elimination of the moist rainforest around 40 ka, that was associated with an increase in charcoal, has been the source of continuous debate - was it climate or was it people? An initial explanation that burning by people, on arrival, directly caused the replacement of fire sensitive moist rainforest by fire-adapted sclerophyll vegetation, has been modified by suggesting that, based on recent evidence for a sharp decline in faunal dung fungi at this time, 'overkill' was primarily responsible for megafaunal decline and this resulted in a build up of fuel that led to the burning increase and vegetation change. Those advocating climate as the cause of environmental change at Lynch's Crater and at other sites have failed to demonstrate the unique nature or sustainable impact of this event although evidence for a general drying trend through much of Australia from the mid-Brunhes, may have resulted in an environmental tipping point. There has been a general avoidance of a multiple cause for the 40ka event but a recent examination of interannual variability in climate derived from Lynch's Crater in relation to the pattern of decline in moist rainforest opens the possibility of a dual human/climate explanation.

O-2111

A revised age model and lake-level curve for Lake Naivasha's Late-Holocene sediment record

Thijs Van der Meeren¹, Dirk Verschuren¹, Kathleen Laird², Brian Cumming²

¹Ghent University, Ghent, Belgium. ²Queen's University, Kingston, Canada

Abstract

One of the better-known Late-Holocene climate-proxy records in East Africa is the lake-level reconstruction from Lake Naivasha in Kenya, based on lithostratigraphic interpretation of its sediment record inside Crescent Island Crater (CIC; Verschuren 2001 *Journal of Paleolimnology*). Usually connected to the main basin of Lake Naivasha except during the driest periods, CIC preserved a unique continuous palaeo-environmental archive of a climate-sensitive amplifier lake in the East African Rift (EAR) region, because its deep and wind-sheltered bottom environment limited sediment disturbance and allowed persistence of a remnant salt lake during the most severe Late-Holocene droughts. Adding to this the relatively high sedimentation rates (on average 4 mm/year), the high-resolution CIC record has been favourably exploited for reconstructions of climate history (Verschuren et al. 2000 *Nature*) as well as terrestrial (Lamb et al. 2003 *The Holocene*, Colombaroli et al. 2014 *Global Change Biology*) and aquatic (Mergeay et al. 2011 *Ecology*) ecosystem dynamics in this semi-arid region of the EAR.

Continued interest in the potential of Lake Naivasha's CIC record for environmental reconstruction as well as advances in age modelling have prompted an update and partial revision of the information published almost two decades ago. Concerning core chronology, new computational techniques allow a more robust yet flexible chronological framework, with explicit consideration of changes in sedimentation rate constrained by lithostratigraphic evidence. Especially in the very dynamic depositional environments of fluctuating lakes, this facilitates the construction of age models which incorporate site-specific understanding of the sedimentological context; the CIC record provides a good case study to highlight the advantages of such Bayesian age-depth modeling. Secondly, extension of the diatom-inferred salinity reconstruction which was published by Verschuren et al. (2000) to the lower part of the 1600-yr sediment record created confidence in a more detailed lithostratigraphy-inferred lake-level reconstruction for the period before 1100 cal. yr BP (the part that had been presented originally).

Producing solid palaeoenvironmental reconstructions from tropical continental regions remains challenging, due to the scarcity of natural archives that are demonstrably continuous, can be properly dated, and contain robust climate or ecosystem proxies over sufficiently long time periods. Defects in these aspects are often not explicitly stated or documented in publications; and regional syntheses tend to include also the more ambiguous time series at face value, because stringent selection would leave large geographical data gaps. In this context, the Lake Naivasha record is now more amenable to inclusion in regional and larger-scale palaeodata syntheses, while at the same time our revised data do not substantially affect any major conclusions of previously published work. This study aims to highlight that with respect to future contributions to understanding tropical climate and ecological dynamics, "revisiting the past" may well start in our own drawers.

Savanna in equatorial Borneo during the late Pleistocene

Christopher Wurster¹, Hamdi Rifai², Bin Zhou³, Jordahna Haig¹, Michael Bird¹

¹James Cook University, Cairns, Australia. ²Universitas Negeri Padang, Padang, Indonesia. ³Nanjing University, Nanjing, China

Abstract

Equatorial Southeast Asia is a key region for global climate forcing. Here, the Indo-Pacific Warm Pool (IPWP) is a critical driver of atmospheric convection that plays a dominant role in global atmospheric circulation. However, fluctuating sea-levels during the Pleistocene produced the most drastic land-sea area changes on Earth, with the now-drowned continent of Sundaland being exposed as a contiguous landmass for most of the past 2 million years. How vegetation responded to changes in rainfall that resulted from changing shelf exposure and glacial boundary conditions in Sundaland remains poorly understood. Here we use the stable carbon isotope composition ($\delta^{13}\text{C}$) of bat guano and High Molecular Weight *n*-alkanes, from Saleh Cave in southern Borneo to demonstrate that open vegetation existed during much the Last Glacial Period. This location is at the southern equatorial end of a hypothesized 'savanna corridor' and the results provide the strongest evidence yet for its existence. The corridor operated as a barrier to east-west dispersal of rainforest species, and a conduit for north-south dispersal of savanna species, at times of lowered sea level, explaining many modern biogeographic patterns. The Saleh Cave record also exhibits a strong correspondence with insolation and sea surface temperatures of the IPWP, suggesting a strong sensitivity of vegetation to tropical climate reorganization on glacial/interglacial timeframes.

O-2113

Evolution of the Agulhas leakage to the Atlantic Ocean through the Pliocene and Pleistocene

Erin McClymont¹, Thibaut Caley², Maria Sanchez-Montes¹, Martin West¹, Linda Rossignol², Ian Hall³

¹Durham University, Durham, United Kingdom. ²Université de Bordeaux, Bordeaux, France. ³Cardiff University, Cardiff, United Kingdom

Abstract

The Agulhas leakage is an important contributor to the global thermohaline conveyor system, adding warm and saline subtropical waters from the Indian Ocean to the South-east Atlantic Ocean. It has been demonstrated that during the late Pleistocene there were increases in heat and salt to the Southeast Atlantic Ocean during deglaciations, which have been interpreted as an indication of strengthening Agulhas leakage. In turn, it has been proposed that by reinvigorating the Atlantic Meridional Overturning Circulation, these increases in Agulhas leakage could have been important for the development of interglacial warmth.

However, little is known about the longer-term evolution of Agulhas leakage during the Pliocene and Pleistocene (the last 5.3 Ma). In the Pliocene, the continental ice sheets were smaller in size, and the position and strength of key ocean and atmosphere circulation systems in the South Atlantic region were different. The Pliocene is also characterised by a series of gateway changes which are argued to have affected North Atlantic climate, but the response of the Agulhas leakage system remains unclear. It is also unclear whether the 'early deglaciation' signal is a specific component of the late Pleistocene 100 kyr cycles. Identifying how and when this signal developed could have important implications for understanding the impact of ocean circulation changes on the development of the mid-Pleistocene climate transition (MPT) ~1.2-0.6 Ma, when the period of the glacial-interglacial cycles shifted from ~41 kyr to ~100 kyr.

Here we present initial results from a new Cape Basin site (Site U1479, 35°03.53'S; 17°24.06'E), which was recovered by IODP Expedition 361 in 2016 from the western slope of the Agulhas Bank (Hall et al., 2016). We combine reconstructions of sea surface temperatures (using the alkenone-derived U_{37}^k index) and sea surface salinity (from alkenone δD analysis) with details of planktonic foraminifera assemblages, to identify and understand variability in Agulhas leakage operating across both orbital and longer timescales. There is an overall cooling of ~4°C since the Pliocene, but it is focussed around ~2 Ma and from 1.2 Ma. Orbital scale and longer-term variability in SST, sea surface salinity and Agulhas leakage fauna are also determined, demonstrating that the Agulhas leakage system has evolved across a range of timescales through the Plio-Pleistocene, especially in association with the MPT.

Insolation-triggered millennial-scale glacial climate resonance

Xu Zhang

Lanzhou University, Lanzhou, China. AWI, Bremerhaven, Germany

Abstract

Millennial-scale glacial climate variability, known as Dansgaard-Oeschger events, is a ubiquitous feature during glacial periods of the Pleistocene epoch. To date, changes in the Atlantic Meridional Overturning Circulation (AMOC), especially its bistable behavior, has been commonly suggested to be the mechanism at the heart of the underlying dynamics of these events. However, a coherent triggering mechanism remains elusive. Here I show, by using a comprehensive fully coupled model, that insolation change alone can cause glacial climate resonance, of which simulated periodicity and global responses are in a good agreement with empirical evidence. My results demonstrate that interactions between insolation-induced changes in high-latitudes sea ice cover and low-latitudes hydrological cycle in the North Atlantic – two key processes modulating the AMOC strength – play a critical role on stimulating the millennial-scale oscillations. Specifically, the enhanced sea ice cover and weakened atmospheric moisture export from the subtropical North Atlantic to Pacific, associated with changes in obliquity and precession, respectively, can kick the oscillation from a strong AMOC state under intermediate glacial conditions. The oscillation can be maintained afterwards by the low- and high-latitudes atmosphere-ocean-sea ice feedbacks in the North Atlantic. Additional millennial-scale variability of atmospheric CO₂ (~ 20ppm) appears to modulate the oscillation periodicity – a higher CO₂ level leads to a longer cycle. Altogether, my results for the first time integrate millennial-scale glacial climate variability with Milankovitch theory, providing a coherent framework for systematically understanding the triggering mechanism of abrupt glacial climate changes.

Millennial scale variations in 100-year resolution NW Pacific sea surface temperature over the past four glacial-interglacial cycles

Kyung Eun Lee¹, Steven Clemens², Yoshimi Kubota³, Axel Timmermann⁴, Ann Holbourn⁵

¹Korea Maritime and Ocean University, Busan, Korea, Republic of. ²Brown University, Providence, USA. ³National Museum of Nature and Science, Tsukuba, Japan. ⁴Institute for Basic Science, Busan, Korea, Republic of. ⁵Christian-Albrechts-University, Kiel, Germany

Abstract

To investigate millennial scale variations in sea surface temperature (SST), we reconstructed high-resolution records of alkenone unsaturation index and *Globigerinoides ruber* Mg/Ca ratio and $\delta^{18}\text{O}$ from the northwestern Pacific margin (IODP Site U1429) over the last 400,000 years. Our proxy records have an average resolution of approximately 100 years, constituting the first northwestern Pacific high resolution, continuous SST record spanning the past 400 ka. On orbital scale, *G. ruber* Mg/Ca (summer-biased) and alkenone (annual mean) temperatures are coherent and in phase with one another at the eccentricity (100 ky), obliquity (41 ky), and precession (23 ky) bands; the significant difference between the two is that, compared to Mg/Ca temperature, alkenone temperatures show strong spectral response at the 100 kyr band, typically associated with changes in global ice volume and sea level. In addition, the alkenone temperatures well match the glacial age CO_2 structure, while *G. ruber* Mg/Ca temperatures do not, indicating that CO_2 change appears to be more associated with alkenone temperature than Mg/Ca temperature. The millennial scale variations in the northwestern Pacific SST were identified from both SST anomalies after filtering out the 100, 40, 23 and 19 ka cycles. In general, both SST anomalies tend to covary through the entire period on millennial scale, although Mg/Ca temperatures varied with larger amplitudes compared to alkenone temperatures. Comparison of alkenone SSTs between Site U1429 and the Iberian margin shows that both SSTs match well from a frequency perspective, meanwhile the amplitudes of Iberian margin SST variations were much larger. In addition, comparison to the synthetic record of Greenland climate variations shows that these two records are similar. These observations support that Dansgaard-Oeschger type variations in the surface temperature of the North Pacific, extended to MISs 6, 8 and 10, and they were linked to the Atlantic rapid climate changes.

Assessing the Pleistocene hemispheric climate links through correlating loess, marine and ice-core records

Zhengtang Guo

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

Near continuous loess-soil records in China cover the past 22 million years. Here, we compare various independent climate proxies from the terrestrial, marine and ice-core domains to re-evaluate the regional and global significance of the China loess with special emphases to the Quaternary portion. The results confirm that the intensity of loess deposition in China is closely coupled with the northern high latitude climate from the over-orbital to millennial scales, and that loess accumulation rates (LAR) and loess particle-size reflect many features of the northern high latitude ice conditions. Consequently, correlating the loess and marine records could offer the possibility for addressing the hemispheric climate links. Our loess-marine correlations show that both records are broadly coupled during the Pleistocene. However, numerous decoupled features exist between the two records. Marine oxygen isotope record shows a general trend of increased ice-volume during the Pleistocene. This trend has no clear reflection in the loess LAR and grain-size data. A prominent change at ~ 430 ka, referred to as the Mid-Brunhes Event (MBE), is clearly documented in both marine and EPICA ice records while its reflections in loess are rather ambiguous. Both marine and EPICA data show a cooler-than-average interglacial for the marine-oxygen isotope stage 13 (MIS-13) while a series of terrestrial records show a warm-extreme interglacial for the northern hemisphere. During a number of glacial intervals, such as MIS-16, MIS 14, MIS-12 and MIS-3, interglacial-level of loess grain-size are observed while they have no obvious reflections in the marine and EPICA ice records. Based on a multi-proxy approach, we argue that these decoupled features between the loess and marine records are attributable to the asymmetrical behaviors of the Pleistocene climates between the southern and northern hemispheres.

Increasing Pleistocene permafrost stability and carbon cycle conundrums

Nicole Biller¹, Jeremy Shakun¹, David McGee², Corinne Wong¹, Alberto Reyes³, Ben Hardt², Irit Tal², Derek Ford⁴, Bernard Lauriol⁵

¹Boston College, Chestnut Hill, USA. ²Massachusetts Institute of Technology, Cambridge, USA. ³University of Alberta, Edmonton, Canada. ⁴McMaster University, Hamilton, Canada. ⁵University of Ottawa, Ottawa, Canada

Abstract

Arctic permafrost sequesters a substantial stock of perennially frozen organic carbon that could be released to the atmosphere as methane and carbon dioxide upon thawing. This thaw vulnerability of permafrost organic carbon represents a potentially powerful amplifier of climate change, but little is known about permafrost sensitivity and associated carbon cycling during past intervals of persistent climate warming. Here we reconstruct permafrost history in northwestern Canada during Pleistocene interglacials from 131 uranium-thorium ages on 74 speleothems, cave deposits that only accumulate during intervals of deep ground thaw. We infer that interglacial permafrost thaw was widespread ~0.5-1.5 million years ago, but deep permafrost persisted in much of Arctic and sub-Arctic North America through warm interglacials of the last ~500,000 years, with deep thaw likely limited to sub-Arctic discontinuous permafrost during the Marine Isotope Stage 11 “super-interglacial”. On Pleistocene timescales, interglacial CO₂ concentrations remained within a narrow $\sim 280 \pm 20$ ppm range and were insensitive to differences in the magnitude of interglacial permafrost thaw inferred here. This implies the existence of processes that attenuated the permafrost-carbon feedback during Pleistocene interglacials, including those when the magnitude of inferred permafrost thaw exceeded numerical model projections for extensive ground thaw over the next several centuries.

Abstract

In order to explore past changes in the Mediterranean Outflow Water (MOW) we analyzed the fine sand content in the sediments together with some geochemical proxies and planktic and benthic stable isotopes at IODP site U1389. This site was recovered in the vicinity of the Strait of Gibraltar along the path of the main core of the MOW. The content of fine sand together with Zr/Al ratios were used to investigate the MOW speed variability along the past 500 ky. The MOW speed variability at this site was mainly driven by changes in the density contrast between the Inflow and Outflow, which was, in turn, governed by changes in the Mediterranean heat and freshwater budgets. Events of enhanced freshwater input to the Mediterranean associated to northward shifts of the Intertropical convergence Zone reduced the density contrast at Gibraltar and weakened the MOW at Gibraltar. Weak MOW events were recorded at times of sapropel deposition in the eastern Mediterranean.

At millennial scale, the MOW intensified at times of Greenland stadials and weakened during interstadials. However, during Heinrich stadials typical three-phase events were observed, with a sandy contourite layer at the bottom and top and a phase of weak MOW in the middle of the stadial, coinciding with the arrival of icebergs to the Gulf of Cadiz. For Heinrich stadial 1 this weak MOW event occurred at the time of the massive release of icebergs from the Laurentian ice sheets. However, the inflow of less saline water to the Mediterranean should have increased not decreased the density contrast between the Inflow and Outflow, especially because freshwater discharge to the Mediterranean from the African monsoons was extremely low. We propose different scenarios to explain these weak MOW events in the middle of Heinrich stadials that were certainly triggered by prominent changes in the Mediterranean heat and freshwater budget.

O-2119

Climate impact of orbital forcing from deep times to Quaternary

Gilles Ramstein

LSCE, Gif sur Yvette, France

Abstract

Orbital parameters variations have been accurately computed from Quaternary to Cretaceous (Laskar et al., A&A 2004). For Quaternary, the climatic consequences of orbital forcing have been for long intensively studied using a large hierarchy of models (Berger and Loutre, EPSL, 1992; Paillard, Nature, 1998 and Ganopolski et al. Climate of the Past, 2010). The imprint of climatic consequences of astronomical variations has been documented for deep times in very different contexts than Quaternary. One of the oldest and most amazing illustrations of this imprint is the role of orbital forcing in explaining high resolution sediment records (Svalbard) depicting glacial/lacustrine oscillations occurring at the end of the Marinoan snowball episode (635Ma) in a context of very high CO₂ level (Benn et al., Nature Geoscience, 2015) .

The imprint of so-called Milankovic forcings has also been found for Paleozoic and Mesozoic, such as Devonian (De Vleeschouwer et al, EPSL, 2013) and mid-Cretaceous period (Herbert et al., Nature 1986; Giorgioni et al, Paleoceanography, 2012).

More recently, during the Tortonian period [11-7 Ma], the ultimate shrinkage of a huge epicontinental sea, that extended from Eastern Europe to Western Asia, has been shown to drastically enhance the climate response to orbital changes at the emergence of early hominins (Zhang et al., Nature, 2014).

The huge impact of astronomical forcing during Quaternary leading to glacial/interglacial cycles has been shown to be associated with the long decrease of pCO₂ since Eocene. A first threshold was achieved 34 million years ago corresponding to Antarctica Ice sheet onset (Deconto et al., Nature, 2008; Ladant et al., Paleoceanography, 2014). The second threshold was achieved more than 30Ma later and led to the Greenland glaciation, occurring at the late Pliocene when atmospheric CO₂ reached values low enough to produce first short lasting Greenland ice sheet (Tan et al., EPSL, 2017) before a perennial glaciation (Lunt et al., Nature 2008; Tan et al., Nature Comm. 2018). This permanent glaciation associated with low pCO₂ value favored the onset of Northern hemisphere glacial/interglacial cycles that punctuated Quaternary climate.

This presentation will depict how modeling with sophisticated coupled AOGCMs interacting with ice sheet models are able to simulate the climatic impacts of orbital forcing from deep time to the onset of Quaternary. We will emphasize the very peculiar geological and pCO₂ conditions that explained the periodic oscillations of the last million years.

Assessing anthropogenic impacts on the landscape configuration of coastal areas of Corsica (France) from Early Neolithic to Late Roman times

Matthieu Ghilardi¹, Jordi Revelles², Andrés Curras^{3,4}, Veronica Rossi⁵, Matteo Vacchi⁶, Marta Garcia¹, Kazuyo Tachikawa¹, Edouard Bard¹, Gaël Brkojewitsch⁷

¹CNRS-CEREGE, Aix-en-Provence, France. ²UAB, Barcelona, Spain. ³Consejo Superior de Investigaciones Científicas, Lisbon, Portugal. ⁴Institute of Heritage Sciences, Lisbon, Portugal. ⁵University of Bologna, Bologna, Italy. ⁶University of Exeter, Exeter, United Kingdom. ⁷Pôle archéologie préventive de Metz Métropole, Metz, France

Abstract

We present the first reconstruction of the landscape evolution of the coastal lowlands of the Island of Corsica, in the western Mediterranean, together with the identification of the first human impacts on both vegetational and morphological changes in some of the island's major river mouths. We performed a bio-stratigraphic analysis of a new set of boreholes drilled in saltmarshes and lagoons located in the SE (Bonifacio-Piantarella and Porto Vecchio-San Ciprianu sites), NW (Saint Florent) and in the central-eastern (Aleria-Del Sale) coast of the Island. We reconstructed the paleoenvironmental history of the last eight millennia in these areas, which are amongst the earliest settled areas of Corsica. The laboratory analyses of the borehole cores comprised: i) ostracods, which support and refine facies characterization and the turnover of depositional environments; ii) pollen grains, which enable us to reconstruct the local vegetation history; iii) radiocarbon dating of 20 samples of organic matter, peat, marine and lagoonal shells which provides a robust chronostratigraphic framework for each site; and iv) XRF core scanning of the Saint-Florent core, drilled within a deltaic context, which provides a record of continental sediment detrital input. The principal results highlight the development of a Mediterranean maquis, together with a riparian forest, in the coastal plains of the island since at least early Neolithic times (ca. 5500 cal. BCE). The first signs of human influence appear in SE Corsica around 5450 cal. BCE (Early Neolithic) with the identification of *Cerealia*-type pollen and coprophilous fungi; while in the NW part of the island, the pollen data indicates human impacts on the vegetation since ca. 3300 cal. BC. Archaeological records from the Bonifacio area do not suggest any early agricultural activity. By contrast, in the Saint-Florent area, archaeological finds in the 1980s provided evidence of agricultural practices since ca. 3300 cal. BC (Mid Neolithic times), which is in good agreement with our pollen record. Surprisingly, at all sites there is minimal evidence of agricultural activity during the Roman period. From a paleogeographic perspective, the sedimentological analyses combined with the meiofaunal identifications (ostracods) indicate that major shifts in the shoreline position occurred during key archaeological periods: The first and most significant deltaic progradation occurred around 3500 cal. BC, and it can be related to the sudden decrease in the postglacial sea-level rising rates observed at the Mediterranean Sea. A second phase of major deltaic progradation occurred around 2200 cal. BC in the Aleria-Del Sale and Saint-Florent areas. This date corresponds to the well known 4.2 ka RCC event and also to the shift from the Chalcolithic to the Bronze Age in Corsica. By combining all the proxies, we try to disentangle the climatic and anthropogenic influences on major sediment discharge at the river mouths.

O-2121

The impact of environmental changes during the second half of the Holocene on human subsistence strategies in the Ukrainian steppe

Natalia Gerasimenko

Taras Shevchenko National University of Kyiv, Kyiv, Ukraine

Abstract

The study of pollen and soil successions from 21 archaeological sites (from Chalcolithic to the Iron Age) in different provinces of the Ukrainian steppe has shown drastic environmental changes, which clearly affected material cultures. During the climatic optimum 6.0-5.5 ka BP, forbs dominate mesophytic steppe; broadleaf forests with mesophillous *Carpinus* occupied valleys and gullies, where forest pedogenic processes developed. The settlements occurred on plateaux and in the valleys; the cattle strongly dominated the herds; and *Cerealia* was cultivated in places. The aridification during 5.2-4.8 ka BP lead to a woods reduction (*Carpinus* disappeared), humus accumulation even in the gullies, settlements location mainly near rivers and gullies, and domination either sheep and goats, or horses in the herds of the Late Chalcolithic people. The end of Northgrippian (4.6-4.2 ka BP) was marked by an increase in humidity and a cooling. High floods, the spread of mesophytic steppe and valley woods, dominated by boreal trees, development of forest soils on slopes took place.

The Early Bronze Age settlements existed on plateaux and near rivers, cattle was abundant in the herds, *Cerealia* was cultivated in valleys, and woodworking appeared. The strongest drought occurred at the beginning of Meghalayan (4.2-3.8 ka BP). A dry steppe, dominated by *Artemisia*, spread north, kashtanozems formed in the place of the former chernozems, desiccation fissures and loess-like sediments occurred in the south. Only short-lasting settlements existed there. During the Late Bronze Age (3.5-3.0 ka BP), sedentary settlements existed under humid climate. Woods from broadleaf trees occupied the valleys. In the western and southern steppe, the Sabatynivka farming economy flourished, with dense net of settlements in the areas, which are now too dry for a farming. During the arid phase 2.9-2.7 ka BP, xeric steppe with weak humus accumulation occupied a large part of the modern grassland with well-developed chernozems. The Bilozirka farming culture (the Final Bronze Age) persisted in the lower reaches of rivers, but on steppe plateaux, only temporary camps of cattle breeders occurred.

At 2.6-2.2 ka BP, woods for the last time occupied large areas in valleys. The extensive spread of chernozems to the south also indicates the humid climate of the time, when Greek colonies appeared on the Black Sea shore, the Scythian tribes kept large herds of cattle in the southern steppe, and their tribes in the northern steppe cultivated crops. The very dry phase, with *Artemisia* steppe in the south, took place 2.2-1.6 ka BP, when Scythians were replaced by the successive waves of nomads from the Asiatic steppe. The sedentary Saltiv culture, which existed in the east under the wet climate 1.3-1.0 ka BP, was destroyed by the new waves of nomads during the Medieval Warm Period, which was arid on the steppe.

Ancient water reservoirs and cisterns in the Negev Highlands (Israel): Building a chronology

Andrea Junge¹, Zachary C. Dunseth^{2,3}, Ruth Shahack-Gross³, Israel Finkelstein², Markus Fuchs¹

¹Justus-Liebig-University Giessen, Giessen, Germany. ²Tel Aviv University, Tel Aviv, Israel. ³University of Haifa, Haifa, Israel

Abstract

Ancient open water reservoirs and subterranean cisterns are frequently occurring archaeological installations in drylands. The former type are round open water reservoirs, which were dug into impermeable layers. They may reach 10 m to 12 m in diameter and 4 m to 5 m in depth, and were lined internally with unhewn stones and clay or marl that served as an aquiclude. In comparison, subterranean cisterns are rock-cut, excavated into soft limestone or chalk formations with a capacity up to hundreds of cubic meters.

These installations collect and store water can sustain settlements, agriculture and nomadic pastoralism under dry conditions. Despite the large number of cisterns and reservoirs in the Negev Highlands, they have scarcely been studied systematically.

During precipitation events surface runoff from adjoining slopes erodes and transports sediments, which are then deposited in the reservoirs and cisterns. Therefore, these archaeological installations also serve as sediment traps, representing fluvial processes in their catchments.

Crucial for investigating water harvesting systems and their sediments is the establishment of robust chronologies. Due to the removal of sediments during construction and maintenance, optical stimulated luminescence (OSL) dating proves to be the preferred dating method of these installations, as it enables the determination of the time of construction, utilisation and abandonment of reservoirs and cisterns. Insights into the life cycles of the different installations provide a basis for discussions about their chronology, the circumstance of construction and their purpose.

O-2123

The river culture relationship of the Harappan civilization

Anirban Chatterjee¹, Jyotiranjan S Ray²

¹Presidency University, Kolkata, India. ²Physical Research Laboratory, Ahmedabad, India

Abstract

The Bronze-Age Harappan civilization (5.8-3.5 ka) of the Indian sub-continent is probably the most enigmatic example of pre-historic human-nature connection. How the majority of Harappan settlements developed along the seasonal river Ghaggar at the arid margin of the Indian desert, is a topic of intense debate. The Ghaggar river has been often hypothesized to be the remnant of an ancient perennial channel and compared with the legendary river Saraswati of Indian mythology due to its matching geographical position with the later. However, lack of evidence for uninterrupted flow of the river during the peak of the civilization has made scholars wonder, whether the civilization was riverine to begin with. In the present work we have reconstructed the palaeo-fluvial landscape along the Ghaggar and provided evidence for the existence of a mighty river in the Harappan heartland by studying temporal changes of sediment provenance in the Ghaggar alluvium, along an ~300 km stretch of the basin in the north-western India. This is achieved using ⁴⁰Ar-³⁹Ar ages of detrital muscovites and Sr-Nd isotopic ratios of sediments in fluvial sequences, dated by radiocarbon and luminescence methods. Our results establish that during 80 to 20ka and 9 to 4.5ka, much of the sediments, dominated by coarse-grained sands, originated from the glaciated regions of the Himalaya. In the intervening and subsequent periods, the river had lost its strength becoming seasonal, and deposited recycled finer sediments. The temporal changes in the Harappan settlement dynamics along the Ghaggar river also support the current observations. It is the rejuvenated phase of the river during mid-Holocene (9-4.5ka) that facilitated the development of early Harappan settlements along its banks. These findings endorse the theory of river-culture association.

The collapse of the Terramare culture (Northern Italy): a question of climate change or human overexploitation of natural resources?

Mauro Cremaschi¹, Anna Maria Mercuri², Assunta Florenzano², Eleonora Clò², Eleonora Regattieri³, Iaria Isola⁴, Giovanni Zanchetta³, Filippo Brandolini¹, Guido S. Mariani¹, Andrea Zerboni¹

¹Università degli Studi di Milano, Milano, Italy. ²Università di Modena e Reggio Emilia, Modena, Italy. ³Università di Pisa, Pisa, Italy. ⁴Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy

Abstract

The Terramare civilization developed in the Po Plain of northern Italy between the Middle and the Recent Bronze Ages (XVI–XII cent. BCE). Settlements were banked and moated villages, located in the alluvial plain of the Po River of northern Italy, mostly in present-day Emilia Romagna. The Terramare economy was based upon cereal farming, herding, and metallurgy; moreover, Terramare settlements relied on a well-developed management of water and wood resources and established a wide network of commercial exchange between continental Europe and the Mediterranean region. This civilization lasted for over 500 years, suddenly collapsing at around 1150 years BCE, in a period marked by a great societal upheaval throughout the whole Mediterranean area. The timing and modalities of the collapse of this Bronze Age culture are widely debated, and a combined geoarchaeological and palaeoclimatic investigation – the SUCCESSO-TERRA Project – is shedding new light on this conundrum. We are investigating two main Bronze Age sites in Northern Italy: (i) the Terramara Santa Rosa di Poviglio, and (ii) the San Michele di Valestra site, which is a coeval settlement outside the Terramare territory, but in the adjoining Apennine range. Human occupation at San Michele di Valestra persisted after the Terramare crisis and the site was settled with continuity throughout the whole Bronze Ages, up to the Iron Age. The combined geoarchaeological, palaeoclimatic, and archaeobotanical investigation on different archaeological sites and on independent archives for climatic proxies (offsite cores and speleothems) highlights the existence of both climatic and anthropic critical factors triggering a dramatic shift of the land use of the Terramare civilization, which was mainly based on a radical deforestation and intensive, irrigation-supported agriculture. The overexploitation of natural resources became excessive in the late period of the Terramare trajectory, when also a climatic change occurred. A fresh speleothem record for the same region suggests the occurrence of a short-lived period of climatic instability followed by a marked peak of aridity. The unfavourable concomitance between human overgrazing and climatic-triggered environmental pressure, amplified the on-going societal crisis, likely leading to the breakdown of the Terramare civilization in the turn of a generation.

O-2125

How did Humans Adapt in the Eastern Farming-pastoral zone during the Medieval Warm Period?

Xin Jia

School of Geography, Nanjing Normal University, Nanjing, China

Abstract

With its extremely warm climate, the “medieval warm period” is considered analogous to the climate change humans are likely to face due to future global warming. Thus, the ability of humans to adapt to an extremely warm climate during the medieval period in Eurasia’s farming-pastoral zone has attracted some attention. The warmth of the climate during this period (900-1300 BC) is demonstrated by evidence of bamboo in charcoal remains and phytoliths found in the settlement sites and tomb murals of the Western Liao river basin in Northeast China. This warmth probably promoted agricultural diversification, as the presence of foxtail millet, broomcorn millet, wheat, barley, soybean, hemp, and buckwheat in this region can be seen in plant seeds and phytoliths found in archaeological sites. The bones of deer and birds also provide evidence of hunting, and the practice of animal husbandry is indicated in pig, dog, cattle, ovicaprid, horse and camel bones. Diversity in food structures is also shown in stable isotopes from human and animal bones. Competence in animal husbandry and hunting, and the availability of stable food resources may have contributed to the rise of the Liao people in military prowess and power, and promoted the expansion of Khitan-Liao culture.

Contribution of the modern traveler's accounts (1750-1920) to the geoarchaeology of subsistence strategies and settlement patterns in the Egyptian deserts.

Maël Crépy^{1,2,3}, Alexandre Rabot^{4,3}, Bérangère Redon^{1,3}

¹CNRS - UMR5189 HiSoMA, Lyon, France. ²CNRS - UMR5133 Archéorient, Lyon, France. ³ERC Desert Networks, CNRS UMR5189, Lyon, France. ⁴Université Lumière Lyon 2 - UMR5189 HiSoMA, Lyon, France

Abstract

Egypt is one of the most arid countries in the world with mean annual rainfall ranging from 200mm near the Mediterranean Sea to less than 2mm in the south. The onset of this aridity is dated from around 5000 or 4500 BP. However, even during this arid period, Egypt has been widely occupied along the Nile valley and in the surrounding deserts. Numerous archaeological sites have been excavated, dating from the emergence of the Egyptian central state to the twentieth century, and yielded impressive material and textual data, which has been thoroughly studied by Archaeologists, Papyrologists and Historians. Geoarchaeological study started recently in Egypt, during the 1980's and have been prejudiced by the Egyptian legislation (sample export ban) and the available analytical material which do not allow the use of most of the dating and sedimentological analyses generally applied. It is thus essential to develop new and innovative approaches to produce new results and to fill the gap between geoarchaeology and archaeology and get results despite the practical obstacles.

Without the usual series of analyses applied in geoarchaeology, one of the best ways to gather data is to combine geomorphologic surveys and spatial analysis with the study of travel accounts from the 18th to the beginning of the 20th centuries. This method allowed us to better understand the life conditions and the socio-environmental evolution in the Egyptian part of the Sahara and offers new perspective on the Holocene geoarchaeology of Egypt.

Our communication aims to demonstrate that this method can contribute to one of the main challenges of geoarchaeology in Egypt: to better understand the settlement patterns, subsistence strategies and landscapes mobility since 5 000 BP in the Western desert and in the Eastern desert of Egypt. The first has known a continuous sedentary occupation in some oases linked with terrestrial trade routes and specialized commercial agriculture whereas the sedentary occupation of the latter has been more punctual in time and space and was mainly linked with mining and trading activity, or with harbours on the Red Sea. Nomad populations have also dwelled in these two deserts, probably during the whole period, and maybe since the beginning of the Holocene. The results included in this talk will relate mainly to water management, vegetation cover and sites distribution in the oases of Kharga basin in the Western desert (data from M. Crépy's Ph.D. Thesis) and in the Edfu-Berenice-Qena triangle in the Eastern desert (data from the ERC funded project "Desert Networks", dir. B.Redon).

Peatlands and the Past: When Carbon, Mineral Dust and Climate Meet

Malin E. Kylander^{1,2}, Antonio Martínez Cortizas³, Richard Bindler⁴, Jenny Sjöström^{1,2}, Benedict Reinardy^{5,2}, Adam Booth⁶, Richard Gyllencreutz^{1,2}, Carl-Magnus Mörth^{1,2}

¹Department of Geological Sciences, Stockholm University, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ³Departamento de Edafología y Química Agrícola, Universidad de Santiago de Compostela, Santiago de Compostela, Spain. ⁴Department of Ecology and Environmental Sciences, Umeå University, Umeå, Sweden. ⁵Department of Physical Geography, Stockholm University, Stockholm, Sweden. ⁶School of Earth and Environment, University of Leeds, Leeds, United Kingdom

Abstract

Peatlands in northern regions are an important component of the global biogeochemical carbon cycle where they store a disproportionate amount of the world's soil organic carbon. Ombrotrophic (atmospherically fed) peat bogs are in some cases up to 99% organic and variations in parameters such as C, N and degree of humification can give us information on both carbon stocks and paleoclimatic change. The remaining inorganic fraction can however, also provide important paleoenvironmental information about change occurring both internally (e.g., changes in hydrology, phase transitions) and externally (e.g., effective humidity, mineral dust, pollution) to the peatland.

Store Mosse (the "Great Bog"; N57°13'37", E13°55'17") is a large peatland (77 km²) located in southern Sweden. After deglaciation (ca 14 ka) the region around Store Mosse was covered by an extensive glacial ice lake, Fornbolmen. When this lake eventually drained, its sandy lakebed was eroded by wind, creating a number of aeolian deposits and an ideal substrate for extensive wetland development. In November 2009, a sequence covering the last 9 ka was collected from Store Mosse and analysed for a range of parameters that describe both the organic (C, N, carbohydrates/lignin, carbohydrate/aliphatic, d13C, degree of humification, colour) and inorganic (ash content, elemental concentrations) fractions. By using these in compliment, we identified past shifts in effective humidity and atmospheric mineral dusts.

Perhaps the most distinct feature of the record occurs between 5.2 and 4.2 ka, where a seven-fold increase in net peat accumulation rates occurs. While climatic conditions were wetter during this high peat accumulation event (HPAE), the inorganic geochemistry reveals a distinct change in mineral character, pointing to the addition of phosphate, plagioclase feldspar and less weathered minerals to the bog. This resulted in an increase in P, K and Ca supply to this nutrient poor system, spiking productivity. An HPAE has also been found at another site in the Fornbolmen system, Draftinge Mosse, which is similar in timing, magnitude and dust character change. The source of these dusts is still being investigated but could be linked to (re)activation of local aeolian deposits or unconsolidated glaciogenic materials during the stormier conditions of the time and/or a change in wind direction, which increased additions from a local nutrient (apatite) rich saprolite. In order to establish the importance of the HPAE on broader spatial scales and estimate carbon stocks, we pair our core analyses with Ground Penetrating Radar (GPR). Using this instrumentation we can trace the fen-bog transition and, in some cases, the HPAE across both Store Mosse and Draftinge Mosse. Our work shows the interplay between organic and inorganic fractions in peatlands in stimulating primary production and its impact on carbon cycling.

Millennial-scale interactions between nitrogen, phosphorus and climate in Holocene peatlands

Daniel N. Schillereff¹, J.F. Boyle², E Tipping³, R.C. Chiverrell², J.K. Sjöström⁴, M.E. Kylander⁴, H. Toberman⁵

¹King's College London, London, United Kingdom. ²University of Liverpool, Liverpool, United Kingdom. ³Centre for Ecology and Hydrology, Lancaster, United Kingdom. ⁴Stockholm University, Stockholm, Sweden. ⁵Bangor University, Bangor, United Kingdom

Abstract

Peatlands constitute a globally significant soil carbon sink and an important store for phosphorus and nitrogen accumulation through the Holocene. Meta-analyses of long-term carbon and nitrogen accumulation in global peatlands have shown that certain climatic variables, notably growing season length and evapotranspiration rates, are important drivers of sequestration rates. Less attention has been given to long-term interactions between C, N and P in ombrotrophic peatlands (i.e., those almost exclusively supplied by atmospheric inputs). We have compiled a database of global multi-millennial-scale stoichiometric measurements to explore these long-term dynamics.

Surprisingly few publications on Holocene peat profiles report C, N and P concentrations together ($n = 32$) and even fewer provide chronological and bulk density data that allow mass accumulation rates to be calculated ($n = 17$). Nevertheless, a number of findings can be drawn from this dataset. Firstly, mean Holocene C:N, C:P and N:P stoichiometric ratios show a wide range: 15-40, 500-4800 and 20-70, respectively. Secondly, linear regression on long-term means for individual, independent variables finds surprisingly strong, positive associations between P and N concentrations ($r = 0.67$, $p = 0.0001$) and rates of accumulation ($r > 0.64$, $p = 0.01$). We also find mean annual precipitation (MAP) is positively correlated with N concentration ($r = 0.54$, $p < 0.005$) but exerts a negative influence on the C:N ratio ($r = -0.44$, $p < 0.05$). Applying the multiple regression model of Toberman et al. (2015), developed for global surface peat samples, shows P concentration and MAP can explain 64% of variance in mean Holocene N concentration in global peatlands.

The results point to a dependency of long-term N dynamics on phosphorus and climate, potentially through a direct influence on rates of N fixation. It is plausible that variations in P supply through the Holocene influence rates of long-term burial, although it is difficult to separate the effects of internal cycling in the acrotelm. Enrichment in long-term N relative to carbon content under greater MAP supports the known influence of climatic wetness on rates of peat humification. These findings have implications for global biogeochemical dynamics in peatlands in light of future climate change and amidst growing awareness that agricultural dust represents an anthropogenic pathway for phosphorus deposition. Individual and interactive effects are difficult to quantify at this juncture and require further investigation by the community.

Strong controls by peatland type on Holocene rates of carbon accumulation in the Hudson Bay Lowlands, Northern Ontario, Canada

Sarah A. Finkelstein¹, Maara S. Packalen², Jim McLaughlin²

¹University of Toronto, Toronto, Canada. ²Ontario Ministry of Natural Resources and Forestry, Sault Ste. Marie, Canada

Abstract

The Hudson Bay Lowlands is an extensive boreal peatland in northern, Canada storing ~30 Pg carbon (C). Despite CH₄ emissions from contemporary fens and release of C by slow long-term decay of existing peat, the HBL has likely been a net C sink over the Holocene; the magnitude and even the sign of that sink, however, have varied. Synthesis studies of northern peatland C accumulation suggest strong climatic controls, with the most rapid rates associated with insolation-driven warmer climates of the early/mid-Holocene. The HBL offers a unique opportunity to parse out the role of climate in rates of C burial. Firstly, the HBL is near the centre of the former Laurentide Ice Sheet, thus has experienced rapid uplift over the post-glacial. Thus, a chronosequence of peatlands varying in basal age (from close to 8000 cal yr BP at the southwestern margin to <1000 cal yr BP in coastal areas), allows an evaluation of the relative importance of hydro-climate vs successional processes in driving variability in C dynamics. Further, HBL peatlands are younger than other major peatland complexes in Siberia, Alaska or Western Canada, post-dating insolation maxima by several millennia. Finally, HBL is a heterogeneous landscape spanning numerous peatland types, allowing comparisons between fen, bog and forested peatlands. We present here a comparison of peak values of Holocene C accumulation from several regions within the HBL. Data from >25 peat cores with well constrained chronologies, time series of C accumulation and data on peatland type, corroborate more rapid accumulation rates in the earlier portion of the longest records (7500-5000 cal yr BP). These time periods, however, most often coincide with successional stages characterized by minerotrophic non-*Sphagnum* peat, herbaceous vegetation and higher inferred water table positions. These systems produce more carbon-rich peat (higher overall bulk density and organic C densities) and thus, more C can be buried per unit time. These time periods are often time transgressive, suggesting that vegetation type can override climate in terms of setting local-scale C balance. The role of climate remains difficult to quantify here because of a lack of region-specific paleoclimate records. Available pollen records indicate only subtle changes in Holocene precipitation and temperature, but this reflects in part the low taxonomic diversity of the assemblages and cosmopolitan distributions of major taxa. A lake-derived chironomid records suggests that maximum Holocene temperatures for HBL took place between 7000-5000 cal yr BP with several degrees cooling following 5000 cal yr BP. We conclude that variability in carbon accumulation is controlled by interactions between vegetation type and climate, with fastest rates associated with newly emerged substrates, minerotrophic fen type ecosystems and middle Holocene climates which may have been warmer, particularly between 7000-5000 cal yr BP.

Abstract

The response of Arctic permafrost wetlands - and their large organic carbon store - to climate change is uncertain. Enhanced plant productivity with warming may increase litter accumulation and therefore carbon sink potential, however heightened decomposition could convert these ecosystems from a carbon sink to source. We use a palaeoecological approach to investigate the response to a mid-twentieth century increase in growing degree days above 0°C (GDD₀) in three wetland sites from the Canadian Arctic. These sites cover the main types of Arctic permafrost wetlands and include: an ice-wedge polygon mire, a patchy wetland (valley fen) and a coastal fen. We use plant macrofossil and testate amoeba-based reconstructions in conjunction with radiocarbon dating and analysis of peat physical properties to show differing vegetation, hydrological and carbon accumulation responses to recent warming in each wetland. We observe an increase in wetness, moss diversity and carbon accumulation in the trough of the ice-wedge polygon mire ~AD 2000, likely related to elevated ice-wedge thaw. Contrastingly, the ice-wedge polygon mire raised centre at the same site showed no clear response. In a valley fen, wet and dry-indicator testate amoebae increase concomitantly from ~AD 1980, possibly relating to greater inundation from snowmelt followed by increasing evapotranspiration later in the growing season. This has not thus far negatively impacted carbon accumulation and occurs alongside the presence of generalist hummock mosses. The coastal fen site underwent a shift from sedge to shrub-dominance sometime prior to ~AD 1950, likely linked to warming. The valley and coastal fens underwent a transition from minerogenic to organic-rich wetlands prior to the mid-twentieth century increase in GDD₀. A subsequent shift to moss-dominance in the coastal fen ~AD 2000 may relate to intensive grazing from Arctic geese following a recent explosion in their population numbers. Our findings suggest that wetland type and local-scale processes are key factors influencing the pathways of ecological change in Canadian Arctic wetlands under recent warming and are likely to impact their future carbon sink potential.

Abstract

Atmospheric mineral dust plays a dynamic role in the climate system acting both as a forcing and a feedback mechanism. Despite this, dust is currently poorly represented in Holocene climate models and large regions remain unstudied for past mineral dust deposition (paleodust). To date, the majority of paleodust studies have been conducted on marine sediments or polar ice cores, while terrestrial deposition has been less studied, leaving large regional gaps. In this context ombrotrophic peat bogs are regarded as important terrestrial archives. Scandinavia is currently represented by only one paleodust study, conducted at Store Mosse, southern Sweden (Kylander et al. 2013; 2016; 2018). Here, results from an atmospherically-fed bog (Draftinge Mosse, 57°06'27"N 13°42'54"E) are presented and compared to the nearby Store Mosse (57°13'37"N 13°55'17"E) record.

The sequence has been dated with 17 AMS radiocarbon dates and analysed for botanical composition, bulk density, loss-on-ignition (LOI), and organic chemistry (elemental C, N, and $\delta^{13}\text{C}$). In addition, downcore elemental concentrations were analysed every 3-5 cm by quantitative WD-XRF for major and selected minor elements, as well as by ICP-AES for trace element concentrations. These data are coupled with mineralogical analysis by X-ray diffraction (XRD) analysis to establish the mineral composition throughout the sequence. Based on the concentrations of soil dust elements (e.g. Si, Al, and Ti), several episodes of increased dust deposition are recorded at Draftinge Mosse; c. 5.7, 2.5, 1.8, 1.1 and 0.7 ka BP. Furthermore, a high peat accumulation event (HPAE) is recorded at Draftinge Mosse around 5.5 ka BP with a fourfold increase in peat growth during c. 1000 years. At the same time both the elemental and mineralogical point to a change in the mineral composition of the deposited dust.

These observations are largely consistent with the previous study from the region, but with a distinct mineral composition deposited at Draftinge Mosse during the HPAE (clays and carbonates). This mineralogy potentially suggests a more distant dust source during this period compared to the rest of the record. In this study we also explore mineral weathering processes as well as secondary mineral precipitation by analysing both peat pore waters and $\delta^{13}\text{C}$ values of carbonate minerals. If the mineral composition is partly authigenic, the Draftinge Mosse data-set could be used to identify elements that needs to be interpreted with caution in peat, in response to internal peat processes potentially affecting their concentration.

Abstract

Palsa mires are a common feature in the Subarctic zone of discontinuous permafrost. In these peatlands, the patchy distribution of frozen soil constrains relief, water regime and vegetation distribution. Palsa mires are very sensitive to climate warming. It has been described how permafrost degradation and increasing decomposition driven by raised temperatures lead to unprecedented changes in Carbon (C) cycling, but less is known about changes in Nitrogen (N) and Phosphorus (P) availability. We measured stoichiometry, stable isotopy of C and N, Hedley P fractionation, N extractions and elemental composition (using ICP-MS) across a thawing gradient in a palsa mire complex at Stordalen (Abisko, 68°N, Sweden). We analyzed three site types in a space-for-time approach (palsa, transition zone and collapsed palsa) at four different depths (5-10, 40-45, 70-75 and 95-100 cm). Available or relatively labile P were higher in surface samples compared to deep peat in the palsa and collapsed sites. The main P fraction of these samples was organic P bound to Iron (Fe) and Aluminum (Al) (NaOH-Porg), which made up between 40 and 70% of total P. The collapsed palsa sites had a lower proportion of P in these fractions and higher organic and inorganic available P, especially in the surface samples. Total P (TP) in deep layers (>50 cm) is dramatically reduced (between 15 and 30%) after permafrost thaw. In contrast, in surface samples (5-10 cm), TP increased by 60%. This suggest that redox and microbial activity shifts brought by hydrology and temperature changes contribute to P, Fe and Al mobilization into other forms. Permafrost thaw also results in lower surface N/P ratios, which is a pivotal constrain of ecosystem productivity, C fixing capacity and vegetation composition. Palsa mires are extremely valuable high-latitude terrestrial records. However, both (1) their origin, including their rapid development towards ombrotrophy because of uplift by ice accretion and (2) the irreversible geochemical effects of collapse and permafrost thaw make them challenging environmental archives. A multidisciplinary approach combining actuo-ecological and palaeo-ecological biological (vegetation, macrofossil and pollen), chemical, and climatic proxies is indispensable to identify the processes associated with palsa uplift and collapse and to interpret palaeo-records of palsas and other mires that may have had permanently frozen peat layers in the past.

Stable isotope records of last millennium changes in the Southern Annular Mode from New Zealand restiad peatlands

Thomas Roland¹, Matthew Amesbury^{1,2}, Daniel Charman¹, Jessica Royles³, Howard Griffiths³, Rewi Newnham⁴, Andrew Rees⁴, Joshua Ratcliffe⁵

¹University of Exeter, Exeter, United Kingdom. ²University of Helsinki, Helsinki, Finland. ³University of Cambridge, Cambridge, United Kingdom. ⁴Victoria University of Wellington, Wellington, New Zealand. ⁵University of Waikato, Hamilton, New Zealand

Abstract

The Southern Annular Mode (SAM), a largely zonally symmetric mode of climate variability describing sea-level pressure anomalies of opposite sign between $\sim 40^{\circ}\text{S}$ and 65°S , drives changes in the strength and latitude of the southern westerly winds (SWW). The SWW are a major influence on temperature and precipitation patterns in the Southern Hemisphere (SH) mid-high latitudes and a significant determinant of the SH component of the earth system, including the strength of the Southern Ocean CO_2 sink. A major shift towards a more positive phase of the SAM, associated with a strengthening and poleward shift of the SWW, has occurred since the 1950s, but its longer-term behaviour remains relatively poorly understood. Developing reliable reconstructions of late-Holocene variability of the SAM is therefore critical to understanding SH climate and ocean dynamics and to testing the ability of climate models to project changes in this mode of variability, but current understanding remains incomplete and contradictory and existing hypotheses need to be tested using new proxies from sensitive locations in other sectors of the Southern Ocean.

Here we present decadal- to centennial-scale resolution carbon and oxygen stable isotope results over the past millennium from a series of ombrotrophic restiad peatlands in New Zealand spanning a 10° latitudinal gradient in moisture source that primarily reflects the variable influence of the SAM and sub-tropical climate modes. In addition to the presence of strong climate gradients, New Zealand is an ideal location for this work because it registers strong correlations between the SAM, temperature and precipitation and modern calibration of our carbon and oxygen stable isotope proxies show that they can be interpreted as proxies for temperature and precipitation moisture source respectively. Palaeoclimate data is supported by robust chronologies based on radiocarbon and lead dating. We discuss results within a hypothesis-driven framework. Specifically, we aim to test the hypotheses that 1) the recent positive trend in the SAM is unprecedented over the past millennium, as suggested from limited proxy data in other sectors of the Southern Ocean, and that 2) there is a persistent relationship between SAM and ENSO over the past millennium that supports the contention that tropical Pacific variability is a key influence on past and future SAM variability.

O-2134

Identifying drivers of engineering resilience in long-term records of Central- and South American forests

Carole Adolf, Kathy J. Willis
University of Oxford, Oxford, United Kingdom

Abstract

Recent research suggests that there are spatial patterns across the globe of ecosystem sensitivity to climatic disturbance. Yet, further research is needed to identify possible drivers behind such patterns and behind ecosystem resilience in general. Here we address two hypotheses regarding possible drivers of engineering resilience, often measured in terms of recovery rate, in tropical forests. First, we hypothesise that faster recovery rates are associated to higher biodiversity, as suggested by the insurance hypothesis, which may in turn be spatially linked to more biodiverse regions. And second, we suggest that location specific abiotic factors, such as soils, geology and microclimate, influence ecosystem recovery rates irrespective of the present vegetation assemblages.

To test these two hypotheses, we selected 31 palaeoecological datasets across Central and South American forest ecosystems, which showed evidence of one or more forest disturbance events. More precisely, we chose sequences in which the mean time resolution between samples during a disturbance event was below 100 years. As disturbances can be either gradual or abrupt (“press and pulse”-disturbances), high-temporal resolution records are especially important to identify disturbance events and to study their effect on ecosystems. We applied a threshold approach to identify disturbances to the forests within each sequence and calculated recovery rates by looking at points of maximum decrease and maximum recovery of arboreal pollen percentages. We then compared recovery rates to pollen richness before the disturbance event to address the first hypothesis. To test the second hypothesis, we used a published global vegetation sensitivity index and compared it to the mean recovery rate of each site. Preliminary results show indeed a positive relationship between diversity and faster recovery rates, highlighting the importance of preserving ecosystem biodiversity to ensure functioning ecosystems. This is especially important as ecosystems are likely to face increased disturbances due to global and climatic changes.

Climate drives stability of vegetation biomes after the last glaciation in North America

Yue Wang, Benjamin Shipley, Daniel Lauer, Rozenn Pineau, Jenny McGuire
Georgia Tech, Atlanta, USA

Abstract

Changing climates, human arrivals, and megafauna extinctions in North America all had the potential to culminate in major shifts in vegetation communities and their stability on the landscape. We seek to determine the relative importance of these potential drivers of vegetation community stability following the last glaciation (20 ka BP to present). Quantifying dynamic responses of vegetation communities to these drivers has important implications for understanding biome resilience and management strategies under projected climate change.

We analyzed vegetation biome stability from two perspectives: biome dynamic stability represented by residence time, and recovery ability after a shift in biome types represented by recovery time. We used 16,043 fossil pollen assemblages from 310 sites in the Neotoma database to reconstruct vegetation community residence time and recovery time across North America during the past 20,000 years after the last glaciation. We use the established modern analog technique for 10 currently present vegetation communities and the biomization method to identify two no-analog communities.

Results suggest that the median residence time of any given biome is 310 years. Forest biomes have a longer residence time of 340 years while shrub/herb biomes have a shorter residence time of 260 years. Median recovery time of any given biome is 130 years, and nearly 84% of vegetation biomes recover back after a shift in the biome types. Residence time decreases during deglaciation (19 – 14.7 ka BP) and remains short until the Pleistocene-Holocene transition (14.7 – 11.7 ka BP), when climate continues to change abruptly, including fluctuating temperature and widespread drought events. Then residence time increases and remains high throughout the stable, warm Holocene, though residence times do decrease temporarily during climate events, including Mid-Holocene Warm Period (7 – 5 ka BP). Residence time displays another decreasing trend towards the present in the late Holocene after 3 ka BP under intensified human influences, especially after European settlement in North America (0.3 ka BP). Recovery time shows an opposite trend compared to residence time, that recovery time is longer in the Pleistocene-Holocene transition when vegetation biomes have shorter residence time, and that recovery time is shorter in the stable warm Holocene when vegetation biomes have longer residence time. Neither residence time nor recovery time demonstrate a latitude gradient across North America, though biomes track glacial retreat during deglaciation. Landscape characteristics do not show strong relationships with either biome residence time or recovery time. There is no obvious change before and after megafauna extinction in residence time and recovery time.

Our work demonstrates that vegetation biomes in North America have short residence times, on the timescale of centuries. Vegetation biome stability is primarily controlled by climate, while top-down biotic influences had little impact on biome stability.

A Virtual Ecology Approach to Assessing the Application of Resilience Indicators to Palaeoecological Data

Quinn Asena¹, George Perry¹, Janet Wilmshurst^{2,1}

¹University of Auckland, Auckland, New Zealand. ²Manaaki Whenua - Landcare Research, Lincoln, New Zealand

Abstract

As contemporary ecosystems experience increasing and novel anthropogenic pressures, there is growing concern over the occurrence of abrupt regime shifts and growing interest in their prediction. Resilience indicators (RIs) have been developed to detect changes in a system's behaviour prior to regime shifts; however, the application of RIs to palaeoecological data, (i.e., sediment-core data), has had mixed success. Palaeoecological data provide insights into past regime shifts, providing opportunities to analyse the dynamics of abrupt changes. However, palaeo-data are subject to several sources of inherent uncertainty that may influence the robustness of RIs applied to them. Uncertainties may be introduced at: (i) an *environmental-level* by, for example sedimentation rates or catchment erosion; (ii) a *sample-level* by, for example, dating frequency or sampling resolution; and (iii) the *analysis-level* by post-sampling data processing such as time-averaging and RI selection.

Uncertainties introduced during sampling and analysis may decrease the robustness of RIs; furthermore, there is a danger that RI detection can become an artefact of data collection and processing themselves. We take a virtual ecology approach to assessing the robustness of RIs applied to palaeoecological data when confronted with process and observational error. We present a framework that draws together a modelling approach from (1), and concepts from (2) to create a synthetic, error-free palaeoecological record (Fig 1A) that mimics a real proxy record. The synthetic record (Fig 1C) emerges from the result of individual species' responses (Fig 1B) to a set of external forces (Fig 1A); in the model, the combined effect of forces acting through the lens of the species' responses (niche) determines the species abundance.

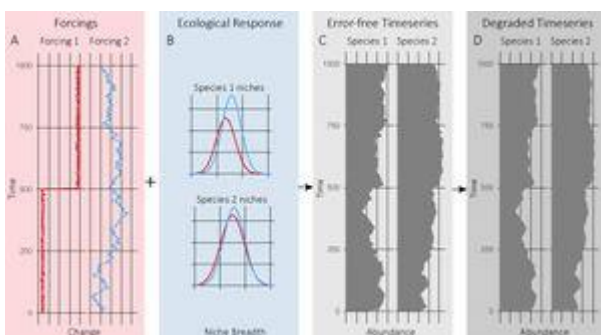

Figure 1: Framework in which an error-free synthetic palaeo-proxy record (C) is simulated as the result of a set of forcing variables (A) acting on individual species' responses (B). *Environmental-level*, *sample-level* and *analysis-level* conditions are then imposed on the data to develop a degraded record (D) (in this case time-averaging with a 20 time-step rolling window).

A set of conditions, such as decreased sampling resolution (*sample-level* uncertainty) and time averaging (*analysis-level* uncertainty) are then imposed on the data and both the error-free and degraded records are analysed for RIs (Fig 2A, B) to determine the effect of uncertainties and stochastic processes on RIs.

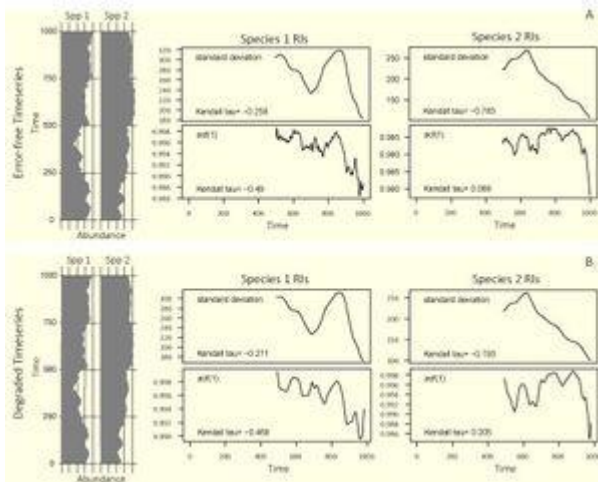

Figure 2: Illustration of RIs (lag-1 autocorrelation and standard deviation) applied to the error-free (A) timeseries and the degraded record (B) showing less variability is detected by RIs on degraded data.

We will be presenting this framework and results from the model assessing RIs.

Quaternary vegetation responses to a range of volcanic disturbances in the Northern Rocky Mountains (USA)

Christopher M Schiller, Mio Alt, Cathy Whitlock
Montana State University, Bozeman, USA

Abstract

Volcanic processes produce a wide range of terrestrial disturbances, and the ecological response depends on the characteristics of the event as well as the nature of prevailing climate and vegetation. Paleoecological records from the Northern Rocky Mountains (USA) provide three examples of past volcanic disturbances with varying responses: (1) On long time scales, Pleistocene rhyolitic lava flows in Yellowstone National Park (YNP) created infertile landscapes that have shaped vegetation evolution and fire regimes for millennia. Pollen data suggest that the well-drained, nutrient-poor soils overlying these flows supported low-diversity grassland in the late-glacial period and *Pinus contorta* forests in the Holocene. These pine forests have persisted for the last 11,000 years with little change, despite variations in climate and fire activity that have altered forest composition in adjacent more-fertile locations. (2) Ash layers from eruptions of Pacific Northwest stratovolcanoes are commonly preserved in lake-sediment records in the Northern Rockies, and pollen records indicate that these events led to short-term vegetation shifts in some settings and long-term changes in others. For example, forested sites register a pulse of *Artemisia* and disturbance-adapted herbaceous pollen types following the deposition of Mazama ash (Crater Lake O, 7680-7580 cal yr BP). *Artemisia* was probably favored by the enhanced soil moisture capacity of ash-rich soils. Vegetation returned to pre-Mazama composition within 100-200 years in places with little ash accumulation. In areas of thick deposition, the ashfall catalyzed unidirectional shifts in plant composition that accelerated the gradual vegetation changes already underway as a result of climate variations. At one site in northern Idaho, for example, *Pseudotsuga/Abies* forest was abruptly replaced by *Pinus contorta* forest following Mazama ashfall (~140 cm thick). Similarly, deposition of Glacier Peak ash (B and G, 13,710-13,410 cal yr BP) at many sites may have facilitated late-glacial forest establishment, reinforcing the influence of rising temperatures at that time. Step-like changes in vegetation have also been described in New Zealand and central Oregon following ash deposition. (3) Local hydrothermal explosions have also resulted in short-lived vegetation changes in volcanic areas. In YNP, large hydrothermal explosions deposited ejecta of up to 1 m in thickness in lake-sediment records. Pollen records indicate short-lived pulses of *Artemisia* following large explosion events in late-glacial and middle-Holocene time. Apparently, the explosion detritus created substrates that were initially suitable for *Artemisia* establishment, but vegetation returned to pre-explosion composition within years to decades as soils developed. The response of vegetation to volcanic disturbances, thus, is highly varied and contextual. The composition of post-disturbance communities and their persistence are influenced by the type and intensity of the volcanic events, the antecedent vegetation, and the climate conditions at the time of the disturbance.

O-2138

Resilience of lake biogeochemistry to boreal wildfires during the late Holocene

Melissa Chipman¹, Feng Sheng Hu²

¹Syracuse University, Syracuse, NY, USA. ²University of Illinois, Urbana, IL, USA

Abstract

Disturbance regimes play a critical role in the structure and function of ecosystems, and climate-driven increases in the frequency and severity of disturbance processes may reduce the ecological resilience of impacted terrestrial and aquatic systems. Anthropogenic climate warming is amplified in flammable boreal forests, which are characterized by strong threshold-like climate-fire relationships at present. Novel fire regimes are expected in many boreal areas under predicted warming scenarios, with the potential for feedbacks with the global climate system related to large boreal carbon stocks. However, it is unclear how biogeochemical cycles in boreal systems will respond to changing fire regimes. Paleoecological records offer a unique perspective on the response and resiliency of environments to climate-driven disturbance. In this study, we leverage well-documented fire history and vegetation records from the Yukon Flats, Alaska, one of the most flammable regions of the boreal biome. We present new geochemical analyses of lake sediment cores to 1) examine the response of boreal aquatic systems to fire over the past 5300 years and 2) constrain the timescale of recovery following disturbance.

We measured carbon and nitrogen content, $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, C:N, and magnetic susceptibility of lake-sediment samples at decadal resolution for 110-year intervals centered on fire events over the past 5300 years. We found no significant difference between values of pre-fire, post-fire, and fire-decade samples for most of the geochemical metrics, (one-way ANOVA, $\alpha=0.05$), suggesting that aquatic systems may be insensitive to fires in lowland boreal areas such as the Yukon Flats, where low topographic gradients impede lateral movement of terrestrial materials following fire. However, sediment $\delta^{15}\text{N}$ values were significantly different based on time relative to fire (pre-fire, fire, post-fire) ($F=4.02$, $p=0.024$, $df=2$). Specifically, $\delta^{15}\text{N}$ values of sediments deposited in the fire decade (3.2 ± 0.3) were significantly higher than pre-fire values (2.4 ± 0.2) ($t=3.76$, $p=0.0005$, $df=48$). However, post-fire $\delta^{15}\text{N}$ values (2.2 ± 0.1) show a return to pre-disturbance conditions within 50 years. We interpret this short-term increase in lake-sediment $\delta^{15}\text{N}$ as a signal of enhanced aquatic productivity and N-cycling associated with high N availability, likely related to enhanced terrestrial nitrification rates and *Alnus*-mediated N-fixation immediately following fire. These results were robust when using a linear mixed-effects model to account for the effect of the long-term increase in $\delta^{15}\text{N}$ values over the past 5300 years, likely related to enhanced terrestrial denitrification rates associated with late-Holocene soil development and paludification. Our study suggests that boreal systems were resilient to fire over the late Holocene. However, we caution that other forested ecosystems are currently displaying evidence of decreased resilience to burning, and that some boreal areas may already be approaching climate-driven thresholds of vegetation structure, carbon cycling, and fire activity.

Is the initial plant cover important for the response of vegetation to climate change?

Thomas Giesecke

University of Utrecht, Utrecht, Netherlands. University of Göttingen, Göttingen, Germany

Abstract

Current climate warming raises concerns that plants will not be able to track their climatic niche. This lag may be due to dispersal limitation and/or the resistance of the established vegetation to new arrivals. However, monitoring periods are too short to evaluate the effects of ecosystem resistance. Climate change at the end of the last ice age provides the best opportunity to study the dynamics of climatically induced vegetation change, which is documented in pollen diagrams from around the world. Here I will use selected pollen diagrams from different European regions to explore, whether the initial vegetation occurring at a site at the end of the Younger Dryas delayed the establishment and influenced the population expansion of newly arriving taxa. Pollen diagrams from the Alps are particularly insightful as sites at different elevations or geomorphological situations were characterized by different vegetation cover at the onset of the Holocene. At low elevations a forest with boreal elements persisted during the Younger Dryas and presented an inertia for the establishment of newly arriving trees during the Early Holocene. As a result, populations of temperate trees started to grow earlier in higher locations. I will compare these examples to sites north and south of the Alps where Early Holocene forest development occurred under different competition regimes. Preliminary results indicate that a dense forest cover may delay the establishment and population increase of newly arriving trees by several hundred years. These insights indicate that land use and disturbance regime may have a strong effect on the dynamics of climate induced vegetation change and the management of protected areas should consider facilitating vegetation change.

Abstract

Disturbances influence ecosystems at various scales and with different intensity, triggering changes in species community composition. Resilience of ecosystems is especially important when ongoing climate changes are considered. *Sphagnum*-dominated peatlands are highly important because changes in peatland functioning from sink to source of carbon can intensify already progressing warming. Here, we investigated 2000 years environmental history of two peatlands located in the lowlands of northern Poland in order to understand their contrasting hydrological response to human and climate induced disturbances. We looked at long-term functional responses of testate amoeba (TA) communities and their trait composition from two small peatlands: disturbed (Linje poor-fen, covering an area of 6 ha) and undisturbed (Jaczno bog, 1 ha). Abrupt changes recorded in Linje mire (landscape opening by human, fires and drainage) triggered rapid changes in TA communities that led to disappearance of mixotrophs and large TA, and caused the establishment of functionally different TA communities. Moreover, moss composition changed completely as an effect of disturbances. In Jaczno bog, however, we recorded almost no changes in TA community composition. The bog maintained close to pristine moss composition and stable high water table due to very low (or no) direct human impact on the mire. Mixotrophs that are typical for healthy bogs were highly abundant throughout the profile up to present times. We show that traits of TA functional trait composition can serve as good indicator of peatlands' state, mirroring environmental changes happening in and around the mire in the long temporal scale.

Glacial curvilineations along the southern fringe of the Scandinavian Ice Sheet: geomorphology and mechanism of formation

Aleksander Adamczyk¹, Wojciech Wysota¹, Jan A. Piotrowski²

¹Nicolaus Copernicus University, Toruń, Poland. ²Aarhus University, Aarhus, Denmark

Abstract

Glacial curvilineations (GCLs) are spectacular landforms recently detected in glaciated landscapes. They were first described in Poland (Lesemann et al. 2010, 2014) as complex sets of parallel, sinuous ridges occupying parts of tunnel valleys and interpreted as erosional features carved in older landscapes by subglacial meltwater flows. Recently, Clark and Livingstone (2018) discovered GCL sets along the southern margin of the Laurentide Ice Sheet and suggested that they were produced by subglacial slope failures in tunnel valleys or near the shores of subglacial lakes.

Our research aimed at detecting GCLs along the southern fringe of the last Scandinavian Ice Sheet in Poland, Lithuania, Germany and Denmark and analysing their geomorphic characteristics using high-resolution LiDAR data. We document around 60 GCL fields grouped into three geomorphic types. (1) *Tunnel channel GCL fields* are the smallest fields with areas of less than 5 km² and containing only a single swarm of maximum 10 ridges. (2) *Tunnel valley GCL fields* have areas between 5 and several dozen km². They consist of up to 50 ridges in several swarms located at one, two or three topographic levels. (3) *Complex GCL fields* consist of two or more tunnel channel or tunnel valley GCL fields. They cover areas of up to several hundred km² and contain the highest number of single GCL ridges.

The biggest GCL field in the study area is the Zbójno GCL field in Poland. It is a complex field consisting of 21 separate GCL swarms with more than 300 individual GCL ridges. We document their geomorphic characteristics together with the characteristics of the inter-ridge troughs including their lengths, widths, depths, average slopes and vertical and horizontal sinuosity.

The geomorphological properties of GCLs such as: (1) occurrence in both wide and narrow tunnel valleys, (2) substantial lengths, (3) parallel, non-intersecting arrangement of ridges and troughs, (4) large horizontal sinuosity, and (5) convex-upward and irregular longitudinal profiles of the inter-ridge troughs (typical for subglacial channels), all yield support to the subglacial meltwater origin of the GCL landscapes.

Subglacial landscape evolution, piecing together the mosaic of subglacial processes in southwestern Hudson Bay

Samuel Kelley^{1,2}, Tyler Hodder³, Michelle Gauthier³, Martin Ross¹, Ying Wang¹

¹University of Waterloo, Waterloo, Canada. ²University College Dublin, Dublin, Ireland. ³Manitoba Geological Survey, Winnipeg, Canada

Abstract

The deposition of sediment and development of landforms within the subglacial environment are the net result of subglacial processes at work beneath an ice sheet. Furthermore, the presence or absence of subglacial sediment, as well as subglacial topography, play an important role in governing the flow of the overriding ice. Thus, the glacial–geomorphic record holds information about the dynamic nature of bed–ice-sheet interaction, sediment availability, and the subglacial environment, which are key boundary conditions in glaciologic studies of paleo-ice-masses. We examine well-preserved glacial deposits in southwestern Hudson Bay, located within a core region of the former Laurentide Ice Sheet, as a record of past subglacial conditions. This region contains a highly fragmented geomorphic ice flow record, with numerous disjunct flowsets and palimpsest terrain, indicative of a variable basal thermal regime consistent with recent modeling experiments. We analyze quantitative till compositional data (matrix geochemistry and clast lithology) using multivariate statistics (principal component analysis and cluster analysis) and compare our results to ice flow indicators, such as striations and clast fabrics, in an effort to elucidate spatial-compositional patterns within the till deposits. While we identify till composition variations that are recorded across the study area, indicative of varying input from the Keewatin and Québec/Labrador dispersal centers of the Laurentide Ice Sheet. Our compositional analysis finds a lack of laterally continuous till sheets, with rare occasions where correlations can be made between multiple sections spanning a few kilometers. The heterogeneity of the till, as well as numerous localities containing of far-traveled exotic lithologies from eastern Hudson Bay and central mainland Nunavut provenance, is indicative of hybrid tills produced by multiple cycles of till entrainment, reworking, and deposition. Thus, we interpret the till stratigraphy to be a vertical continuation of the fragmentary surface record, resulting from a variable subglacial environment driven by ice sheet dynamics related to the waxing and waning influence of the Keewatin and Québec–Labrador dispersal centers. In total, the high degree of inheritance exhibited in this region, via the disjunct landform assemblages, patchy-preservation, and areas of hybridized tills, is indicative of a landscape that underwent a spatially punctuated evolution with periods of local remobilization and modification separated by areas and time periods of quiescence under cold-based, or sluggish, basal conditions. This fragmented geological record suggests large portions of southwestern Hudson Bay experienced limited erosion and sediment advection to the Laurentide Ice Sheet margin during the last glacial stage.

Morphological evidence for rapid, marine ice stream shut down, central Barents Sea

Bartosz Kurjanski¹, Brice Rea¹, Matteo Spagnolo¹, Monica Winsborrow², Karin Andreassen², David Cornwell¹, John Howell¹

¹University of Aberdeen, Aberdeen, United Kingdom. ²The Arctic University of Norway, Tromsø, Norway

Abstract

Marine-based ice streams are responsible for a significant proportion of the ice mass loss of the present-day Greenland Ice Sheet and West Antarctic Ice Sheet (WAIS) but the processes controlling their initiation, evolution and shutdown remain elusive, hindering our understanding of how existing ice masses will respond to predicted future warming. The exposed beds of palaeo-ice streams offer a unique opportunity to study subglacial processes which are largely inaccessible in contemporary settings. We use high resolution multibeam swath bathymetry data from the Barents Sea to map the geomorphology of a palaeo-ice stream bed, located in Olgastretet (Olga Trough), approximately 75 km southeast of Kong Karls Land and 200 km east of central Svalbard. Mapping of the seabed reveals evidence for shut down of a marine-based ice stream, followed by a phase of passive retreat or lift-off of the ice stream allowing for preservation of crevasse-squeeze ridges (CSR). Subsequently, active retreat of the ice margin was re-established and is marked by recessional moraine ridges. Previously, preserved CSRs have been mainly associated with surging land-terminating ice margins, however our work adds to recent observations of CSRs on the beds of marine-based ice streams, implying that they may be more common than previously thought. It also indicates that marine-based ice streams may switch on- and off in a surge-like manner which has important implications for our understanding of ice stream life cycles and the modelling of ice sheets.

New geomorphological observations of changing subglacial conditions in the central part of SIS based on the LiDAR-based mapping

Pertti Sarala^{1,2}, Linnea Kaislo¹, Heta-Maria Korkala¹, Markus Raatikainen¹

¹Oulu Mining School of the University of Oulu, Oulu, Finland. ²Geological Survey of Finland, Rovaniemi, Finland

Abstract

On-going glaciomorphological mapping in Finland based on airborne LiDAR (Light Detection And Ranging) interpretation has revealed new data for the morphological interpretation that can be used in an examination of landscape development and glaciodynamic themes in the glaciated terrain. The mapping process combines the main geological unit (deposit) and new, landsystems-based glacial geomorphological feature information. Recently, the focus has been in the areas of active ice lobes in southern and central Finland, where previously detected large mega-scale glacial features, such as mega flutings, drumlins, end moraine complexes and glacial melt water systems show up in LiDAR-based digital elevation models (DEM) in greater detail than ever before. For mapping, a new definition of the landform categories has been launched (Putkinen et al. 2017).

Here we present new LiDAR-based mapping results (of the project funded by the K.H. Renlund's Foundation) close to the Late Weichselian ice-divide zone, in the central part of the Scandinavian Ice Sheet (SIS) in Finnish Lapland. The area is mostly dominated by the passive-ice, basal till cover without significant indication of ice movement. However, on both sides of the ice divide zone, there are some narrow areas having well-formed drumlin fields and onset areas for active ice lobes; Salla Ice lobe towards SE and Inari Ice Lobe towards NE. Further on south, the glacial morphology is composed mainly of moraine morphologies such as the glacial streamlined lineations of the Kuusamo drumlin field in the eastern part and different hummocky and ribbed moraines in the western part, i.e. at the core of the Kuusamo Ice Lobe. The drumlin field was formed under surging type glacial movement during the Younger Dryas while the core part of the glacier remained cold-based. Glaciofluvial deposits (eskers and delta formations) occur in places representing the last melting phase of SIS. Particularly, ribbed moraines represent the depositional formations formed under subglacial conditions at the transitional zone between the warm and cold based glacier. However, new LiDAR-based mapping showed that large areas in eastern Finnish Lapland are rich in Pulju moraine type ring-ridges and hummocks. In addition, small end moraine ridges occur in close connection to the ring-ridges, which indicate the formation of both moraine types in the marginal zone of glacier during the late phase of last deglaciation. Presence of deep pre-glacial weathered crust and tor formation are the evidence of repeated, prevailing passive and cold-based subglacial condition through the Quaternary.

Quantitative measurements of subglacial processes: a comparison of till and hydrological processes from four soft bedded glaciers.

Jane Hart, Kirk Martinez
University of Southampton, Southampton, United Kingdom

Abstract

We use a range of environmental sensing techniques to understand subglacial processes, including *in situ* multi-sensor probes, web connected dGPS, time lapse cameras, GPR and geophones. We are able to compare and contrast subglacial behaviour from four soft bedded glaciers: Briksdalsbreen (Norway) and Skálafellsjökull, Fjallsjökull and Breiðamerkurjökull (Iceland). We are able to show that deformation occurs all year, and are able to contrast seasonal behaviour. From this we are able to reconstruct the rate and nature of subglacial till deposition. We are also able to reconstruct the different styles of subglacial hydrology which have implications of glacier response to climate change in both modern and Quaternary glaciers

A multiphase model for a soft-sediment striated surface of subglacial origin

Daniel Le Heron¹, Pierre Dietrich², Marie Busfield³

¹University of Vienna, Vienna, Austria. ²University of Johannesburg, Johannesburg, South Africa. ³Aberystwyth University, Aberystwyth, United Kingdom

Abstract

The aim of this paper is to showcase an ancient (Late Palaeozoic) striated surface in South Africa, and discuss its interpretation in the context of a soft-bedded ice sheet during the retreat phase. The quality of glacial geomorphic evidence, preserved in semiarid terrains of Africa, is extremely high, and allows special insight into aspects of an ancient glaciation that has gone to completion. The Dwyka Formation evidences multiple cycles of glacial advance and retreat which include a thick succession of diamictites and heterolithic strata. Painstaking work in the 1970s and 1980s produced regional palaeogeographic reconstructions, among which complex ice flows were identified. Trunk glaciers and / or ice streams appeared on a variety of palaeogeographic maps, many of which highlighted highly complex flow structures within the ice sheet. Nowhere is complex ice flow directions more apparent than in the northern Cape province, which exposes an outstanding soft-sediment striated surface at Oorlogskloof (Fig. 1). Using a combination of field observations, aerial photograph interpretations, and new digital elevation models collected from an Unmanned Aerial Vehicle (UAV), we map the macrostructure of the surface.

Fig. 1. Images of the spectacular Oorlogskloof glacial pavement near Nieuwoutville, Northern Cape Province. Upper image is UOV (drone) imagery from 30 m altitude, gathered in March 2018, with detailed features of the pavement shown in more detail in photographs A-C

beneath.

the Oorlogskloof pavement, revealing the extent of flutes and grooves, with a consistent WNW-ESE orientation. Palaeo-ice flow right to left.

Fig. 2. UAV imagery of

The inventory of structures, which include grain flow lobes at the flanks of flutes (Fig. 1), suggests that the surface was largely generated at the ice-sediment interface, with local evidence for internal deformation and shearing of the sediment pile. Most importantly, the aerial images reveal two features that reveal a composite history to this pavement. Firstly, flutes and grooves to have high length to width ratios, potentially implying rapid ice flow. Secondly, the UAV images reveal a discontinuous network of bulbous ridges which traverse, fold and distort the striations and flutes (Fig. 1). The latter features are interpreted to result from bulldozing beneath a floating ice mass. Collectively, therefore, the assemblage of structures may record two distinct phases in the construction of this spectacular pavement.

³Universidad de Almería, Almería, Spain. ⁴Northumbria University, Newcastle upon Tyne, United Kingdom. ⁵Banaras Hindu University, Varanasi, India. ⁶University of Bern, Bern, Switzerland

Abstract

The Thar Desert (NW India) has numerous evaporative saline playa lakes. Some are still active and others are dry and preserve up to several meters of sedimentary deposits. These deposits feature a variety of evaporite minerals, including the hydrated mineral gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$). Here we present new palaeohydrological records from dry playa lakes in the Thar Desert using the triple oxygen and hydrogen isotopic composition of gypsum hydration water. Assuming no secondary exchange, the isotopic composition of the gypsum hydration water preserves the $\delta^{18}\text{O}$, $\delta^{17}\text{O}$ and δD of palaeolake water at the time of gypsum formation. This method provides a means for understanding the hydrologic balance in a part of the world where it is typically very difficult to obtain palaeoclimate records. Furthermore, the derived ^{17}O -excess and d-excess potentially enable us to quantitatively model past changes in relative humidity, which may be used as an input for vegetation and ecosystem models. Preliminary results from two sections indicate that gypsum deposits from the Thar Desert span the Holocene from ~ 12 to 1 ka BP, with an average resolution of ~ 10 -40 yrs/cm. The gypsum sequences were sampled at 2-cm intervals, producing a record of decadal to centennial resolution. Results show that a source of water maintained active playa lake basins in the central Thar Desert for much of the Holocene, either by enhanced direct precipitation and/or fluvial sources. This period was marked by several intervals of drier climate, including after ~ 4.4 ka BP and sometime within the last ~ 1 ka BP. These records provide a valuable history of the changes in moisture balance and relative humidity in the Thar Desert over a period that included important cultural transformations in the region. These include the appearance of the earliest South Asian Neolithic agricultural societies around ~ 8 ka BP, the full span of the Indus Civilization from ~ 5.3 -3.3 ka BP, and later periods of human occupation and urbanization after 3.0 ka BP.

O-2149

Aeolian activity in the Mu Us dune field in response to climate change during the late Quaternary and at present

Zhiwei Xu¹, Huayu Lu¹, Joseph A. Mason²

¹Nanjing University, Nanjing, China. ²University of Wisconsin Madison, Madison, WI, USA

Abstract

There are vast area over northern China covered by semi-arid dune fields and arid deserts, and this region is one of the largest sources of dust in the world. A significant weakening in dune activity during the recent decades has been observed in the Mu Us, a semiarid dune field in north-central China. Using remote sensing techniques and geomorphic analysis, it is found that this long-term change in dune activity and vegetation restoration is strongly associated with the dramatic decline in wind strength since the 1970s in northern China. The high sensitivity of dune field activity to climate change is also clear during the late Quaternary. A large dataset of dune chronostratigraphies accumulated in recent years clearly indicates that both monsoon precipitation and wind strength play a major role in controlling dune mobility in the Mu Us dune field. At glacial-interglacial time scale, the changes in the dune field were directly responded to ice-volume forced monsoon climate change, that the dune field was active and expanding during the cold and dry glacial period while stabilized during interglacial period. Our study also highlights that the chronology of dune records must be interpreted in light of how geomorphic processes influence dune turn-over and sand preservation.

O-2150

Environmental evolution characteristics and orbital period of arid and semi-arid areas since 3.4 Ma in the Yinchuan Basin

Yanyan Tian, Mingjian Wei
Capital Normal University, Beijing, China

Abstract

At present, the loess and lake sediments are often regarded as the good carrier to reconstruct regional paleo-environment and paleoclimate with high resolution. However, the land still lacks long term, continuous and high-resolution records especially in areas with rare loess and lakes. It is generally known that there are a large number of floodplain deposits on land. Is it possible to use these floodplain sedimentary records to obtain relatively continuous and high-resolution climate records? For this reason, Yinchuan Basin is chosen as research region.

The Yinchuan Basin is located in the arid and semi-arid climate transition zone. The Cenozoic fault basin continued to sink and collect eroded materials from the surrounding mountains and the Tibetan Plateau. The core PL02 (the depth is 720 m), located in the center area of deposition in the Yinchuan Basin, has a thick deposit with a higher resolution and sedimentation rate, making itself practical for the reconstruction of the paleoclimate and the coupling relationship between regional tectonic activities and climate change.

The chronostratigraphic sequence of the core is established by palaeomagnetic dating. The magnetostratigraphic correlation to the geomagnetic polarity timescale shows that the PL02 core recorded the Brunhes, Matuyama, Gauss, Jaramillo, Olduvai, Kaena and Mammoth polarity chron or subchron. The results indicate that the onset of the core PL02 in this section occurred at ~3.4 Ma BP. The analysis of the core established a detailed chronological framework for regional geological research.

In addition, we present a well-dated, high-resolution pollen record for the last 3.4 Ma from the Yinchuan Basin. Variations in the *Artemisia*/Chenopodiaceae (A/C) ratio reveal the changes in moisture conditions in the Yinchuan Basin during glacial-interglacial cycles, as well as a gradual long-term aridification trend which is consistent with progressive global cooling. The *Picea* and *Abies* records reveal two phases of increased representation, at 2.1 and 1.2 Ma, which may indicate phases in the uplift of the northeastern Tibetan Plateau. Meanwhile, spectral analysis of the *Artemisia*/Chenopodiaceae(A/C) ratio shows periods of about 100-kyr and 41-kyr, which may correspond to Milankovitch periods, reflecting eccentricity and obliquity cycles, respectively. Spectral analysis of the percentage of *Picea* and *Abies* shows extra period of about 600-kyr, which is the second discovered 600-kyr period after sedimentary record of Lake Baikal in global. Besides, the high-resolution pollen record also indicates that the short humid and cold climate during Olduvai Subchron.

Thus, we believe that the floodplain deposits on land are a good carrier for studying global climate change.

Abstract

A range of palaeoclimatic and palaeoenvironmental evidence suggests the Asian sub-continent experienced phases of arid-humid alterations on centennial and millennial scales during the Holocene, which were set against a backdrop of insolation-driven weakening of the Asian Monsoon system. These oscillations would have affected fluvial regimes on the plains of northwest India, which were occupied by the Bronze Age Indus Civilisation during the mid-Holocene. It has been suggested that a decline in regional river systems contributed to the decline of the Indus at ~4 ka (e.g. Giosan et al., 2012 (PNAS 109, E1688), Singh A. et al., 2017 (Nature Communications 8, 1617)). In a recent study Orengo and Petrie (2017, Remote Sensing 9, 735) identify a complex channel network on the Sutlej/Yamuna interfluvies, and Durcan et al. (in press, Quaternary International, doi.org/10.1016/j.quaint.2017.10.012) have highlighted complexity in the response of regional geomorphic systems to climatic/environmental change. Therefore, further work is required to understand the spatial and temporal dynamics of regional hydrological systems in order to assess the importance of changing climatic and environmental conditions in the establishment and decline of the Indus Civilisation

This paper presents luminescence dates from palaeochannel sediments and associated dune deposits on the Ghaggar-Hakra floodplain in northwest India, with particular focus on the area around the Indus site of Rakhigarhi. Rakhigarhi is the largest and potentially most important site in northwest India (Singh R.N. et al., 2010, Man and Environment, 35, 37-53), although its relationship to local and regional fluvial systems is unclear. Reconstructing fluvial activity and palaeoenvironmental variability allows a comparison between the documented archaeological record of the Indus Civilisation and an absolute chronology of regional landscape dynamism. Luminescence dating shows that the fluvial network around Rakhigarhi pre-dates the establishment of the site, and that regionally, there is no simple relationship between documented climatic deterioration and changing fluvial activity. This study presents a new reconstruction of palaeoenvironmental change on the Ghaggar-Hakra floodplain, and provides new insights into the fluvial landscapes occupied by the Indus Civilisation during the Holocene.

Abstract

Despite being one of the world's oldest deserts, and the subject of decades of research, evidence of past climate change in the Namib Desert is extremely limited. As such, there is significant debate regarding the nature and drivers of climate change in the low latitude drylands of southwestern Africa. Here we present data from stratified accumulations of rock hyrax urine that provide the first continuous high-resolution terrestrial climate record for the Namib Desert spanning the last 50,000 years. These data, spanning multiple sites, show remarkably coherent variability that can be clearly linked to orbital cycles and the evolution and perturbation of global boundary conditions. Contrary to previous predictions orbital-scale phases of increased summer insolation coincide with periods of increased aridity in the region. Supported by climate model simulations, we link this to variations in atmospheric pressure cells modulated by hemispheric and land-sea temperature gradients. These dynamics induce cycles of hydroclimatic variability driven by upwelling and sea-surface temperature variations, and are in phase with the northern tropics. In contrast, millennial-scale reductions in the strength of Atlantic meridional overturning circulation, such as those occurring during Heinrich stadials, triggered periods of interhemispheric asynchrony due to a progressive build-up of heat in the Southeast Atlantic, and are strongly manifested in the Namib as phases of increased humidity. These findings provide new perspectives on the synoptic-scale dynamics determining multi-millennial and abrupt changes in low latitude climate.

Increased hillslope activity in the hyper-arid core of the Atacama during the Pleistocene – evidence for palaeo-climatic fluctuations?

Simon Matthias May¹, Dominik Brill¹, Alicia Medialdea Utande¹, Dirk Hoffmeister¹, Marie Gröbner¹, Florian Steininger¹, Lennart Meine¹, Ramona Möhrchen², Eva Lehndorff², Olaf Bubenzer³

¹University of Cologne, Institute of Geography, Cologne, Germany. ²Bonn University, Institute of Crop Science and Resource Conservation (INRES), Bonn, Germany. ³Heidelberg University, Institute of Geography, Heidelberg, Germany

Abstract

Hillslopes represent areas of predominant denudation and constitute the transition and trajectory to floodplains; they play a crucial role in understanding the long-term landscape evolution of desert environments. However, although hillslope processes are known to be very slow or even stagnant in (hyper-)arid environments, process mechanisms under the absence of water are poorly understood, and process rates are essentially unknown. Therefore, sub-project C03 of the DFG-funded Collaborative Research Centre 1211 (CRC 1211) “Earth – Evolution at the dry limit” is dedicated to the investigation of hillslope processes in the (hyper-)arid zones of the Atacama Desert. It aims at contributing to a better understanding of controls and processes of hillslope dynamics in the driest parts of the earth on both recent and geological time scales using a variety of different methods. Based on irrigation experiments, different monitoring techniques, geomorphological, stratigraphical, geochronological, sedimentological and geochemical investigations, as well as μ CT scans of sediment cores, this contribution presents detailed insights into the chronostratigraphy of tongue-shaped, 70 m-long and 30 m-wide fine sediment lobes located along a 10-20° steep thrust-related slope east of the Salar Grande (Atacama, Chile). Irrigation experiments were performed in order to gain insights into precipitation thresholds for surface runoff or moisture-driven hillslope dynamics using a simple and portable irrigation device (2 x 5 m plot size). Although artificial rainfall intensities were ~ 46 l/m²/h, infiltration was 100 %, and none of the experiments initiated surface runoff or (detectable) slope material displacements. Nevertheless, we detected increased post-irrigation TOC concentrations in the moist sediment layers, i.e. the uppermost ~ 15 cm of the irrigated sediment. However, we found a distinct stratigraphic pattern with buried palaeo-surfaces and palaeo-biological surface crusts in several trenches, suggesting increased slump-, creep-, or solifluction-like hillslope activity in the past. OSL datings of stratigraphic units point to a late Pleistocene age of the sediment lobes, potentially activated by changes of (fog-induced?) humidity, salt and gypsum shrink and swell processes, or palaeo-seismicity. While a variety of geo-bio-archives document periods of increased precipitation in the Andean parts of the Atacama Desert throughout the quaternary, evidence for contemporaneous paleoclimatic changes from areas disconnected to Andean precipitation fluctuations (i.e., the coastal cordillera) is scarce. In this regard, the investigated landforms potentially represent one of only few sediment records recording paleoclimatic changes in the central desert, independent from Andean rainfall.

Abstract

Climate in arid Central Asia is controlled by the Westerlies and the Siberian High. As precipitation is mainly provided by the Westerlies, even minor changes in their interplay with the Siberian High can lead to major differences in the water budget. Here we present a chironomid-based ecosystem reconstruction from a 141 cm long sediment core from the lake Son Kol, Central Kyrgyz Tian Shan, that covers the last 6000 years. Diatom- and ostracod-based reconstructions suggest that the lake transformed from a closed-basin saline lake to an open freshwater lake (Schwarz et al. 2017). Preservation of these two bioindicators is rather poor in core sections characterized by stronger Westerlies influence. Thus, we used chironomid data to establish a continuous paleoenvironmental record.

We observed two abrupt shifts in the chironomid abundances. Prior to 5050 cal. yr BP, the salinity indicators *Psectrocladius sordidellus*-type and *Cricotopus intersectus*-type formed the major part of the chironomid assemblages. After the first abrupt shift, they were replaced by the dominating *Chironomus anthracinus*-type. After the second abrupt community change around 4400 cal. yr BP, *Tanytarsus gracilentus*-type dominated the chironomid assemblages. In contrast to the sediment-bound *Chironomus anthracinus*-type, this taxon is associated with aquatic vegetation, similar to the first two taxa. From 4400 to 3800 cal. yr BP, chironomid concentrations increased while at first moderate *Procladius* percentages decreased. The increase in concentration suggests an increase in productivity which is supported by carbon isotope data from chironomid head capsules and ostracod shells.

Combined bioindicator and stable isotope data suggest a phase of strong Westerlies influence lasting from 5050 to 4400 cal. yr BP. This led to a lake level increase combined with a shift from saline to freshwater conditions. The abrupt shifts at the onset and end of this phase may have resulted from collapsing macrophyte vegetation, potentially due to increased turbidity caused by higher sediment input as a result of increased precipitation. The gradual change observed after 4400 cal. yr BP may have been driven by increasing macrophyte density or decreasing water depth due to the establishment of the modern outflow. Alternatively, increasing productivity may have favored the *Tanytarsus gracilentus*-type over the free swimming *Procladius*.

Our results show how Son Kol shifted from a hydrologically closed to an open system marked by two tipping points at the onset and end of a ca. 650 year-long phase of increased Westerlies influence.

Climatic variations during mid Holocene in Ladakh (Karakorum Himalaya), India

Binita Phartiyal, Randheer Singh, Debarati Nag, Priyanka Joshi, Anupam Sharma
Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

The monsoonal precipitation over Indian subcontinent is largely controlled by the thermal gradient between the Tibetan Plateau and Indian subcontinent and is highly variable with contrasting precipitation patterns seen from east to west and north to south, especially over Himalaya. This can be contributed significantly to the varied geomorphology of different sectors of the Himalaya. In Indian part of Himalaya itself, hydro-climatology of the central and northeastern parts is largely influenced by Indian summer monsoon, but for western Himalaya the winter time weather and westerlies bring moisture from northwest of Indian sub-continent and plays a lead role. Bulk of the precipitation over Ladakh and Karakoram region is received as snow between November-April which is crucial to replenish and maintain the water budget of the ten major rivers originating from the third pole area and catering almost 20% of the world's population. This mid latitude, high altitude glaciated region thus hold key to understanding of several climate uncertainties. Recent uprising trend in flash floods induced by abrupt and intense precipitation events in the high altitude Himalaya are becoming worrisome. A spatial variation exists in the studied records and to understand this concurrent variability it is very important to have good knowledge of past variability especially since mid-Holocene. As the proglacial lakes have significance in assessments of glacier dynamics and aquatic ecosystem monitoring, a multi-proxy study using mineral magnetism, sediment texture, total organic content, palynofacies and diatoms as proxies was taken up to give the picture of the lake productivity and past climatic variations at North Pulu (NP; 5098 m AMSL) in Ladakh, bracketing between 4585 to 360 cal yrs BP (^{14}C AMS). The first high-resolution palaeolimnology record from Karakorum Himalayas shows that between 4585-4294 cal yrs BP, an oxic lake condition existed with freeze-thaw action, prominent weathering and less organic productivity. The following period is of 320 year, severely cold and dry phase. Between 3974-2064 cal yrs BP, an initially cooler climate but a transition phase with some moderate warm climatic condition and high lake levels are recorded. Glacial melting due to a warm climate, high TOC%, and well-preserved OM, reducing conditions were prevailing, due to high lake level, is followed by a 260 year period between 1244-984 cal yrs BP of warmer climatic conditions. LIA in the region is documented at between 984-620 cal yrs BP. However at 620-360 cal yrs BP warm climatic condition which were of a local extent and were not severe. This mid-Holocene record is culturally important being a rich heritage of ancient India as well as the Chinese civilization and can throw light on the appearance and decline of the Indus valley and Chinese civilizations reigning during this time span.

Fossil green algae indicated middle-late Holocene abrupt temperature change in central Asia and its impact on cultural evolution

Xiaozhong Huang¹, Lixiong Xiang¹, Xuemei Chen²

¹College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, China. ²State Key Laboratory of Frozen Soils Engineering, Northwest Institute of Eco-Environment and Resources, Chinese Academy of Science, Lanzhou, China

Abstract

We present the results of a synthesis of the modern distribution of *Pediastrum* (including *Pediastrum. simplex*, *P. duplex* and *P. boryanum*) in freshwater bodies in Asia, together with a stratigraphic study of *Pediastrum* in the Holocene sediments of Bosten Lake in Xinjiang, China. The results show that *P. simplex* and *P. duplex* have an unambiguous thermophilic character compared to *P. boryanum*. In addition, *P. simplex* has a narrower ecological amplitude, preferring warm water, and thus it can be used to indicate climatic warmth. According to the fossil *Pediastrum* record from Bosten Lake, the largest inland freshwater lake in China, the only occurrence of subfossil *P. simplex* is during 4.8-3.5 cal kyr BP; its occurrence indicates a relatively warm climate interrupted by several abrupt cold events. The concentration of *P. simplex* peaked during 4.7-4.2 cal kyr BP, and reference to independent geological records indicates that this interval corresponds to a strengthened global monsoon and intensification of drought in arid central Asia (ACA). By contrast, the low concentration or total disappearance of *P. simplex* reflects several cold events, such as at 4.2 and 3.5 cal kyr BP. The prosperity and decline of human civilizations was probably linked to the transitions between warm and cold conditions during the middle-late Holocene. A favorable climate would have promoted the development and enhanced the prosperity of ancient civilizations in the monsoonal regions of both Asia and Africa. By contrast, a series of collapses and cultural transitions in Asia and Africa at ~4 cal kyr BP were probably linked to abrupt cooling and a weakened monsoon. In ACA, the 4.2 kyr cold event may have led to population migration southwards from the Eurasian steppe to lower latitudes such as the Tarim Basin, Hexi Corridor, and even to Indian sub-continent. This event may have enhanced the prosperity of the Xiaohu and Siba cultures along the edge of deserts, which was associated with the introduction of wheat, sheep and related agricultural technologies.

A Multi-Proxy Reconstruction of Late Holocene Climate and Environmental History in Western Sri Lanka

Kasun Gayantha¹, Joyanto Routh², Krishnamurthy Anupama³, Jean Lazar³, Srinivasan Prasad³, Rohana Chandrajith⁴, Patrick Roberts⁵, Gerd Gleixner¹

¹Max Planck Institute for Biogeochemistry, Jena, Germany. ²Department of Thematic Studies-Environmental Change, Linköping University, Linköping, Sweden. ³Laboratory of Palynology & Paleoecology, Department of Ecology, French Institute of Pondicherry, Pondicherry, India. ⁴Department of Geology, University of Peradeniya, Peradeniya, Sri Lanka. ⁵Max Planck Institute for the Science of Human History, Jena, Germany

Abstract

The distinct geographical location of Sri Lanka in the Inter-Tropical Convergence Zone makes it an ideal place to track past variations in Indian Ocean monsoon intensity and related climate and environmental changes. A 4.1-m undisturbed sediment core retrieved from the coastal lake of Bolgoda reveals the terrestrial climate and environmental history since 3000 yrs BP in south-western Sri Lanka that is influenced mainly by summer monsoon rainfall. Different biomarkers (*n*-alkane, *n*-alkanoic acids, *n*-alkanol and triterpenols) were analysed together with compound specific stable carbon isotopes of *n*-alkane to reveal source specific paleoenvironmental information. In addition, a pollen analysis was also conducted to understand the vegetation changes in the watershed. Salinity in this coastal lake is controlled by seawater intrusion due to variability in freshwater input to the lake. Presence of brackish water molluscs in the lake and the density of mangrove vegetation showed a direct link to the lake salinity. Based on the results of these palaeoenvironmental proxies, and a Bayesian model based on radiocarbon dates, we divide the depositional history of Bolgoda Lake into four zones. *Zone 1* (2942 – 2391 cal yr BP) is characterised by decreasing salinity with increasing stream water input. Rhizophoraceae mangrove is dominant during this period whereas tree taxa such as *Dipterocarpus*, *Mallotus*, *Macaranga* and *Trema* indicate wet conditions in the catchment. *Zone 2* (2391 – 1782 cal yr BP) is characterised with rapid and abrupt changes of salinity and rainfall. The first phase of this zone (2391 – 2064 cal yr BP) is clearly identified as a dry phase, as inferred by high lacustrine salinity together with dominance of Avicenniaceae mangroves. Shrubs and small trees that are characteristic to arid conditions were common in the catchment. Rainfall increased but was mostly steady in *Zone 3* (1782 – 1299 cal yr BP) lowering the salinity level because of higher freshwater input. As a result, the mangrove vegetation was sparse, and the catchment was dominant with trees growing under wet conditions. *Zone 4* (1299 cal yr BP - present) is characterised by very slow accumulation rate with high clay content. Salinity increased during this period, and Rhizophoraceae reappeared during the latter part of this stage (545 – 217 cal yr BP). This suggests a higher rainfall in *Zone 4*, though the overall intensity of precipitation was decreasing slowly with the time. Vegetation in the upper catchment was similar to *Zone 3*. The paleoclimate and paleoenvironmental evidence in this study showed a good agreement with our previous investigation in the Bolgoda Lake based on bulk geochemical proxies. This study reveals high-resolution information about past climate and environmental changes in the lake and its catchment, providing detailed and specific information that is relevant for reconstructing the regional climate history.

O-2159

Investigating the impacts of climate variability on prehistoric communities using a multi-proxy salt lake archive from the Iberian Peninsula, Spain.

Samantha Jones

University of Aberdeen, Aberdeen, United Kingdom

Abstract

This preliminary paper aims, through detailed environmental analysis (pollen, NPP, a strong chronology (eight ^{14}C ages) and XRF analysis) to expand our understanding of Pictish settlement, landscape and land-use during the early medieval period. A 1.86 m core was extracted from a valley fen adjacent to the Waters of Bogie, slightly south of the village of Rhynie in north-eastern Scotland, and within 270 m of a Pictish settlement and Craw stone dated to the 6th century. The bottom of the core produced a calibrated age of AD 260-415 and all but one of the radiocarbon dates are in good chronological order. Initial pollen counts have revealed relatively good preservation with a number of distinct changes in the vegetation record. Most of these changes appear to be associated with natural environmental transitions linked to a weakening in fluvial/stream energy after the 12th century and a gradual accumulation of peat, although some evidence also suggests agricultural activity.

In the archaeological record evidence, from the nearby Pictish settlement, highlights high status metalworking as well as a range of Continental imports (e.g. late Roman Amphora pottery and fragments of imported glass drinking vessels from western France), signifying that Rhynie was an important power centre during the early Medieval period. A series of radiocarbon dates and Bayesian modelling however indicate only a short phase of construction and use during the late fifth to mid-sixth centuries. What is particularly interesting about the palaeoecological results is that there is evidence of cereal pollen and a pronounced representation of herbivore dung fungi throughout the record, which suggests continuity of farming activities from AD 260-415 onwards, despite the 6th century abandonment of the Pictish settlement.

MWP and LIA revealed by multiple proxies in varved lake sediments in the Tibetan Plateau

Juzhi Hou¹, Weiguo Liu², Jimin Sun³

¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China. ²Institute of Earth Environment, Chinese Academy of Sciences, Xian, China. ³Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The Tibetan Plateau (TP) is alternatively controlled by the Indian monsoon and the westerlies at glacial-interglacial, millennial scales. It remains unclear how the two climate systems influenced the TP climate at decadal- to centennial- scales because that high-resolution climate records with reliable chronology are scarce. Here we present sub-annual to biennial scale multiple proxies at a varved lake in the central TP over the past two millennia. The biennial-resolution oxygen isotope records revealed temperature variation, while the Titanium reflect precipitation, both based on proxy validation with meteorological data. The temperature records showed evident warming at 600 and 1000AD, coinciding with the Medieval Warm Period (MWP), while the relatively cool temperature at 1400-1700 AD indicating Little Ice Age (LIA). However, the precipitation showed different patterns on the TP, suggesting decoupling between temperature and precipitation over the past 2000 years. The decoupling could be attributed to changes in the monsoon intensity and interplay between the monsoon and the westerlies, which likely played an important role in civilization on the TP.

Abstract

Increased frequency of extreme weather events is considered to be closely linked to recent global warming. However, reliable meteorological data are available only since the industrial revolution, i.e., after the beginning of the present global warming. Before that, it is generally difficult to find geological archives that enable us to detect extreme weather events, which, in turn, prevents us from assessing the relationship between present global warming and instability of weather.

Sediment cores recovered from Lake Petexbatún (Guatemala) in 2015 (GPB15) are ideal materials for this purpose. Counts of their clear varves (annual laminae) and 29 ¹⁴C dates for the last 600 years enabled us to establish a chronology with exceptionally high precision and accuracy. We then performed ultra-high resolution (on average, ca. 180 data points per varve, i.e. ca. 2 days interval) X-ray fluorescence scans of the cores. Changes in the Ca/Fe ratio, a proxy for precipitation – evaporation balance, show that long-term drying proceeded in parallel with contemporary warming. More importantly, amplitude of the estimated dryness has increased during the same interval, suggesting a dramatic change in the instability of the climate system. On the other hand, during the Little Ice Age (LIA, ca. 16th to 17th century CE), rainfall increased and became unstable (the frequency of extreme rainfall events increased). During the 300 year period from the LIA to the 1970's, we were in the narrow window of the 'stable' climatic mode.

A clear increase of the both dryness and wetness oscillation amplitudes is only visible, and is very visible, in monthly data because impacts of spiky events are not suitably represented in long-term means. Strong weather extremes included in the climatic oscillation cannot be seen in the geo-archives at annual or lower resolution.

Abstract

The earliest hominid expansions from Africa into Eurasia date to at least 2 Ma. It is evident, that records in Southern Europe (notably from Spain and Italy) are much younger and extend back to up to 1.4 Ma. Climate change is considered a major driving factor of hominin evolution and dispersal patterns. In fact directly or indirectly by its severe influence on vegetation, physiography of landscape, and animal distribution, climate modulates the availability of resources. As plants contribute to the amount and variety of obtainable food resources vegetation and vegetation diversity are important factors for human habitats. Based on own results from the Caucasus region, we extrapolate the maximum extend of forests and mosaic landscapes for different climatic phases during Early Pleistocene as a prerequisite for the reconstruction of early human environments and evaluate different vegetation units with respect to their potential plant food.

This study aims at exploring the resource space of early humans in the Early Pleistocene. The main research questions here are, which and how many edible plant parts can be found in different vegetation units and how is the availability distributed in the course of the year. Vegetation units are chosen according to palaeobotanical reconstructions in the region, based on fossil records from plant macro fauna and pollen data. The units range from steppes to altimontane forests, comprising published taxa lists of dominant and most frequent species. The database PlantBITES hosts the relevant information compiled from the literature.

It is widely assumed that *Homo erectus* relied on a mixed diet of meat and plant food. However, it is not yet assessed in detail which plants may have contributed to their diet and to what extend different vegetation types can deliver necessary nutrition. This study is an attempt to quantify plant food resources and their availability for early *Homo* showing the importance of access to edible plant parts from forests for a stable supply of an energy- and nutrient rich diet.

Abstract

Considerable attention has been paid to dating the earliest appearance of hominins outside Africa. We found a new successive and multicycle aeolian loess-palaeosol section, which is located in Shangchen area (34° 13' 33" N, 109° 28' 39" E) of Lantian county, Shaanxi province of north China and lies on the southern margin of the Chinese Loess Plateau. This section is complete from L5 to L28 (equivalent to marine isotope stage 12 to marine isotope stage 80). The section contains 17 bring-artefact layers within the segment from S15 to L28, which of the age ranks from 1.26 to 2.15 Ma BP during the Early Pleistocene. In Shangchen the 82 flaked and 14 unmodified stones between S15 and L28 were collected from 6 loess and 11 palaeosol strata. The stone artefacts include cores, flakes, scrapers, points, borers, hammerstones, picks and bifaces. These oldest artefacts (2.12 Ma), which were found within L28 layer between the Olduvai Subchron and the Réunion Excursion of palaeomagnetic stratigraphy, are c. 270,000 years older than the 1.85 million year old skeletal remains and stone tools from Dmanisi, Georgia, which were previously the earliest evidence of humanity outside Africa. Because no skeletal remains were found with the stone tools from Shangchen, we do not know who made them, but it is likely to be an early form of our own genus *Homo*.

The oldest artefact age of approximately 2.12 Ma at Shangchen implies that hominins had left Africa before the date suggested by the earliest evidence from Dmanisi (about 1.85 Ma). This makes it necessary to reconsider the timing of initial dispersal of early hominins in the Old World. Moreover, the length of our artefact sequence – of 17 stone cultural horizons (probably with a high average occupation of ~ 50 ka) found in the same locality – is very rare world-wide, and indicates a repeated hominin occupation of the Chinese Loess Plateau for almost a million years between 1.26 and 2.12 Ma, and most occupations were in the palaeosol layers (11 layers of total 17 layers) which indicate a kind of warm-wet climate. This breakthrough expands a new direction of research on the internationally leading Chinese loess-palaeosol sequence.

This research was supported by the National Basic Research Program of China, projects of NSFC and Projects of Chinese Academy of Sciences.

Feeding ecology of European Early Pleistocene Deer: what does it tell about the paleoenvironmental context early Homo faced in Europe?

Emilie Berlioz¹, Dimitris S. Kostopoulos², Cécile Blondel¹, Gildas Merceron¹

¹PALEVOPRIM (UMR 7262, CNRS & University), Poitiers, France. ²Faculty of Science – School of Geology, Department of Geology, Thessaloniki, Greece

Abstract

Due to their taxonomic diversity and marked abundance, cervids represent a major component of the European terrestrial fauna during the Early Pleistocene. In paleoenvironmental reconstructions, deer are traditionally considered as forest inhabitants, witnessing a substantial tree cover. However, insights into extant deer ecology uncover a marked diversity of feeding behaviors and occupied habitats. For example, *Cervus elaphus* is present from the arid Spanish dehesas, consuming up to 95% of herbaceous monocotyledons, to the Polish primeval forests, behaving there as a browser. The plasticity of *Cervus elaphus* feeding behavior reflects the principal resources available in the habitat. Exploring the trophic plasticity of extinct eurytopic cervids hence constitutes a key to better apprehend paleoenvironments and paleoenvironmental variations through time.

By reflecting what has eaten an animal during the last few days or weeks of its life, dental microwear textures of herbivores constitute a bridge between an organism and its environment. Textures of 211 specimens of *Eucladoceros ctenoides* and 176 *Metacervoceros rhenanus* from 11 Early Pleistocene European localities were analyzed using a Dental Microwear Texture Analysis via Scale Sensitive Fractal Analysis.

Results illustrate the diversity of the resources these two taxa are able to consume: either dicot foliage, seeds or tough and abrasive monocots. These Early Pleistocene deer are therefore eurytopic and constitute appropriate proxies to track vegetal resource availability in paleoenvironments. For some localities, our results corroborate previous paleoenvironmental interpretations. For others, it brings new perspectives. Senèze (MNQ 18, France) for example, was previously considered as a mosaic habitat based on the co-occurrence of cervids and bovids in the fossil record. Alternatively, our results show that Senèze deer were engaged in grazing, indicating a much more opened habitat than previously considered. For both deer, similar oscillations through time were identified between a browsing and a grazing pole. We propose that these results witness vegetation changes from steppe-like to wooded conditions induced by the Early Pleistocene glacial interglacial oscillations.

This large scale work challenges the paradigm considering deer as a paleoenvironmental indicator of an important tree cover and therefore modifies our vision of the paleoenvironments of several European Early Pleistocene localities. This approach impacts our understanding of the paleoenvironmental context of Early Pleistocene *Homo* dispersion.

Figure 1: Evolution through time of the complexity and anisotropy of dental facets for *E. ctenoides* (green) and *M. rhenanus* (red). Localities from Western Europe are on the left side of the figure. Localities from Eastern Europe are on the right. A grazing diet corresponding to a more opened habitat is represented by herbaceous monocotyledons on the bottom of the figure while a browsing diet in a more forested habitat is illustrated by trees.

Paleoenvironmental reconstruction of the Early Pleistocene of Baza Basin, Southern Spain

Yul Altolaquirre^{1,2}, Angela A. Bruch¹, Luis Gibert³

¹ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt am Main, Germany. ²Goethe University, Dept. of Geosciences/Geography, Geology, Frankfurt am Main, Germany. ³Polytechnic University of Catalonia. Mining Engineering and Natural Resources Dept, Barcelona, Spain

Abstract

The Early Pleistocene of the intramontane basin of Baza (Granada, SE Spain) contains a long and continuous sedimentary record depicting a lacustrine environment that spans from the late Miocene to Middle Pleistocene. The Basin has provided numerous vertebrate fossil sites, including some of the oldest *Homo* findings of Western Europe in the locality of Orce (1.2-1.4 Ma) in the form of fossil teeth and lithic industry. Analysis of pollen grains is conducted on the Early Pleistocene lacustrine facies of Baza, sampled by the Palominas drill core which is dated between 1.6 to 1.1 Ma. Paleoclimatic parameters for temperature and precipitation are obtained by applying the Coexistence Approach method. The biome succession for the Early Pleistocene of Baza is reconstructed using the Biomization technique of assigning Plant Functional Types (PFTs) to each pollen taxa. The resulting pollen profile shows high taxa diversity, typical for that time in the Iberian Peninsula, but dominated by a few pollen groups. The paleoclimatic parameters picture an overall wetter climate when compared with modern values. The biome succession alters between a clear steppe biome during the dry phases and semi-open temperate/cool forest biomes appearing during the wet stages. It is concluded that the Early Pleistocene environments in SE Spain were heavily controlled by humidity. The dry stages would see the development of steppe with xeric elements while the wet stages allowed for the formation of a *mosaic* landscape with open environments and patches of forested areas. These environments with more humid climatic conditions would allow access to a variety of plant resources and, thus, be favorable for the development of hominin communities.

Abstract

The environmental context of early human dispersal in Eurasia has been a popular topic for decades, but lack of vegetational and climatic proxies in many of the sites has limited comparisons between individual sites. In the absence of direct environmental proxies, the rich and well-documented large mammal fossil record in western Eurasia has been studied extensively to investigate the timing and potential causes of early human occupation. A largely unexplored approach to this question is using computational models based on large mammal communities to characterize fossil sites with and without humans over large spatial and temporal scales.

Species interact in their abiotic and biotic environment via traits that allow them to persist and maintain populations. An important feature of these interactions relevant to community and dispersal dynamics over time is species sorting; species differ in their ability to perform and compete in environments that vary in their abiotic conditions. Therefore, the composition of local communities in terms of their functional traits is expected to be informative of certain aspects of local environments that the traits in question are associated with. The computational approach that quantifies the distribution of functional traits in communities to reconstruct past environments is called ecometrics. Dental functional traits of large herbivorous mammals are useful for the study of hominin environments because they can be used to estimate past climate, a likely limiting factor for early humans. The composition of local herbivore communities is influenced by climatic variables that limit the availability of edible plants over the year, mostly precipitation and temperature, the latter of which has been found to be better predictable from herbivore teeth in western Eurasia. The ecometric estimates of temperature are comparable to other independent proxies absent in many sites, therefore enabling a larger sample size for quantitative analyses of Pleistocene palaeoenvironments. It moreover seems that humans already occupied a wide variety of environments at that time, which could indicate ecological flexibility, or specific, favoured microhabitats.

Our analysis presents a comprehensive overview of the climatic setting when humans first entered European ecosystems, changing from mostly absent towards extensively present, in the climatic context of a mild overall cooling trend. Dental ecometric estimates currently reveal no clear distinction between sites with and without positive records of humans. However, ecometric species distribution modelling, treating humans as part of the large

mammal community, may yet allow estimating relative abundance of humans across environments by modelling the suitability of environments based on co-occurring large herbivorous mammals. Pilot results indicate that, for example, of the Orce sites (southern Iberian Peninsula), Venta Micena, lacking lithic artefacts, appears ecometrically less suitable for human occupation than do Fuente Nueva 3 and Barranco León, which both have a rich lithic record.

Abstract

The Early Pleistocene terrestrial climatic conditions in the Mediterranean Region, especially for the time range between 1.3 and 1.7 Ma, are poorly known. The Early Pleistocene palaeontological record of Pirro Nord (southern Italy; locality also known as Cava Pirro or Cava Dell'Erba) is preserved inside a karst network at the top of Mesozoic limestones and filled with continental sediments, often containing numerous vertebrate remains, both macro and micro, representing highly diversified palaeocommunities: 23 amphibians and reptiles, 47 birds, and over 40 mammals. Even if such vertebrate assemblages have been found in different fissures, nevertheless, they have been considered almost contemporaneous from a biochronological point of view on the basis of the evolutionary degree of the analyzed mammals. These fossils refer to a homogeneous vertebrate fauna aged latest Early Pleistocene that represents the last Faunal Unit (Pirro Nord FU or Pirro FU) of the Villafranchian Mammal Age in the Italian biochronological scale. The most important bioevents characterizing the Pirro FU are the first occurrence of *Equus altidens*, *Bison degiulii* and *Xenocyon lycaonoides*. The Pirro FU is also characterized by the European first occurrence of *Homo*, as indicated by the rich lithic tool record found at Pirro 13. Here, the amphibian and reptile fossil record from various karstic fissures is used to infer quantitative paleoclimatic and paleoenvironmental reconstructions. From such numeric data, it is shown that mean annual temperatures may have been lower (-1.6/-3.6°C) than present ones and mean annual precipitations higher (+90/+240 mm) in comparison with modern values. Seasonality was much higher with cooler summers (-0.4/-2.0°C) and colder winters (-1.2/-6.0°C). Distribution of rainfall during the year shows higher precipitations during winter (+14/+43 mm), but summer rainfall similar (-1.7/+6.6 mm) to modern values. Associated landscape is reconstructed as open dry environment with scattered patches of woodlands eventually along water courses or swamps. Such ecological scenario fits with Early Pleistocene "glacial" conditions. Such results are concordant with other sites of similar age in the Mediterranean Region as Venta Micena (Spain). The temporal homogeneity of the different sites from Pirro Nord is strengthened by such an analysis. Paleobiogeographic interpretation also suggests an interesting pattern of Balkan influence when climate is colder, thus bringing a scenario for trans-Adriatic dispersals as it may have probably been also the case for the earliest Europeans. This paper is part of projects SGR2017-859, CGL2016-80000-P, and UV-INV_AE17-708551.

O-2168

Resources availability and hominin subsistence strategies in European Pleistocene.

Kamilla Pawłowska

Institute of Geology, Adam Mickiewicz University in Poznań, Poznań, Poland

Abstract

The term *Mammuthus–Coelodonta* Faunal Complex means more or less cold-adapted Pleistocene large mammal assemblages with similar or identical faunistic structures, known from transregional expansion in Eurasia (Kahlke, 2014). A crucial ecological factor in the formation of *Mammuthus–Coelodonta* Faunal Complex was the formation of the Eurasian steppe–tundra (MIS 12; marine isotope stage), a biome that no longer exists today, but which enabled species of Arctic tundra origin to disperse towards the south and southwest, as species of steppe origin spread into northern and western regions.

The various animal species are included in the Middle Pleistocene faunal complex and the Late Pleistocene faunal complex, respectively, which is related, among other things, to the evolution of the fauna at that time. Potentially, all of them could have contributed to hominin subsistence level.

This paper is intended to present the current state of knowledge concerning mega-fauna that have been established in Poland in order to examine their contribution to the subsistence level along with evaluation of its diversity. Both well-known localities and those more recently discovered (such as Bełchatów, Sitkówka and Sierakówko in Poland) will be shown and compared between the European Early and Middle Pleistocene. The data suggest that large mammals, in contrast to plant resources, constituted the main subsistence resource for hominids in the European Pleistocene. The overall picture of the resource availability, where ruminants predominate, as the results show, will be discussed along with the evaluations of the development of resource exploitation strategies.

A novel approach to local and regional application of paleoecological perspectives in dry forest management and restoration

Geoffrey Johnson

University of Oregon, Eugene, USA

Abstract

A relatively new development in the discourse of Quaternary science, which has yet to be rigorously evaluated, concerns the utility of long term perspectives for addressing land and resource management and other socially mediated practices. To test this notion, I conduct a case study of the Quaternary science perspective on the management and restoration of fire-prone dry forest of the Pacific Northwest region of North America. To frame this research agenda, I ask the following questions:

1. When management plans are being written, who contributes to the pool of scientific knowledge considered, how is that knowledge integrated, and how are long-term perspectives represented in these decision processes?
2. Can long-term perspectives be retooled and re-framed to better address the existing challenges of land management groups at local and regional scales?

With this study, I have two aims. First, I provide a reference point to the Quaternary science community to frame paleo-data for use by agencies and organizations actively engaged in managing landscapes and resources. Second, I produce an epistemic road map for land and resource management communities to access long-term perspectives on management issues they face. The methodological approach of this study is to engage personnel involved in public, private and tribal resource management to assess the potential for collaboration between Quaternary science-workers and land managers in this region with diverse land ownership and management strategies. The qualitative research plan involves two primary efforts: first, a series of interviews with the personnel of management groups; and second, analysis of planning documents and other relevant documents identified by interview participants.

Planning document analysis reveals that as practiced, Quaternary science perspectives are not well represented even as context for resource management plans. This holds even for issues such as fire regime shifts related to changes in climate, about which Quaternary perspectives may be most useful. Interviews with resource managers suggest that capacity for interpreting and synthesizing data and findings from scientific publications is a primary barrier to more integration of these perspectives in planning. Further, access to information about Quaternary science appears to be highly mediated by the social and professional networks of resource managers, suggesting novel approaches to science communication and co-producing knowledge will be important and effective. For Quaternary science researchers interested in the applications of their work to environmental issues, this study suggests beginning projects collaboratively is vital to realizing the potential of paleo-data for guiding society toward better informed natural resource policy and outcomes.

Contemporary applications for the study of Quaternary geology in the Canadian mining sector

Annabel Ruksys¹, Wayne Savigny^{2,1}

¹BGC Engineering Inc., Vancouver, Canada. ²Savigny Geoscience Inc., Vancouver, Canada

Abstract

The Quaternary Period, defined by many glacial and inter-glacial cycles, is relevant to all who practice in British Columbia, Canada, as it has left a landscape fraught with engineering challenges. The study of Quaternary Geology is often overlooked in engineering assessments and will go unnoticed until “unforeseen” geological conditions result in poor performance of engineered structures. As practitioners in applied earth sciences we must take initiative to expand our influence and recognize the importance of our work to the modern world.

BGC Engineering Inc., an applied earth sciences consulting company, in Vancouver, Canada recognized the need internally to maintain a culture of getting the geology right. To support this, BGC developed a training program focused on glacial landforms and processes and specific training in air photo interpretation. These training opportunities have been developed with support from project teams. The Red Chris mine in northwestern British Columbia is an example, where the complex glaciated landscape provided BGC with an invigorating training and mentoring ground for teaching and developing an understanding of glaciolacustrine environments and the associated implications on engineered structures. The geologic model for this project has been recognized by the project independent external review board as industry leading and the framework for how geologic models should be carried out.

Proactive training initiatives for young professionals is only one method to support skill development in the study of Quaternary geology. Effective communication and partnership with industry, government, academia and the public to promote education and outreach is another key component. As an example, BGC took their internally developed glacial landforms and processes training seminar and offered the session to undergraduate and graduate students at a Canadian University to help support the teaching of Quaternary geology and bridge the gap between practitioners and students. The positive feedback was overwhelming and has led to further collaboration efforts. Initiatives such as this, internally at BGC and externally in academia illustrate an excitement and commitment to optimize our collective ability in Quaternary geology.

The key to instilling relevance in the Quaternary will be realizing potential opportunities for mentoring and inter-generational knowledge transfer, thereby instilling curiosity and excitement in others. Given the complexity of this field and the collection of site specific experiences, mentoring is a key component of maintaining relevance, encouraging collaboration, and ensuring continued commitment to our science.

The 3D Pollen Project: a new, free source of scans and 3D-printable models for outreach, engaging teaching, and research.

Oliver Wilson¹, Francis Mayle¹, M. Jane Bunting²

¹University of Reading, Reading, United Kingdom. ²University of Hull, Hull, United Kingdom

Abstract

The study of fossil pollen has been described as ‘the single most important branch of terrestrial palaeoecology for the late Pleistocene and Holocene,’¹ although most people only know pollen as an irritating allergen. Pollen also plays key roles in areas as diverse as forensics, biotechnology, honey identification, and cuisine – as well as being essential to reproduction in higher plants. Pollen shells (exines) are made of sporopollenin – ‘one of the most extraordinarily resistant materials known in the organic world’², ‘the diamond of the plant world’³ – and their shapes exhibit beautiful diversity.

But despite all this, engaging others about the importance and relevance of pollen is extremely challenging without the use of microscopes, something which is impossible in many outreach settings. And even with microscopes, it can be difficult to interpret a pollen grain's three-dimensional structure from flat, two-dimensional images – a fact which makes learning pollen identification (using photos and drawings in a process that has hardly changed for decades) a significant challenge.

3D-printing has the potential to transform these areas. Methods of preparing, scanning and printing pollen have been developed, but the few accurate models that have previously been produced are not freely available to the public. In this talk I introduce the 3D Pollen Project, which aims to address these shortcomings.

Firstly, I will discuss the motivation and methods underpinning the project, in which we are using laser scanning confocal microscopy to produce accurate, printable 3D models of pollen grains from reference and herbarium material, and making the resulting files available online for free.

Secondly, I will present the results of research into the impact of using physical pollen models and interactive scans on the learning experiences of students in pollen identification modules. The use of these resources in undergraduate modules represents a logical – yet so far impossible – enhancement to existing teaching practice which could be integrated with minimal disruption and little monetary cost, bringing potentially significant benefits. Students have already expressed the opinion that these resources would make the task ‘more fun and so easier to learn’; this talk will discuss how the use of 3D pollen models affects the different stages in learning pollen identification, and highlight its impact on overall student experience.

Finally, I will share examples of the models’ use in outreach and engagement activities worldwide, examining how they affect people’s interest and understanding of pollen and its relevance – to the Quaternary and beyond.

Quaternary palaeo-environment and archaeology skills enhancement in Uganda

Elizabeth Kyazike¹, Julius Lejju²

¹Kyambogo University, Kampala, Uganda. ²Mbarara University of Science and Technology, Kampala, Uganda

Abstract

The main aim of the project was to provide skills and enhance the teaching and researching of archaeology and palaeo-environment in Uganda through vibrant multi-proxy and inter-disciplinary research and exchange, within Uganda and the wider eastern African region. The skills enhancement training was also meant to impart relevant skills to explore the long-term environmental dynamics in the interlacustrine region of Uganda and provide a historical context of interpreting human-environment interactions and the response to climate variations in the region. Despite a long history of archaeological and palaeo-environmental investigations in Uganda since the 1960s, there was little public awareness and appreciation of the rich heritage in Uganda. Furthermore there was limited teaching, researching and public promotion of history, heritage, archaeology and palaeo-environment in Uganda. The skills enhancement training was a strategy to create public awareness and appreciation of the rich history, archaeology and heritage in Uganda and impart knowledge and skills through field training. The objectives of this training were to: enhance hands-on practical skills combining significant original research and data collection with extensive theoretical and practical training for students; Impart skills on survey and descriptions of archaeological sites, including excavation of archaeological materials, identification of artifacts, attribute analysis, and interpretation; impart skills on methods of extracting sediments from peat / swamps, lakes and archaeological sites for macro fossils and micro-fossils analysis; impart skills on analysis of sediments for macro fossils and micro-fossils to reconstruct palaeo-environment; Impart knowledge on sediment analysis, radiocarbon dating techniques and use of sedimentary proxies to detect the nature and timing of past vegetation changes, including anthropogenic activity and interaction with the environment; To integrate innovative research approaches to reconstruct environmental history from multi-proxy records to understand the dynamics of past climate and environment and the main drivers of such changes. A major component of the skills enhancement project involved an intensive training of students in the theory and practices of archaeology, heritage and palaeo-science. This was intended to present a vital opportunity to promote and strengthen Quaternary research and create an informed generation of Quaternary research scientists in Uganda and build capacity of paleo-scientists in the region to join the INQUA research community. The long-term plans of the Skills Enhancement Project were to bring together experts within east Africa and outside the continent for a future plan to develop an INQUA International Focus Group to address the Quaternary palaeo-environmental changes in East Africa. The activities begun with a two days training seminar /workshop at the Uganda Museum followed by three days of field training at Nsongezi in western Uganda. Students participated in excavation and coring and laboratory analysis. The result indicate an increased awareness and zeal for quaternary sciences in Uganda.

UNESCO global geoparks; a natural habitat for teaching quaternary sciences

Benjamin Thébaudeau

Joyce Country and Western Lakes geopark project, Tourmakeady, Ireland

Abstract

With over 140 geoparks present in over 35 countries and 4 continents, the concept of geoparks has been rapidly taking hold since their early beginnings 20 years ago, in large part due to the creation of the UNESCO global geoparks label in 2015. This label has elevated geoparks at the same status as World Heritage status. They not only focus on the geological heritage of an area but are also strong vectors of regional economic developments through local community involvement.

The very nature of geoparks lend themselves to strong links with quaternary sciences outreach and education. The mission of a geopark is to promote and enhance the knowledge on the local geological heritage but also the influence the geology has on the landscape, habitats and biodiversity and culture. It carries a de facto multidisciplinary approach with the added interest of involving continuous human interaction with their environment. Quaternary sciences are the perfect framework for presenting these various interactions and their evolution through time.

This paper will take the point of view of the Joyce Country and Western Lakes aspiring geopark in the west of Ireland but expand for comparison to other geoparks worldwide. The developing nature of this project and its underlying landscape offer many opportunities to develop a strong message on the importance of quaternary science to sustainable rural development driven by the pride of local communities.

Reconstructing past climatic changes using deep sea microfossils and neural network classification: a citizen science experiment

Thibault de Garidel-Thoron¹, Holy Ravalason², Ross Marchant¹, Solène Merer²

¹Aix Marseille Univ, CNRS, IRD, INRA, Coll France, CEREGE, Aix en Provence, France. ²Les Petits Débrouillards, Marseille, France

Abstract

Citizen science has raised over the last decade as an innovative way to (i) explain the scientific process, (ii) educate people and pupils on a range of societal issues, and also to (iii) give access to scientists to large scale process studies, based on crowd experiments. Though a wide range of studies have been designed in natural sciences, from botany (e.g. observation of phenological stages, cross identification of organisms), to seismology (involving cell phone accelerometers) or marine sciences (sampling and genomics of plankton), no studies, to our knowledge, has been developed for paleoecological studies.

Here, we will present a project aiming to involve a large number of kids into a single paleoclimatic reconstruction. In this experiment, we are sharing some deep-sea sediments (foraminiferal ooze) from a single deep-sea core with multiple groups of pupils in schools in Southern France. They are given some sieves to extract the coarse fraction ($>63\mu\text{m}$), and will take some pictures under the microscope of foraminifera and microfossils included in the larger ($>150\mu\text{m}$) coarse fraction. To process those images in the different schools, we will classify the images using a common classifier. This classifier is based on an in-house convolutional neural network, developed under TensorFlow (ForamTrieur). Using this classifier, the pupils will be able to recognize the main species of planktonic foraminifera. Based on those faunal changes, they will document the main climatic shifts. All pupils from the different schools will join an event at our institute where they will compare their results. In our research group, we will also check some random data to verify their analyses, and assess the confidence level of this experiment.

We plan to run this experiment in the spring 2019, in close collaboration with an outreach organization, les "Petits Débrouillards", with a final meet up in late 2019. Each analytical step is detailed in technical notes, and contextualized in the largest frame of the wide questions tackled by the project : e.g. climatic change, artificial intelligence, oceanography, marine biology, etc...A dedicated website is also underwork.

In this presentation, we will report the advances of this project, and discuss the lessons and outcomes from this unique experiment.

Stable and clumped isotopes in shell carbonates of land snails *Cathaica* and *Bradybaena* in China and implications for paleoclimate studies

Xu Wang, Jixuan Zhai, Linlin Cui, Zhongli Ding
Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

Knowledge of eco-physiological characteristics of different land snail species is crucial for defining climatic significance of snail faunal assemblages. However, little work has been done in this aspect, hindering our obtaining unambiguous paleoclimatic information using these proxy indicators. Here we document for the first time the different eco-physiological characteristics of *Cathaicasp.* and *Bradybaenasp.* land snails in China using the stable isotopes and clumped isotope (Δ_{47}) of the shell carbonates. The Δ_{47} -derived temperatures ($T_{\Delta_{47}}$) for both species were apparently higher than both mean annual and seasonal temperatures. Nevertheless, the $T_{\Delta_{47}}$ revealed a robust correlation with growth season temperature. Moreover, the temperatures for *Cathaicasp.* are 3~5°C higher than those for *Bradybaenasp.* land snails, possibly indicating different eco-physiological adaptations. Specifically, *Cathaicasp.* snails prefer living in trees with more chances to expose to sunlight, whereas *Bradybaenasp.* snails are inactive and stay in shady and damp litter layers under trees. Differences in color, thickness and appearance of shells between the two species lend support to the contrast eco-physiological traits. The result testifies to the Δ_{47} in snail shell carbonates as a promising paleothermometer in monsoonal region and presents new insight into paleoclimatic explanation of these land snail species. This finding highlights the importance of constructing species-specific Δ_{47} -T transfer function for precise paleotemperature reconstruction using clumped isotope in land snail fossil shell of the kind.

O-2177

Stable carbon and oxygen isotopes in shell carbonates of modern land snails in China: their relationships to environment variables

Jixuan Zhai¹, Xu Wang¹, Linlin Cui¹, Shuhua Zhang², Zhongli Ding¹

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²Brigade 606 of Sichuan Metallurgical and Geological Exploration Bureau, Chengdu, China

Abstract

Stable isotopes of land snail fossil shell carbonates ($\delta^{13}\text{C}_{\text{shell}}$ and $\delta^{18}\text{O}_{\text{shell}}$) open a window to decipher paleodietary and paleoenvironmental changes. However, the environmental meanings of $\delta^{13}\text{C}_{\text{shell}}$ and $\delta^{18}\text{O}_{\text{shell}}$ remain elusive especially in monsoonal climate region. To fill the gap, we analyzed $\delta^{13}\text{C}_{\text{shell}}$ and $\delta^{18}\text{O}_{\text{shell}}$ of the two common species of land snails (*Cathaica* and *Bradybaena*) in China.

Results show that $\delta^{13}\text{C}_{\text{shell}}$ of *Bradybaena* and *Cathaica* exhibited robust correlations to mean annual precipitation (MAP), mean annual temperature (MAT) and altitude. For example, the $\delta^{13}\text{C}_{\text{shell}}$ values for *Bradybaena* and *Cathaica* showed a generally decreasing trend with increases in MAP and MAT. By contrast, the $\delta^{13}\text{C}_{\text{shell}}$ values of both species displayed a positive correlation to altitude. The observed negative response of $\delta^{13}\text{C}_{\text{shell}}$ to MAT doesn't represent a real relationship, which is biased by precipitation since temperature and rainfall co-varies in monsoonal region. Instead, we obtained a positive correlation of *Bradybaena* $\delta^{13}\text{C}_{\text{shell}}$ to MAT when merely using the $\delta^{13}\text{C}_{\text{shell}}$ data around a 500 mm contour line of precipitation. To reveal dietary information, we measured carbon isotopes in shell-bound organic matter ($\delta^{13}\text{C}_{\text{SBOM}}$) for the two species from some selected sites with a goal to determine carbon isotopic fractionation (CIF) of shell carbonate relative to diet. A strong positive correlation was observed between $\delta^{13}\text{C}_{\text{shell}}$ and $\delta^{13}\text{C}_{\text{SBOM}}$ for both species, with a mean ^{13}C enrichment factor of $+15.18 \pm 0.26\text{‰}$ for *Bradybaena* and $+13.89 \pm 0.15\text{‰}$ for *Cathaica*. Accordingly, the inferred dietary $\delta^{13}\text{C}$ for *Bradybaena* documents isotopic signal of C_3 plants even in C_3/C_4 mixing region and retrieves water stress, temperature and altitude effects on $\delta^{13}\text{C}$ of C_3 plants (i.e., decreases with rainfall and increases with temperature or altitude). Comparatively, the inferred dietary $\delta^{13}\text{C}$ for *Cathaica* registers C_3/C_4 mixing signal in C_4 maximum zone and exhibits strong altitude effect and moderate water stress influence.

At the same time, an overall positive correlation can be found between *Bradybaena* $\delta^{18}\text{O}_{\text{shell}}$ and MAT ($R^2=0.26$) and can be obviously improved after eliminating two deviated data points in southern China where amount effect emerged ($R^2=0.52$). By contrast, correlation of *Cathaica* $\delta^{18}\text{O}_{\text{shell}}$ to MAT is not statistically significant. Furthermore, the positive correlation became more significant for *Bradybaena* ($R^2=0.84$) and *Cathaica* ($R^2=0.55$) in northeast China. The robust positive correlation of *Bradybaena* $\delta^{18}\text{O}_{\text{shell}}$ with MAT over a broad area testifies its usefulness to paleotemperature reconstruction at least in inland China. However, in Southern China, a strong negative correlation between precipitation and *Bradybaena* $\delta^{18}\text{O}_{\text{shell}}$ is convincing ($R^2=0.71$) and this becomes further prominent for study sites in coastal area ($R^2=0.97$). A weak negative correlation existed between *Cathaica* $\delta^{18}\text{O}_{\text{shell}}$ and MAP ($R^2=0.11$). Meanwhile, the $\delta^{18}\text{O}_{\text{shell}}$ of both *Bradybaena* and *Cathaica* showed a moderate correlation to $\delta^{18}\text{O}_p$. The strong $\delta^{18}\text{O}_{\text{shell}}$ -MAP relationship means a potential to reconstruct MAP in coastal area.

U-Th dating of a cold seep carbonate chimney in the Okinawa Trough

Zhibang Ma^{1,2}, Lisheng Wang^{3,4,5}, Zhilei Sun^{6,7}

¹Laboratory for Marine Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²Institute of Earth Science, Chinese Academy of Sciences, Beijing, China. ³Laboratory for Marine Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ⁴University of Chinese Academy of Sciences, Beijing, China. ⁵Institute of Earth Sciences, Chinese Academy of Sciences, Beijing, China. ⁶Laboratory for Marine Mineral Resources, Qingdao National Laboratory for Marine Science and Technology, Qingdao, China. ⁷Qingdao Institute of Marine Geology, Qingdao, China

Abstract

The Okinawa Trough, a back-arc basin formed by extension within the continental lithosphere, is one of the most significant ocean basins between the East China Sea and the Pacific Ocean, where cold seep carbonate deposits has been found. In this study, U-Th geochronological techniques have been applied to seawater and cold-seep carbonate chimney at the Okinawa Trough (OT). One well-structured chimney (MS), 19-cm thick in diameter, having a cylindrical shape with a vent hole at the center, was selected by submersible on the western slope of the northern section of the OT. To assess the composition of the detrital end-member, three sediment samples were also analyzed which were collected in the studied area. These samples were recovered at ~800m water depth.

Seven seawater samples for ST12 vertical-profile analyses indicate that U concentration is 3.170 to 3.226 ppb, with an average value of 3.189 ± 0.035 ppb, and $\delta^{234}\text{U}$ range from 145.8 to 147.1‰, with a mean of $146.3 \pm 0.9\%$. The $^{230}\text{Th}/^{238}\text{U}$ activity ratios are $0.00009 \sim 0.00052$ for seawater samples, and indicate that the seawater may contribute a minor amount of non-radiogenic ^{230}Th to the OT carbonate deposits. Five carbonate samples drilled across the section from inside to outside for MS chimney, ^{238}U concentrations ranging from 3354-7020 ppb in the inner samples to 1322-1438 ppb in the outer samples. Contents of ^{232}Th follow an inverse trend from 3994-6247 ppb in the inside to 6627-8854 ppb in the outside of the MS chimney. The $\delta^{234}\text{U}$ of all samples ranged between 134 and 207‰ with a mean of 158.0‰, which is slightly higher in comparison to seawater value. Correction for initial ^{230}Th has been made by Rosholt regression approach. We obtained ages of 142.1 ± 1.5 , 146.2 ± 7.0 , 150.7 ± 4.1 , 159.2 ± 4.7 and 167.7 ± 5.1 ka for MS chimney, which provides evidence for continuous growth from outer to inner at the studied site during the 167.7-142.1ka BP. These new $^{230}\text{Th}/\text{U}$ ages of carbonate chimney in association with biogeochemical processes of cold-seeps at the OT area provide valuable geochronologic information for study of active fluid venting on continental margins.

O-2180

Spatial core top variation of planktonic foraminiferal assemblages on the Uruguayan Margin

Andrew Mair, Tracy Aze, Ruza Ivanovic, Robert Newton, Jason Harvey
University of Leeds, Leeds, United Kingdom

Abstract

Oceanographic processes offshore Uruguay are exceptionally complex and energetic, with the mixing of warm equatorial waters (Brazilian Current and North Atlantic Deep Water) and cold Antarctic waters (Malvinas Current, Antarctic Intermediate Water and Antarctic Bottom Waters), bathing the margin¹. Planktonic foraminifera show ecological affinities for water masses based on temperature and thus within an oceanic mixing environment a transitional assemblage may be expected. Plankton tow transects conducted during the 1990s provide a regional picture of the relationship between planktonic foraminiferal communities and the associated oceanic water masses of the South American margin^{2,3}. This project aims to relate surface sediment planktonic foraminifera distributions and assemblages to the overlying water masses, in order to assess any population heterogeneity present in the core tops across a portion of the margin associated with oceanic mixing.

The dataset covers a region of 7400 km², within which a series of 200 piston cores were collected. A subset of this collection has been sampled, ranging from one to three kilometres water depth and covering the breadth of the margin, including drift, channel and terrace deposits. This range of environments is sampled to assess the spatial difference in planktonic foraminiferal assemblages and whether potential differences reflect the expected ecological affinities of taxa based on the oceanographic setting, or if ocean current transport and sedimentary affinity influence assemblage compositions.

Initial findings relating to the heterogeneity of planktonic foraminiferal assemblages obtained from core top samples will be presented. Results will be focusing on the variability of the assemblage signal margin-wide and correlation to the modern oceanic setting using current species ecological preferences, and whether transport effects explain assemblage variation and species distributions. Ecological mapping of the region lays the groundwork for this project, enabling assessment of assemblage variability in a geographically dense region coinciding with complex oceanographic boundaries.

Replicated small-sample radiocarbon measurements as a corrective lens for sedimentary proxy records.

Andrew Dolman¹, Jeroen Groeneveld², Sze-Ling Ho³, Thomas Laepple¹

¹Alfred Wegener Institute (AWI), Potsdam, Germany. ²Center for Marine Environmental Sciences (MARUM), University of Bremen, Bremen, Germany. ³Institute of Oceanography, National Taiwan University, Taipei, Taiwan

Abstract

Due to mixing processes, sediment samples taken from a single depth can contain particles (e.g. foraminifera) with a wide range of ages. When radiocarbon measurements are made on samples containing many of these individual particles, the resulting values can hide a lot of internal age variation. Furthermore, if the measured samples contain a material from only a small number of individual particles, the resulting ¹⁴C ages will be noisy estimates of the true mean age of material from that depth. Similarly, for proxies such as Mg/Ca, or d¹⁸O, the range of ages contained in a single sample results in measurements that represent average values for an extended time period. Again, these values will be noisy if the number of particles per sample is small, but even with large samples, the resulting proxy records are “smoothed out” and the reconstructed amplitude of climate transitions is reduced.

The advent of ultra-small-sample ¹⁴C dating means that samples consisting of very small numbers of foraminiferal shells now can be dated. This poses both a problem, as individual ¹⁴C ages will be less representative of their layer, but also an opportunity as it allows for a direct estimate of the heterogeneity in the age of material at a given depth. We used ¹⁴C measurements on samples of 3-30 foraminifera to estimate the underlying standard deviation in the age of individuals picked from the same depth. We repeated this for cores with sedimentation rates ranging from 3-30 cm/kyr and found age-variances consistent with simple sediment mixing models and typical bioturbation depths.

These direct estimates of age-variance allow for more realistic estimates of age uncertainty and have already proven useful to use in reconciling apparently inconsistent age-depth profiles from adjacent sediment cores. They also allow for a better-informed interpretation of proxy records, both in terms of the relative timing of events and in terms of the amount of amplitude reduction of the climate signal to be expected at different timescales. Knowing the length of time represented in a single sediment sample also allows us to more clearly interpret changes in the statistics of individual foraminifera variation, whether they can be interpreted as changes to the amplitude of the seasonal cycle, the strength of ENSO variations, or multidecadal climate variation.

Tracing the trigger of the Younger Dryas event: Spread of freshwater at 13 ka in the Arctic and Nordic Seas

Robert F. Spielhagen¹, Andreas Mackensen², Niels Nørgaard-Pedersen³

¹GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany. ²Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany. ³GEUS Geological Survey of Denmark and Greenland, Aarhus, Denmark

Abstract

Recently published sediment core data from the Beaufort Sea continental margin, Arctic Ocean (Keigwin et al., 2018, *Nature Geoscience*), provide the long-sought convincing evidence for an oceanic freshwater event at the onset of the cold Younger Dryas interval. To significantly affect northern hemisphere climate, the freshwater which entered the Arctic Ocean via the Mackenzie River had to reach the area of deepwater renewal in the Greenland Sea where it could impact on the Atlantic meridional overturning circulation. Here we present foraminiferal stable oxygen and carbon isotope records from a collection of >20 radiocarbon-dated sediment cores along the pathway of the freshwater from the Canada Basin of the Arctic Ocean through the Fram Strait into the Greenland Sea. Only few cores from the central Arctic show evidence of the freshwater event. Usually it is hidden due to very low sedimentation rates and bioturbation. However, in several cores from continental margins in the Siberian Arctic and both sides of the Fram Strait, as well as the central Greenland Sea, sedimentation rates exceed 1-2 cm/ky. Here, low-oxygen isotope spikes are found which point to a clockwise spread of the Beaufort Sea freshwater in the Arctic Ocean and an export through the western Fram Strait into the Greenland Sea. Our data from older and from recently recovered sediment cores provide convincing proof of a strong freshwater export from the Arctic at 13 ka and support the hypothesis of an oceanic trigger of the cold Younger Dryas event.

Spatial fingerprint of temperature changes in eastern North America during the Younger Dryas

David Fastovich¹, James Russell², Stephen Jackson³, Teresa Krause^{3,4}, John Williams¹

¹University of Wisconsin - Madison, Madison, WI, USA. ²Brown University, Providence, RI, USA. ³Southwest Climate Science Center, US Geological Survey, Tucson, AZ, USA. ⁴Augsburg University, Minneapolis, MN, USA

Abstract

The Younger Dryas cold event is clearly identifiable throughout much of eastern North America (ENA) in lacustrine and palustrine pollen records and geochemical proxies, but the signal varies spatially. Sites in New England and Maritime Canada record a cooling during the Younger Dryas, apparently synchronous with Greenland records. In contrast, fossil pollen records from Florida exhibit increases in plant taxa associated with warm/wet conditions during the Younger Dryas. This suggests the existence of a temperature dipole in ENA, but the spatial structure of this apparent temperature dipole remains unknown.

We present pollen-inferred temperature reconstructions for sites throughout eastern North America combined with branched glycerol dialkyl glycerol tetraether (brGDGT) inferred temperatures for five sites on a latitudinal gradient. Pollen-inferred temperature anomalies between the Holocene and Younger Dryas show a strong Younger Dryas cooling (2.5 to 5 °C) in New England and Maritime Canada and a more moderate Younger Dryas (0 to 2.5 °C) cooling in sites surrounding the Great Lakes. All sites south of 40° latitude indicate a warm Younger Dryas with cooling into the Holocene. Linear regressions of pollen-inferred temperatures against latitude indicate that the latitudinal temperature gradient became more gradual from 18 ka to 8 ka. The latitudinal temperature gradient steepened during the Younger Dryas, indicating diverging temperature trends in New England/Maritime Canada and Florida.

Independent brGDGT inferred temperatures support the spatial patterns in the pollen-inferred temperatures. Bonnet Lake, Ohio and Silver Lake, Ohio, near the Great Lakes, cool by 2-3°C, but lag the onset of the Younger Dryas at Greenland and New England. In addition, brGDGT temperatures from White Pond, South Carolina agree with pollen-inferred temperatures, with no Younger Dryas cooling. Instead, temperatures remain constant from ~14 ka until ~9 ka, after which temperatures begin to cool. However, the brGDGT temperature record from Sheelar Lake, Florida seemingly contrasts that of nearby pollen-inferred temperatures with a cold Younger Dryas. This apparent cooling may be an artifact within the brGDGT proxy, as both southern sites exhibit high sample variability relative to the two northern sites. Possible mechanisms that could generate a spatial dipole in temperature changes include changes in oceanic heat transport from the equatorial Atlantic or changes in atmospheric circulation advecting heat from the Gulf of Mexico.

Abstract

The Baltic Sea-Skagerrak region shows evidence of strong coupling with North Atlantic climate over recent glacial-interglacial cycles, but insufficient long, continuous, high-resolution Baltic region climate records have often limited evaluating such links. Ultra-high-resolution sediment cores collected during IODP Expedition 347 allow such records to be generated, including foraminiferal geochemistry records reflecting seawater environmental changes directly adjacent to the Scandinavian Ice Sheet (SIS) during the most recent deglaciation. We present deglacial benthic foraminiferal oxygen and carbon isotope, trace element, and species assemblage results from IODP Site M0060 (located between Sweden and Denmark in the Kattegat seaway) to constrain bottom water environmental changes (salinity, temperature, and oxygenation) between ~18-13 kyr BP. We also demonstrate a screening method for appropriately interpreting trace element proxies for paleoenvironmental reconstruction in an inherently challenging proglacial environment (where typical proxy controls may be altered).

Three clear deglacial phases occurred at this site: 1) an initial large, rapid freshening event at ~17.9-17.8 kyr BP; 2) a slower, step-wise freshening from ~17.8-15.6 kyr BP with poor ventilation of bottom waters, sea-ice formation and fjord-like conditions; 3) a change to more saline, warmer and more ventilated conditions between ~15.6-13.0 kyr BP, beginning before the Bølling-Allerød (as defined in ice-core stratigraphy at 14.7 kyr BP). These phases reflect the fluctuations of the SIS and major meltwater releases from the SIS, and likely indicate key phases in northern European deglacial climate.

Our data suggest that 2-3 large meltwater releases from the SIS occurred at ~17.8 kyr, ~17.1 kyr (smaller), and ~16.5 kyr. These meltwater releases are driven by the fluctuations of the SIS, which represent either responses to or drivers of changes in Atlantic Meridional Overturning Circulation (AMOC) observed in various other North Atlantic records during early deglaciation. The timing of these $\delta^{18}\text{O}$ declines is similar to other negative $\delta^{18}\text{O}$ excursions seen in records from the North Atlantic and Nordic Seas, indicating that these are regional rather than local signals. The ~16.5 kyr meltwater release in our record corresponds approximately to Heinrich Event 1, and suggests a potential role of melting of the SIS in Heinrich Event 1.

Variability of sea-surface conditions along the west Greenland margin over the Holocene

Allan Estelle¹, Anne de Vernal¹, Marit-Solveig Seidenkrantz², Marie-Michèle Ouellet-Bernier¹

¹Centre de recherche sur la dynamique du système Terre (Geotop) Université du Québec à Montréal, Montréal, Canada. ²Centre for Past Climate Studies, Arctic Research Centre, and iClimate, Department of Geoscience, Aarhus University, Aarhus, Canada

Abstract

Marine sedimentary cores were collected off western Greenland margins to reconstruct changes in sea-surface conditions during the Holocene and to document the climate-ocean-ice dynamics. In the south, close to Nuuk in eastern Labrador Sea, core SA13-ST3-20G provided records with a centennial resolution over the last 12,000 years. North of Davis Strait, in the eastern Baffin Bay, core MSM343300 from Disko Bugt permitted to document changes through the last 10,000 years in complement to other Baffin Bay records (cf. Gibb et al. *the Holocene* 2015). The dinocyst assemblages provided information on past sea-surface conditions, including temperature (SST), salinity and sea ice based on modern analogue technique. Both cores recorded significant changes throughout the Holocene. At regional scale, during the early Holocene, a change from harsh conditions with dense sea-ice cover to interglacial conditions occurred in two steps: at ca. 10 ka BP significant decrease of heterotrophic taxa (*Islandinium minutum* and *Brigantedinium* spp.) and the occurrence of phototrophic taxa (*Pentapharsodinium dalei*, *Spiniferites* spp. *Operculodinium centrocarpum*), corresponds to an increase of summer SST and a decrease of the sea ice cover; after 7.5 ka BP, the establishment of full interglacial conditions both south and north of Davis Strait is marked by maximum percentages of phototrophic taxa and the occurrence of *Nematosphaeropsis labyrinthus* in dinocyst assemblages, which corresponds to onset of minimum sea ice, optimum SST and salinity. Optimal conditions persisted until about 2.5 ka BP south of Davis Strait and 1.5 ka BP in the Disko Bugt. The change towards more unstable conditions during the Late Holocene is notably marked by decrease in the percentages of *Pentapharsodinium dalei* and increase of *Islandinium cezare*. It corresponds to spreading of sea ice and successive cooling pulses. The changes towards harsher and more unstable conditions seem to coincide with the disappearance of the Saqqaq culture at about 3 ka BP and to the gap of human occupation in western Greenland, which was recorded from about 2 to 1 ka BP between the Dorset and the Norse settlements.

Oceanic pacing of the Late-Holocene summer moisture variability in northern continental Europe

Ate Korhola¹, Lasse Holmström², Heikki Seppä³, Eeva-Stiina Tuittila⁴, Minna Väliranta⁵

¹Faculty of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland. ²Department of Mathematics, University of Oulu, Oulu, Finland. ³Department of Geosciences and Geography, University of Helsinki, Helsinki, Finland. ⁴Department of Forestry, University of Eastern Finland, Joensuu, Finland. ⁵Faculty of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland

Abstract

Century-to-millennial scale shifts in moisture and temperature are important to understanding variability in European Holocene climates and future water availability. Unfortunately, the spatial patterns and mechanisms behind these swings are poorly understood. Most records stem from the marine realm, whereas terrestrial records are rare and loaded with dating uncertainties for which reason acquiring a coherent picture of these climatic events and their drivers is difficult. Moreover, most of the existing hydroclimate records reflect predominantly winter precipitation, while information about summer moisture variability is scarce. Here we present high-resolution record of the summer moisture variability during the last five millennia obtained from an exceptionally well-dated peat core from a southern boreal raised bog in Finland. The record was based on calibrating fossil plant macrofossil data against the modern vegetation/water table relationship. We further examined, which of the detected features in the reconstruction were statistically significant in different time scales using a Bayesian scale space analysis (BSiZer) to the reconstruction. The reconstruction showed that the mire water table depth varied between 38 and 2.5 cm during the late-Holocene, and included repeated periods of seasonal moisture deficit. Significant increases in effective moisture occurred during the Dark Age Cold Period (DACP) about 300-800 AD, Little Ice Age (LIA) between 1550-1800 AD and during the Current Warm Period (CWP), from 1920 onwards, whereas drier conditions prevailed during the Roman Warm Period (RWP) prior to 300 AD, Medieval Climate Anomaly (MCA) 800-1200 AD, transition period between the MCA and LIA between 1400-1550 AD, and during the latter part of the LIA, i.e. about 1800-1920 AD. The inferred moisture increases correlated well with recurring episodes of unusually cold North Atlantic surface water (Bond Cycles), showing that these Bond events have left their signature in the Finnish peat record. We discuss the role of ocean dynamics in triggering abrupt climate change at centennial scales during the Holocene.

Lipid biomarkers quantify Holocene temperature in Icelandic lakes and soils

David Harning^{1,2,3}, Lorelei Curtin⁴, Áslaug Geirsdóttir³, Gifford Miller^{1,3}, William D'Andrea⁴, Thor Thordarson³, Sigurveig Gunnarsdóttir³, Julio Sepúlveda^{1,2}

¹INSTAAR and Department of Geological Sciences, University of Colorado Boulder, Boulder, USA. ²Organic Geochemistry Laboratory, University of Colorado Boulder, Boulder, USA. ³Faculty of Earth Sciences, University of Iceland, Reykjavík, Iceland. ⁴Lamont-Doherty Earth Observatory, Columbia University, Palisades, USA

Abstract

Iceland currently lacks reliable and continuous quantitative records of Holocene temperature, which are vital to better understand the Holocene climate history of Iceland. We first report downcore paired branched glycerol dialkyl glycerol tetraethers (brGDGT) and alkenone records that quantify Holocene temperature change in Skorarvatn, a 25-m-deep lake in northwest Iceland. A combination of recent qualitative proxy-based climate reconstructions from Skorarvatn lake sediment and modeling experiments from the nearby Drangajökull ice cap provide a framework to evaluate the veracity of biomarker paleothermometers. Due to the lack of an Arctic calibration that removes the influence of 6-methyl brGDGT isomers, we apply the existing global lake calibration to quantify mean summer air temperature (MSAT). Compared to previous records from Skorarvatn, relative changes in brGDGT-inferred MSAT closely tracks biogenic silica (BSi), a proxy for qualitative summer temperature in Iceland. Furthermore, brGDGTs and BSi both show synchronous cooling at ~ 2.4 ka, consistent with the first late Holocene appearance and subsequent growth of the temperature-sensitive Drangajökull ice cap. Analysis of alkenones from Skorarvatn show an abundance of C_{37:4} alkenones in addition to an isomeric C_{37:3} alkenone component. These distributions, in addition to RIK₃₇ values between 0.48 and 0.63, indicate that alkenone producers in Skorarvatn are Group I haptophytes and, thus, allow the application of published Group I calibrations. Alkenone-based temperatures exhibit less variability than brGDGT and qualitative climate proxies from Skorarvatn, and instead, closely track smoothly decreasing Northern Hemisphere June insolation. In addition to the lake-based proxies, we also examine brGDGT-based temperature reconstructions from stacked soil sequences that span the last 10,000 years in the central highlands. Due to the region's proximity to the active volcanic zone, the soil sequences are separated by thick ash layers, which have diagnostic geochemical fingerprints that permit robust correlation to tephra of known age. Additionally, soil-derived records may circumvent complications associated with multiple brGDGT producers contributing to lake sediment. Using the global soil calibration, brGDGT-inferred temperatures from the soil sequence conform to regional qualitative lake sediment climate records and capture periods of documented abrupt climate change in Iceland. Modeling experiments for Drangajökull and Langjökull, an ice cap in central Iceland, both pin peak Holocene Thermal Maximum (+3°C modern) and lowest late Holocene (-0.8°C modern) temperature estimates near those inferred from lake sediment and soil brGDGTs, as well as alkenones. Hence, these new quantitative records will provide valuable constraints on the glacier and climate sensitivity of Iceland during the Holocene, and important insight into the warming expected over the current century.

O-2189

Holocene oceanic conditions and sea-ice variability off North-East Greenland

Teodora Pados, Marit-Solveig Seidenkrantz, Christof Pearce, Henrieka Detlef
Aarhus University, Aarhus, Denmark

Abstract

The acceleration of climatic changes in the Arctic and Subarctic regions is particularly marked by the drastic reduction of summer sea-ice cover. According to model simulations, the Arctic Ocean may become seasonally ice-free as early as 2040-2050. Despite the extreme societal and environmental relevance, our understanding of processes determining sea-ice cover and variability is associated with significant uncertainties. The insufficient knowledge about late-Holocene marine environments and natural sea-ice states around Greenland makes it essential to develop high-resolution reconstructions extending back in time beyond the instrumental and satellite era. For this purpose, a sediment core sampled on the North East Greenland shelf (79°06'N, 11°90'W) was analyzed in order to establish multidecadal to millennial-scale time series of general oceanic conditions and sea-ice variability during the Holocene, with primary focus on the last few millennia. Water temperature, salinity and bioproductivity reconstructions were based on a combination of foraminiferal assemblage and Mg/Ca analyses. The sea-ice record was established using IP₂₅ and IRD analyses.

Assembling a jigsaw puzzle: An introduction to the International Quaternary Map of Europe project (IQUAME2500)

Kristine Asch

Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover, Germany

Abstract

The project of the International Quaternary Map of Europe project (IQUAME 2500) is a major international initiative coordinated by BGR under the auspices of the CGMW (Commission of the Geological Map of the World, Sub-Commission Europe) and with support of INQUA. It started in 2011 at the INQUA congress in Bern. Using the first edition of the map (BGR and UNESCO, 1967 – 1995) as a base, the project aims to show the distribution of Quaternary deposits at the land surface and general marine deposits across the entire European continent. The map is planned as geographical information system (GIS) with accessibility on the internet and is going to include the Quaternary on- and off-shore information on:

- age and lithology of Quaternary units,
- extent of permafrost,
- last extent of ice sheets (Weichselian, Saalian, if possible Elsterian)
- directions of ice movement,
- genetic descriptions of the units,
- faults, active faults
- off-shore Quaternary information (in cooperation with the EU EMODnet Geology project).
- key localities (e.g. geologically and anthropologically interesting sites)

For a multinational and cross-boundary project like this, international collaboration is the key to success. Partner institutions from more than 30 countries including geological survey organisations from Russia in the East, Portugal in the West, Norway in the North and Cyprus in the South are participating; a scientific board of Quaternary researchers ensures the high scientific quality of resulting map. This project requires also that data originally set up in a plethora of regional and national classifications need to be adapted, integrated and harmonized in respect to semantics, structure and geometry. To achieve this aim common rules needed to be set up and applied by all participants: structured vocabularies to describe the above contents, cartographic guidelines to suite the scale and last but not least generally applicable tools to aid the partners to submit their data to the project.

Ultimately, the aim is to create a harmonized, comprehensive, spatial, pan-European geological database where relevant properties of the Quaternary layers can be retrieved, combined, selected and cross-referenced across political boundaries and to provide a summary of the current status of European Quaternary geological research.

The presentation will show the current status of the map compilation and demonstrate aspects of the project's challenges while assembling the jigsaw puzzle of the International Quaternary Map of Europe.

O-2191

The Quaternary Map of Europe and the alpine Glaciations

Christian Schlüchter¹, Reto Burkhalter²

¹Inst Geol Sciences, University of Bern, Bern, Switzerland. ²swisstopo, Wabern/BE, Switzerland

Abstract

The main question when producing geological maps is simple: at what stage of the process is a map finished? This inspiring dilemma is illustrated by the early history of the Quaternary Map of Europe as it has been planned during the "classical period" of INQUA with the administrative form of a commission. After a decade-long quiet phase and as the result of some diplomatic steps, fortunately, the BGR has resumed the process and IQUAME has been formally installed by INQUA. The Quaternary Map of Europe will soon be finished.

In 2009 swisstopo has published a map at 1:500'000 on "Switzerland during the Last Glacial Maximum". This map in itself has a history too and will be evaluated 10 years after publication. Field mapping has continued and especially numerical modelling of the LGM ice build-up in the Alps has opened relevant questions: in the central inner-alpine areas of both major ice lobes (Rhein to the east and Wallis/Rhone to the west) some ice volume is "missing" in order to produce the ice extension as it is given on the map. New paleoglacial and glacial morphological observations are contributing to the final map - in this case 10 years after the first publication

O-2192

The development of an All-Ireland Quaternary map

Xavier Pellicer¹, Sam Roberson², Michael Sheehy¹

¹Geological Survey of Ireland, Dublin, Ireland. ²Geological Survey of Northern Ireland, Belfast, United Kingdom

Abstract

The Geological Survey Ireland (GSI) and Geological Survey Northern Ireland (GSNI) collaborative project to develop an All-Ireland Quaternary map at the scale of 1: 500,000 involved the reconciliation of Quaternary geology classification schemes and concomitant rationalization of terminology across two jurisdictions with a common political boundary. The project exploited available Quaternary mapping products of both geological surveys and soil geochemical and airborne Gamma-ray detection data collected by the Tellus and Tellus Border surveys.

The GSI 1: 50,000 classification scheme consist of eighty-three sediment types. These categories were generalised for the 1:500,000 scale map into sixteen broader categories: peat, lacustrine sediments, alluvium, windblown sands, marine and estuarine sediments, slope deposits, glaciofluvial sand and gravels, glaciomarine sediments and tills. Twenty-seven till types categorised in the 1:50,000 scale map according to their dominant petrologic component and their age were generalized into eight classes indicating the dominant clast lithology. Thirteen man made ground categories (e.g. Urban, Industrial, Spoil heap) were manually reclassified into the above categories based on neighbouring categories and geomorphological expression.

The GSNI 1: 250,000 Superficial classification scheme consists of twelve categories. Of these twelve categories, four were generalised: glacial sands and gravels and glaciolacustrine deposits were combined to glaciofluvial/glaciolacustrine sands and gravels, and diatomite was combined with lacustrine sediments. The till category, composed of undifferentiated glacial till, was subdivided into the eight classes listed above.

To achieve this subdivision a number of steps were taken. Firstly, the geochemical properties of different GSI till types were classified by compositional data analysis of soil geochemistry data. Secondly, this classification scheme was applied to NI Tellus soil geochemistry to determine till lithology types in NI. Finally, remaining till types that are not represented in RoI (e.g. basaltic till) were reclassified using principal component analysis of the Tellus Border soil geochemistry data.

The project used a combination of Python and Matlab scripting to implement both the topological generalisation and subdivision of Northern Irish (NI) till domains. Furthermore, lookup tables to enable two-way translation between Geological Survey Ireland (GSI) iQuaD database and GSNI NIDigMap database attributes.

The All-Ireland Quaternary Map is an important scientific and educational product for both geological surveys and, in a modified form, is part the data contribution to the 1:2.5 Million International Quaternary Map of Europe project.

A new, comprehensive geological map of the Kingdom of the Netherlands

Jeroen Schokker, Sytze Van Heteren, Michiel Van der Meulen, Marcel Bakker, Anuska Kaliar, Reinder Reindersma, Nikki Trabucho
TNO-Geological Survey of the Netherlands, Utrecht, Netherlands

Abstract

In 2018, TNO-Geological Survey of the Netherlands created a new geological map of the Kingdom of the Netherlands at the centennial anniversary of systematic geological mapping by the Survey. This first nationwide map since 1975, presented to an international audience at the end of the year, includes not only the onshore and offshore European Netherlands, but also the Caribbean part of the Kingdom.

The new map, at scales of 1:600,000 (European part) and 1:400,000/300,000 (Caribbean part) summarises our present knowledge of the subsurface. It illustrates the geological history of the Kingdom to professionals and the general public alike. From an applied perspective, it highlights the potential of geological resources and the presence of geohazards. Onshore and offshore sand and gravel are mined for construction and infrastructural works and for coastal maintenance, and dense Pleistocene sand forms a solid foundation for buildings. Two of the Caribbean islands are dominated by active volcanoes, all of the islands run the risk of earthquakes and tsunamis, and tropical hurricanes frequently lead to coastal erosion, flooding and landslides.

By applying a profile-type legend, describing unit sequences rather than just the top unit, we are able to show 3D information on a 2D map. It gives maximum insight into the geological history of the country and clearly demonstrates the occurrence of similar deposits on both sides of the current coastline. Our biggest challenge was the construction of a harmonised legend respecting the diversity of the onshore and offshore geology, yet simple enough to be understandable to the intended user. The number of map units was kept to a minimum; much of the active open-marine sand, for example, was included as a potential cover of various profile types defined for the onshore realm.

The map forms the Dutch contribution to international projects like the International Quaternary Map of Europe (IQuaME 2500) and the European Marine Observation and Data network (EMODnet). It is also the starting point of renewed and intensified mapping of the Caribbean islands Aruba, Bonaire, Curaçao, Saba, Statia, and St. Martin (Dutch part). Finally, it helps the Survey to market state-of-the-art subsurface models that are much more suitable for resource and risk analysis but more difficult to understand.

Quaternary geological mapping in Spain and contribution to the update of the International Quaternary Map of Europe

Ángel Salazar¹, Juan Antonio Rodríguez¹, Verónica Cañas², Ana Sevillano³, Inés Galindo⁴, Nieves Sánchez⁴

¹Instituto Geológico y Minero de España, Tres Cantos (Madrid), Spain. ²Freelance GIS technician, Gamiz-Fika, Spain.

³Instituto Geológico y Minero de España, Palma de Mallorca, Spain. ⁴Instituto Geológico y Minero de España, Las Palmas de Gran Canaria, Spain

Abstract

Accelerated erosion is an essential attribute of geological environments in the Mediterranean area, which distinguishes them from those of northern Europe. In addition, young mountain ranges (Alpine orogeny) are also common features in countries like Spain (average elevation 660 m). Therefore, Quaternary deposits are scarce, soils are thin (Leptosols, Regosols) and the bedrock frequently outcrops. Larger Spanish Quaternary formations are associated with local specific geological conditions, among which the following can be highlighted:

- Alluvial deposits of the main rivers (terraces and floodplains) over soft-rocks of the Cenozoic basins (e.g. Duero river).
- Estuarine and coastal sediments of the Gulf of Cádiz.
- Neogene - Quaternary sedimentary basins linked to the fault-systems of the Betic mountains (figure 1)
- Shore sediments, delta-fans and deltas in the Gulf of Valencia.
- Aeolian sediments in the central plateau.
- Volcanic rocks of Canary Islands.

Other Quaternary materials, such as mountain glacial deposits, continental volcanic rocks or materials related to karstic processes are usually very small in size, but of great scientific interest (e.g. Atapuerca).

Geological mapping in Spain start in 1849, with the creation of the "Commission for the Geological Map of Madrid and General of the Kingdom", later "Geological and Mining Institute of Spain (IGME)". The first maps were made with the same standards used at that time in Europe (mid nineteenth century), portraying the bedrock and the key Quaternary deposits in a single map. Due to the characteristics of the territory, the preparation of detailed thematic maps of Quaternary materials in a systematic way for the whole country, as is usual in Northern and Eastern Europe, would be as useless as expensive. Other thematic maps, such as geomorphological maps showing slope-slides and other erosion processes (in addition to key Quaternary deposits), are more helpful in Spain and are made regularly.

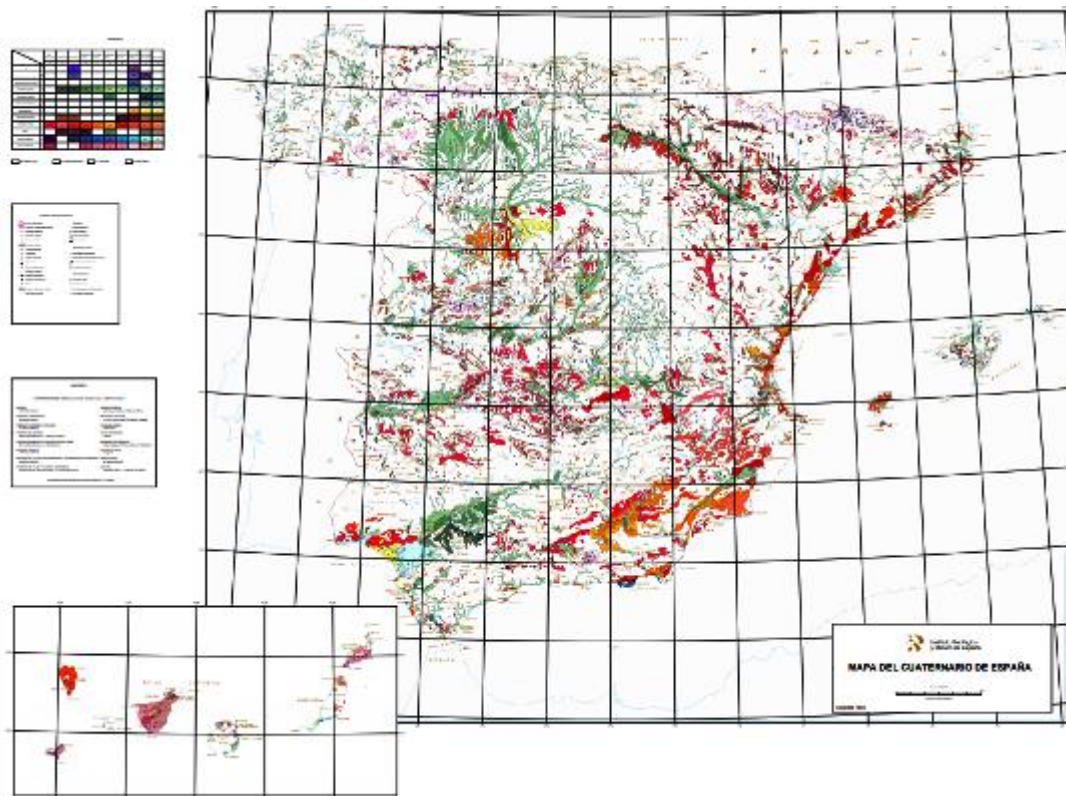

Geological maps of the Quaternary are only made in Spain to meet special needs, such as cooperation on European maps. The IGME published in 1989 a "Map of the Quaternary of Spain" at scale 1:1,000,000, with a vector version in 2010, but with no update (Figure 2). This map is outdated because at that time (1989), only half of the basic geological maps (scale 1:50,000, MAGNA project) of the country had been finished.

A new digital version of the Quaternary Map of Spain is being finalized (scale 1: 1,000,000, resolution 500 m), with reference systems ETRS89 (Iberian Peninsula and Balearic Islands) and REGCAN95 (Canary Islands). The data model

for the new map is in accordance with the specifications and vocabularies of the INSPIRE directive and meets the requirements established for the IQAME-2500 project.

Compilation of the Quaternary Deposits Map under the international project “Atlas of 1:5 M Geological Maps of the Circumpolar Arctic”

Oleg Petrov

Geological Research Institute (VSEGEI) , Saint-Petersburg, 199106, Russian Federation

Abstract

Large international project Atlas of 1:2.5 M Geological Maps of the Circumpolar Arctic, which has been conducted since 2003 by Geological Surveys of Russia, Norway, Denmark, Canada, Germany, Sweden, and the United States with the participation of experts from national universities and academies with the active support of the Commission on the Geological Map of the World at UNESCO was devoted to the geological and tectonic structure of the Arctic. In 2009, the Geological Map of the Arctic coordinated by the Geological Survey of Canada was compiled as part of the project, and in 2012, the maps of the magnetic and gravity fields, supervised by the Geological Survey of Norway, were finalized. In 2017, the new Tectonic Map of the Arctic coordinated by the Russian Geological Research Institute was created.

It is planned to compile the Quaternary Deposits Map of the Circumpolar Arctic as part of this project. In the course of preparations, we had discussions with representatives of the Geological Surveys of Norway, Canada, Germany and the United States and we are ready to be a coordinator of this work.

We compiled the 1:2.5 M Quaternary Deposits Map of Russia, which covers the land, inshore and adjacent offshore water areas. This is the first general map of Quaternary formations of our country based on the Neopleistocene Scale, correlated with the stages of the global oxygen-isotope scale, and built in compliance with the stratigraphic-genetic principle. In the map legend consisting of two blocks: genetic and stratigraphic, genetic types and their parageneses are distinguished as main mapped genetic taxa. When compiling the map, space and airborne photographic materials were used to clarify the position of the most recent faults, genetic diagnostics of sediments, particularly closed or poorly studied areas, through the documentation of specific landforms typical of them related to permafrost, aeolian, glacial and gravity processes.

Compilation of the Quaternary Deposits Map of the Circumpolar Arctic is necessary to identify the latest tectonic movements as part of constructing the up-to-date plate tectonic model of the Arctic.

O-2197

The role of climate in peat initiation since the Last Glacial Maximum

Paul Morris¹, Graeme Swindles¹, Paul Valdes², Ruza Ivanovic¹, Lauren Gregoire¹, Mark Smith¹, Lev Tarasov³, Alan Haywood¹, Karen Bacon¹

¹University of Leeds, Leeds, United Kingdom. ²University of Bristol, Bristol, United Kingdom. ³Memorial University, St. John's, Canada

Abstract

Since the Last Glacial Maximum peatlands have spread across nearly 3% of the Earth's land surface, and have sequestered between a sixth and a third of all global soil carbon. Postglacial peat initiation therefore represents the activation of a globally-important carbon sink, but the drivers of peat initiation remain unclear. A variety of mechanisms have previously been proposed to explain the spatiotemporal dynamics of peatland initiation in such diverse biogeographical locations, but until now the role of climate has been relatively understudied. We used palaeoclimate simulations from a state-of-the-art Earth system model to estimate local changes in climate during the initiation of 1,097 peatlands around the world. First peat initiation in deglaciated landscapes in both hemispheres was driven primarily by warming growing seasons, likely through enhanced plant productivity, rather than by any increase in effective precipitation. In Western Siberia, which remained ice-free throughout the last glacial period, the initiation of the world's largest peatland complex was globally-unique in that it was triggered by an increase in effective precipitation that inhibited soil respiration and allowed wetland plant communities to replace pre-existing forest and tundra. Peat initiation in the tropics was no more than weakly related to climate change, and seems likely to have been driven mainly by non-climatic mechanisms such as waterlogging due to tectonic subsidence. Our findings shed light on the genesis and Holocene climate-space of one of the world's most carbon-dense ecosystem types, with implications for understanding trajectories of ecological change under changing future climates.

11,000 years of atmospheric dust deposition in NW Spain recorded by Tremoal do Pedrido bog

Antonio Martínez Cortizas¹, Olalla López Costas¹, Lisa Orme², Tim Mighall³, Malin Kylander^{4,5}, Richard Bindler⁶, Angela Gallego Sala⁷

¹Universidad de Santiago de Compostela, Santiago de Compostela, Spain. ²Maynooth University, Maynooth, Ireland. ³School of Geosciences, University of Aberdeen, Aberdeen, United Kingdom. ⁴Department of Geological Sciences, Stockholm University, Stockholm, Sweden. ⁵The Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden. ⁶Dept. Ecology and Environmental Science, Umeå University, Umeå, Sweden. ⁷Department of Geography, University of Exeter, Exeter, United Kingdom

Abstract

Atmospheric dust (AD) plays an important role in terrestrial and marine ecosystems, particularly in those which are nutrient-limited. Despite most AD being emitted from arid and semiarid regions, recent research has shown that past dust events may have also been involved in boosting productivity in boreal peatlands.

We investigated dust deposition in a small, raised bog located in mid latitude, oceanic area (Xistral Mountains, NW Spain). The geology surrounding the bog is quite complex, including paragneiss/schist (where the bog is located), granite, quartzite and granodiorite. Peat properties (ash content, bulk density, total C and N, and colour) were used to assess the nature and stratigraphy of the bog. As proxies for dust fluxes we used accumulation rates (AR) of lithogenic (Ti, Zr, Rb, Sr, Y) as well as two major (K and Ca) elements. Principal components analysis of the AR records enabled to identify four main geochemical signals. The first one reflects total AD deposition; the second is essentially related to the Sr, and partially to Ca and K fluxes; the third accounts for the superficial enrichment of biophilic elements (K, Ca and Rb); and the fourth reflects secondary controls on Y fluxes.

Change point modelling suggests that the largest AD deposition occurred between ~8.6 and ~7.4 ka, with a maximum at ~8.1 ka (most probably during the 8.2 ka climate event). This event had a large impact in the evolution of the mire since from ~8.1 ka to ~6.7 ka it transitioned from a fen into a raised bog. In the early Holocene, by ~9.9-9.7 and ~9.2-8.8 ka, AD deposition may have also been elevated but the lower time resolution of this section of the core increases uncertainty of the results. From ~6.7 to ~4.0 ka AD fluxes were very low. After ~4.0 ka relatively major AD deposition events occurred at ~3.2-2.5, ~1.4 ka and ~0.35-0.05 ka, and minor events at c ~4.0-3.7, ~1.7, ~1.10-0.95 ka and ~0.74-0.58 ka. While sharing part of this chronology, most particularly from ~11 to ~6.7 ka, Sr fluxes were decoupled from those of the other lithogenic elements since the mid Holocene. Two large deposition events occurred during ~6.7-5.1 ka and from ~1.1 ka to present. This seems to be a specific source signal as the granodiorite batholith, located nearby the mire, has a Sr anomaly.

The reconstructed variations in mineral fluxes were more likely driven by climatic events (in particular the 8.2 ka, 4.2 and 2.8 events), including increases in storminess, and human activities. This finding agrees with a previous study of a shorter core from the same peatland. Both geochemical and pollen research in the area suggests that human impacts on forests were accompanied by enhanced dust emissions from soils.

Peatland carbon balance controls and fire frequency in the western Hudson Bay Lowlands, Ontario, Canada

Marissa Davies¹, Sarah Finkelstein¹, Jim McLaughlin², Maara Packalen²

¹University of Toronto, Toronto, Canada. ²Ontario Forestry Research Institute, Sault Ste. Marie, Canada

Abstract

The Hudson Bay Lowlands (HBL) is a vast continuous peatland region surrounding the Hudson and James bays of eastern Canada and is therefore an important region for understanding the role of peatlands in the global carbon cycle. Peatland initiation and long-term carbon accumulation are influenced by Holocene climate, succession, hydrology, and isostatic uplift in the region. This study presents multi-proxy paleoecological records of long-term environmental change to understand spatial and temporal variation of these influencing factors due to local to regional-scale landscape variation. Further, we provide a Holocene paleo-fire record to increase our capacity for predicting long-term impacts of changing fire regimes on carbon balance. This paper addresses how local vegetation, hydrology, and disturbance have impacted Holocene carbon balance by analysis of peat cores from three sites on the western margin of the HBL. A bog and a fen site with basal ages of >7500 cal yr BP were selected to investigate local changes in vegetation and hydrology. Through comparisons between these and regional paleoclimate records, we aim to isolate the role of Holocene climatic change. At the bog site, a transition from N-rich (1.1-2.5%) to moss-dominated and N-poor (0.3-0.7%) peat occurs early in the record, around 7400 cal yr BP. A transition to ligneous peat and increased nitrogen content (0.6-1.5%) occurs around 5800 cal yr BP; these changes reflect successional trajectories coupled with hydro-climatic drivers. At the fen site, in contrast, C and N values remain relatively consistent through the record, underscoring the role of peatland type in estimating paleo- and future C balance. Plant macrofossil and testate amoeba records are used to further constrain peatland types through the Holocene. By assigning average methane and carbon dioxide fluxes derived from contemporary data from the region to each peatland type, we estimate carbon fluxes through the Holocene. The potential role of fire on carbon accumulation in the HBL is investigated at a recently burned site by analyzing charcoal within three cores along a transect of burned to unburned area. Carbon accumulation rates are compared to the charcoal records to determine to what extent fire has decreased carbon accumulation rates for the HBL, as shown for western boreal regions of North America. Overall, using paleoecological approaches at multiple sites within the same region will allow for an improved understanding of the role of local-scale processes in the long-term carbon balance of HBL peatlands. Furthermore, by providing more robust multi-proxy paleoecological datasets in underrepresented areas of the HBL region, this work will contribute to future regional synthesis for Holocene climatic change.

Holocene blanket peatland development in eastern Scotland

Ward Swinnen^{1,2}, Nils Broothaerts¹, Gert Verstraeten¹

¹KU Leuven, Leuven, Belgium. ²Research Foundation Flanders, Brussels, Belgium

Abstract

To study long-term peatland dynamics, several models have been developed in recent decades. Most modelling efforts have focussed on peat bogs, but for other peatland types, such as blanket peatlands, modelling studies are limited. Although blanket peatland is a relatively rare ecosystem type on the global scale, 87 percent of the peatlands in the UK is of this type. Hillslope topography is fundamental to blanket peatland development and an improved representation and understanding of the relationships between climate, topography, hydrology and peat growth is crucial to better understand the effects of environmental change on blanket peatland evolution and the carbon balance.

Here, a new spatially explicit peat growth model is presented for blanket peatlands, which couples a detailed hillslope hydrology model with a peat accumulation and decomposition module. The resultant model allows to study the hillslope hydrology and blanket peatland development along topographically complex hillslopes over a Holocene timescale. Calibration and validation of the model parameters is based on a dataset of more than 900 peat thickness measurements along 56 hillslope transects in the headwaters of the river Dee (Cairngorms National Park, north-eastern Scotland).

For the 56 hillslope transects, the Holocene peatland development was modelled using pollen-based land cover and climate reconstructions, resulting in a current mean peat thickness of 0.4 metre or 20 kg per square metre of organic carbon for the studied area. The model results further show that the hillslope topography has a strong influence on the resultant peat development, stressing the need for spatial models in studying blanket peatlands. The simulated peat growth initiation dates are situated mostly in the period 9000 – 6000 a BP, which corresponds largely to periods with increasing temperature. Parameter sensitivity tests further indicate that an increase in tree cover results in higher peat accumulation rates because the positive effect of the increased biomass production exceeds the negative effect of higher evapotranspiration rates. The model simulations show that the blanket peatlands developed during the early Holocene before the decline in woodland cover and under low human impact. This points towards a natural peatland formation driven by climate and topography rather than by (anthropogenic) land cover changes. Overall, the model allows to study the effect of changes in environmental factors such as land cover, temperature and precipitation on the resultant peatland dynamics, providing a new tool to study blanket peatland evolution on long time scales.

Bering Sea peat cellulose oxygen isotopes show late-Holocene hydroclimate is influenced by Arctic sea-ice extent

Miriam Jones¹, Katherine Keller^{2,3}, Matthew Wooller⁴, Max Berkelhammer⁵

¹U.S. Geological Survey, Reston, VA 20192, USA. ²Natural Systems Analysts, Reston, VA 20192, USA. ³Harvard University, Cambridge, MA 02138, USA. ⁴Alaska Stable Isotope Facility, University of Alaska Fairbanks, Fairbanks, AK, 99775, USA. ⁵University of Illinois, Chicago, IL 60637, USA

Abstract

Bering Sea climate is strongly influenced by the Aleutian Low (AL) and sea-ice extent, which can influence atmospheric and ocean circulation in the region. Holocene records of northern Bering Sea paleoclimate remain sparse, largely because of low sediment accumulation on the Bering shelf. Here we present a 5.5 kyr record of stable oxygen isotopes from analyses of peat cellulose ($d^{18}O_c$) from St. Matthew Island, Alaska. St. Matthew Island (60.4°N, 172.7°W) is a small (357 km²) island in the central Bering Sea. It lies within the median winter sea ice extent but can be surrounded by open water during some winters. The $d^{18}O_c$ primarily reflects the source water at the time of plant cellulose synthesis and therefore should record changes in ocean-atmosphere circulation. Results from St. Matthew Island show a strong anti-correlation to Greenland ice core $d^{18}O$, a temperature proxy, over the last 5.5 kyr and to changes in inferred Arctic and North Pacific influence. From 5.5-3.2 ka, the St. Matthew Island record shows millennial-scale cyclicity, with an amplitude of ~5‰ and anticorrelation to Greenland $d^{18}O$. A positive $d^{18}O_c$ shift of ~5‰ occurs at 3.2 ka, with lower amplitude (18O record). The directionality of the shift suggests wind and moisture were dominated by a southern (North Pacific) influence. A ~10‰ decrease from 1.8 to 1.0 ka coincides with the Medieval Climate Anomaly and a strengthened relationship with Greenland $d^{18}O$ record that continues until 0.15 ka, suggesting a strengthened connection with North Atlantic climate and a predominant wind and moisture source from the north (Arctic). Overall, the patterns are consistent with modern isotope anomalies that show higher $d^{18}O_c$ when the dominant wind direction is from the N. Pacific, while lower $d^{18}O_c$ values correspond to dominant wind direction from the north, consistent with more zonal flow (weak AL) or Arctic influence, a pattern that could be related to sea-ice extent. After ~0.15 ka, St. Matthew Island $d^{18}O_c$ becomes progressively higher, despite rapid warming in Greenland, a pattern not observed over the last 5.5ky. The relationship of the St. Matthew Island record to the Greenland $d^{18}O$ record and Arctic Ocean seasonal sea-ice extent suggests Arctic climate responded to similar forcing mechanisms during the Holocene. Furthermore, the results suggest that the St. Matthew Island hydroclimate is strongly related to sea-ice extent.

Widespread drying of European peatlands in the last 300 years

Graeme Swindles¹, Paul Morris¹, Donal Mullan², Angela Gallego-Sala³, Mariusz Lamentowicz⁴, Thomas Roland³, Matthew Amesbury⁵, Richard Payne⁶, Thomas Sim¹

¹University of Leeds, Leeds, United Kingdom. ²Queen's University Belfast, Belfast, United Kingdom. ³University of Exeter, Exeter, United Kingdom. ⁴Adam Mickiewicz University, Poznań, Poland. ⁵University of Helsinki, Helsinki, Finland. ⁶University of York, York, United Kingdom

Abstract

There is much concern that climate warming and human impacts are causing peatlands to become drier, potentially converting them from sinks to sources of carbon through enhanced aerobic decomposition. However, the current hydrological condition of peatlands, and how this contrasts with their natural baselines, remain unclear. We use testate amoeba-based hydrological reconstructions to illustrate that many European peatlands have undergone a marked shift to drier conditions at some point over the last ~300 years. We identify key shifts to dryness in the records through statistical change-point analysis: Britain and Ireland (CE 1914); Scandinavia (CE 1777 and 1990); and Continental Europe (CE 1756). When data from all regions are combined a change-point at CE 1751 is identified across Europe. We found that 60% of sites are drier now than they have been for the last 500 years and 40% of sites are drier than they have been for >1000 years. This widespread drying of European peatlands was driven by the compound pressures of climate warming, decreasing precipitation and human impacts on the sites (cutting, drainage, burning and changes in land-use). Our results suggest that many European peatlands are in a highly vulnerable condition and highlight the need for effective management and restoration in the context of current and future climatic change.

Geochemical and isotopic records of anthropogenic pollutants and dust input over southeastern Europe during the Holocene

Daniel Veres¹, Jack Longman², Catherine Chauvel³, Volker Wennrich⁴, Aritina Haliuc⁵, Vasile Ersek⁶

¹Romanian Academy, Institute of Speleology, Clinicilor 5, 400006, Cluj-Napoca, Romania. ²School of Geography and the Environment, University of Oxford, South Parks Rd, OX1 3QY, Oxford, United Kingdom. ³Institut de Physique du Globe de Paris, Université Sorbonne Paris Cité, CNRS UMR 7154, Paris, France. ⁴Institute of Geology and Mineralogy, University of Cologne, D-50674 C, Cologne, Germany. ⁵Faculty of Mathematics and Physics, Department of Atmospheric Physics, Charles University, Prague, Czech Republic. ⁶Department of Geography and Environmental Sciences, Northumbria University, NE1 8ST, Newcastle Upon Tyne, United Kingdom

Abstract

Reconstructions of variability in dust flux provide valuable insights into past atmospheric circulation and moisture availability. By investigating several peat archives we provide a detailed record of variability in dust deposition over the Holocene in southeastern Europe. Using qualitative ITRAX core scanning and quantitative inductively coupled spectrometry (ICP-OES; ICP-MS) measurements of lithogenic (K, Si, Ti, Sc, Zr) elements, we identify 10 periods of major dust deposition between 9500–9200, 8400–8100, 7720–7250, 6350–5950, 5450–5050, 4130–3770, 3450–2850, 2000–1450, 800–620, and 60 cal yr BP to present. Our data highlight several discrepancies between eastern and western European dust depositional records including highly complex hydrological regimes over southeastern Europe, as since 6100 cal yr BP, the geochemical indicators of dust flux have appear uncoupled from the local hydrological variability. This shift coincides with the onset of centennial-scale cycles in dust input variability and a change in geochemical composition of dust traceable in different peat records. We show that this is indicative of a shift in dust provenance from local–regional to distal Saharan sources.

Furthermore, exploitation of natural mineral resources during last millennia had a tremendous impact on humanity, leading up to our highly industrialized world. The indirect history of past metal resource exploitation in Europe is based on a limited number of geochemical records from central-western and northern Europe. This is despite archaeological data showing that southeastern Europe experienced a long history of social, economic, and cultural traits revolving around ore processing and long-distance metal trading. Using stable lead isotopes (²⁰⁴Pb, ²⁰⁶Pb, ²⁰⁷Pb, ²⁰⁸Pb) coupled with the stratigraphy of selected elements (ie., Pb, Sb, Cu, Sn) associated with smelting we provide the first long-term reconstruction of past metallurgical activity in southeastern Europe. Our results present a new view on the human impact through resource exploitation, and the results, in conjunction with existing geological, archaeological, and archaeometric evidence, allow for a comprehensive assessment on the history of metal-use development over southeastern Europe. This is then compared with variability induced by natural sources such as dust input. Through a comparison with records from other parts of Europe we document the existence of strong regional differences in the magnitude, temporal, as well as spatial shifts in our understanding of past emission sources.

Long-term trends in algal diversity, stability and community biomass over sub-orbital timescales

Anson Mackay¹, Vivian Felde², David Morley¹, Natalia Piotrowska³, Patrick Rioual⁴, George Swann⁵

¹UCL, London, United Kingdom. ²Bergen University, Bergen, Norway. ³Silesian University of Technology, Gliwice, Poland. ⁴Institute of Geology and Geophysics, Beijing, China. ⁵University of Nottingham, Nottingham, United Kingdom

Abstract

Biological diversity is inextricably linked to community stability and ecosystem functioning, with rapid climate change posing serious threats to both. Our understanding of these relationships in freshwater ecosystems are largely based on short-term observational, experimental, and modelling approaches. Yet because extrinsic and intrinsic forcings linked to climate change often take place over much longer timescales, palaeoecological approaches become essential to determine the ecological dynamics of environmental change which unfold only over longer timescales.

Using a multidecadal (30-yr resolution) diatom record from the world's oldest and deepest lake, Lake Baikal (Russia), we show that on sub-orbital timescales over the past 16,000 years community stability, richness and diversity are impacted by abrupt climate change in a major way. During the Younger Dryas, for example, abrupt changes in diatom richness and diversity are part of a network of responses across southern Siberia as a result of extrinsic forcing, linked to variability in Atlantic meridional overturning circulation. More gradual changes, such as the increasing dominance of autumnal communities during the Holocene may be a response to intrinsic forcing, linked to a gradually cooling climate driven by declining summer insolation. Community biomass (as an indicator of palaeoproductivity) exhibits a weak positive relationship with N2 diversity over the Holocene period, that strengthens considerably when only Spring biomass is considered. Over the whole 16,000 year record however, the relationships become unimodal, similar to those hypothesised from modelling and experimental studies. In contrast, we show that community biomass – diversity relationships are much weaker during the Last Interglacial, highlighting context dependency between measures of productivity and biodiversity especially during time windows with markedly different boundary conditions.

Did fire influence the expansion of *Araucaria* in southern Brazil?

Daniela Piraquive Bermudez¹, Hermann Behling¹, Sonia Fontana¹, Thomas Giesecke^{1,2}

¹Georg-August Universität Göttingen, Göttingen, Germany. ²Utrecht University, Utrecht, Netherlands

Abstract

Woodland - grassland boundaries are generally mediated by fire and understanding the dynamics of such limits requires a long time perspective at high resolution. In the mosaic between *Araucaria* forest and grassland (Campos) in southern Brazil, the forest cover increased during the Holocene, often in a stepwise manner. While the general increase in forest may be due to a raise in summer precipitation the dynamics of it may have been controlled by fire. To investigate this Late-Holocene spread of *Araucaria* forest, we choose to study the small lake "Lagoa Dourada" (815 m asl) in Vila Velha State Park (Paraná State, southern Brazil). The lake is located near an *Araucaria* forest covering a low hill and adjacent remnants of natural grasslands. We obtained a 14,5 m sediment core, of which the upper 9 m cover the last 7 ka allowing high resolution analysis. Results show the dominance of Campos for the last 16 ka, with a stepwise expansion of *Araucaria* around 5.5 ka and 3 ka. We will present a high resolution fire history and explore to which extent fire may have played a role in the expansion of the *Araucaria* forest.

O-2206

Holocene fire dynamics mitigate the negative effect of catchment acidification on mountain submerged macrophytes (*Isoëtes*) in Central Europe

Alice Moravcová¹, Anna Tichá¹, Vachel A. Carter¹, Daniel Vondrák², Jacqueline van Leeuwen³, Willy Tinner³, Petr Kuneš¹

¹Department of Botany, Faculty of Science, Charles University, Praha, Czech Republic. ²Institute for Environmental Studies, Faculty of Science, Charles University, Praha, Czech Republic. ³Institute of Plant Sciences, University of Bern, Bern, Switzerland

Abstract

Modern populations of submerged macrophytes, *Isoëtes*, are classified as a critically endangered species after undergoing large declines in Central Europe. Recent studies have attributed *Isoëtes* decline to modern human impact, namely eutrophication, acidification or alkalization induced by land-use changes. However, anthropogenically driven environmental changes may not be an exclusive cause of *Isoëtes* decline. Paleoecological reconstructions illustrate a wide distribution of *Isoëtes* populations in the past, especially during the Early and Middle Holocene when human impact was less intense. Here, we aim to investigate how local environmental factors may have impacted the distribution and abundance of *Isoëtes* populations during the Holocene. To complete our research aim, we used a multi-proxy approach utilizing plant macrofossils, macrocharcoals, pollen, diatoms and chironomids from four lakes (Prášílské jezero, Plešné jezero, Černé jezero, Rachelsee) located within the Bohemian/Bavarian Forest mountain range in Central Europe. Our results show regional, synchronous patterns, with *Isoëtes* colonization beginning between 10 300 – 9 300 cal yr BP, and substantially declining around 6 500 cal yr BP. Results from Prášílské jezero imply that *Isoëtes* dynamic was mainly driven by processes connected with a change in vegetation structure and composition and fire regime around 6500 cal yr BP. Specifically, *Fagus* expansion and peatland extension coincide with decreasing fire activity, which changed soil chemistry in the lake catchment, and through surface water runoff, altered both the physical and chemical properties of lake water. This is reflected by a shift in diatom assemblages towards more acidophilous species and a distinctive drop in chironomid abundance. These environmental changes likely lead to an attenuation in the light availability, which subsequently resulted in the decline in *Isoëtes* abundance. Our study demonstrates the importance of vegetation development and fire dynamics in determining the abundance and distribution of critically endangered *Isoëtes* populations. These results have major implications for management and highlight the importance of long-term records in policy making.

O-2207

Abrupt late Holocene ecosystem change in Central European mountain forests

Niina Kuosmanen¹, Karen Halsall², Helena Svitavska Svobodova³, Jana Beranova⁴, Gina Hannon², Peter Fleischer⁵, Richard Chiverrell², Petr Kuneš⁴, Jennifer L. Clear^{1,6}

Abstract

The projected climate warming and intense anthropogenic influence cause increasing pressure on the temperate mountain spruce forest ecosystems in High Tatra Mountains in Slovakia. Investigating the past changes in these forest ecosystems and the processes behind them can provide valuable information for understanding the present and future ecosystems dynamics. To investigate the late Holocene stand-scale forest dynamics in the region, we sampled transect of four small forest hollows ranging from lower elevation sites Diera Hollow at 982 m.a.s.l. (circa 1500 cal. yr BP) and Lomnica Hollow at 974 m.a.s.l. (circa 1100 cal. yr BP) to Smokovec Hollow at 1067 m.a.s.l. (circa 4700 cal. yr BP) and to Velicka Hollow at treeline at 1354 m.a.s.l. (circa 3200 cal. yr BP). Temporal resolution of the analysed peat cores ranging between 10 to 40 years provides valuable opportunity to detect the ecosystem response to disturbances and changing environmental conditions.

We used pollen analysis to reconstruct the changes in forest composition during the study period. To investigate the role of natural drivers and anthropogenic influence in the ecosystem change, we assess the role of climate, forest fires and human impact as the potential drivers on the past forest dynamics. The climate variable will be constructed from climate model data for the last 4000 years and for the past 1000 years we will use climate reconstruction from the tree-ring records from the region. Fire history is analysed using macroscopic charcoal counts and charcoal area measurements. We will apply CharAnalysis software for statistical detection of significant peaks in charcoal records indicating fire events. As variable for the human influence on ecosystem dynamics, we will use human indicator pollen taxa to indicate human activity in the area.

Preliminary results demonstrate opening of the landscape circa 800-500 cal yr BP. Presence of the human indicator pollen taxa, such as *Cerealia*-type pollen, suggest landscape opening in connection to anthropogenic activity in the region. In addition, the charcoal records demonstrate change in the fire regime coinciding with the opening of landscape and it is plausible that change in the fire regime is connected to the human activity in the area. However, it is important to note that the ecosystem change occurs first in uppermost site at the treeline at 800 cal yr BP and 200-300 years later in lowermost sites. Furthermore, macroscopic charcoal records show rather simultaneous peak around 700-600 cal yr BP in all four sites suggesting fires across the study region. These results will be discussed further in the presentation in the light of climate data and further data analysis.

At sub-centennial temporal resolution, Icelandic palynological records show environmental responses to the Black Death.

Egill Erlendsson¹, Scott Riddell¹, Lísabet Guðmundsdóttir^{2,3}, Guðrún Gísladóttir¹

¹Institute of Life and Environmental Sciences, University of Iceland, Reykjavík, Iceland. ²Department of Archaeology, University of Iceland, Reykjavík, Iceland. ³Institute of Archaeology, Reykjavík, Iceland

Abstract

Having supposedly escaped the first Black Death outbreak in Europe in the mid-14th century, the plague reached Iceland in AD 1402. Both the nature of the plague and mortality rates are debated. Estimates of the latter range between 25% and 60%. Some scholars argue for long-lasting societal impacts, such as permanent farm abandonment and population decline, and change in land-use strategies. The environmental sciences have mostly ignored this historical feature with only three published records discussing the plague in Iceland in any detail (Jónsson et al. 2012, Streeter et al. 2012, Riddell et al. 2018).

This paper uses palynology at a sub-centennial temporal resolution to examine environmental responses to a reduction in population and a consequent release of pressure from land-use. The examination covers four land holdings, two in Western Iceland (Örnólfsdalur and Norðtungusel) and two in North Iceland (Þingeyrar and Skógar). All the sites classify as “off-sites”, i.e. samples have been accrued from the pastures associated with each farm, whereas much of the available pollen data are from the immediate vicinity of farms. The pollen records are furnished with precise tephra-constrained chronologies, supplemented with ¹⁴C age estimates from macrofossils.

All the sites exhibit a period of land-use over several centuries prior to the 15th century. Woodland and shrub contraction is indicated by decline in *Betula* (birch) and *Salix* (willow). Increasingly open landscapes are shown by e.g. increases in the pollen of Poaceae (grasses), Cyperaceae (sedges) and *Thalictrum alpinum* (alpine meadow-rue). This being the result of land-use rather than climate is indicated by the parallel loss of grazing sensitive taxa such as *Angelica* spp. (angelicas), as well as increases in microscopic charcoal and spores from coprophilous fungi. All four sites show a change in and around the 15th century AD. Although the degree to which the change is reflected varies, the signals indicate reduced land-use pressure. All sites show recovery of *Betula* woodland or shrub. Further signals are different between sites, but include raised organic content values, increased values for *Salix* and other grazing sensitive taxa, and reduced numbers of Poaceae, coprophilous fungal spores and microscopic charcoal. We conclude that the decline in human population associated with the plague and consequent reduction in livestock (grazing) and wood harvesting was of sufficient magnitude to leave its mark firmly in the Icelandic environmental archive.

Abstract

Intensive land use, globalization, and rapid climate change are threatening ecosystems across Europe. Paleoecological studies from natural archives provide valuable information on long-term environmental dynamics and thus contribute to future ecosystem conservation (Lamentowicz et al. 2015). Natural archives are hardly ever used to investigate the long-term impact of industrialization and globalization on continental-scale vegetation. Here we present a unique palynological record from the high-alpine glacier Colle Gnifetti (4452 m asl) in the Swiss Alps, spanning the past millennium with exceptional temporal resolution and precision (Jenk et al. 2009; Sigl et al. 2018). Our ice archive is located at the interface between Western, Central, and Southern Europe, and therefore integrates fire, land use, and pollution dynamics across major important biomes of Europe. We analyze pollen and spores as proxies for vegetation composition and agricultural activity, microscopic charcoal as a proxy for fire activity, and spheroidal carbonaceous particles (SCPs) as a proxy for fossil fuel combustion which preserve in ice cores over millennia (e.g. Brügger et al. 2018). We combine the ice core-derived continuous data with historical sources to provide novel insights into industrial impacts on land use, fire activity, and vegetation dynamics. Our multiproxy-ice core data suggest that in Europe, the transformation from solar to fossil fuel-based industrial land use (e.g. shift to large scale maize production and massive fire increase) started shortly after 1750 AD together with first signs of large-scale atmospheric pollution. We conclude that lowland vegetation such as temperate beech-oak forests suffered from progressive globalization of economies that intensified industrialized production on fertile soils. While these formerly forested areas are still disrupted, marginal areas such as mountain forests and alpine grasslands may benefit from a further concentration and intensification of industrial agriculture.

Abstract

This study compares multi-proxy palaeoenvironmental records (pollen, charcoal, particle size, loss on ignition, C:N ratios and radioisotopes, ²¹⁰Pb and ¹³⁷Cs) from three lakes in the Songnen Plains and five lakes in the Great Hinggan Mountains of northeastern China. These data provide high-resolution records of vegetation history and catchment dynamics over the past 200 years.

Records from the Songnen Plains find vegetation initially responded to a cooler and drier climate during the Little Ice Age with high values of *Pinus*, *Ephedra* and *Amaranthaceae* and low values of *Cyperaceae*. As anthropogenic activity increased in the lowlands of northeastern China, *Pinus* gradually declined while broad-leaved deciduous vegetation increased from 1900 CE. Aquatic taxa in the Songnen Plain lakes increased from 1900 CE as the wetlands responded to changing water levels and agricultural activities. Records from the Great Hinggan Mountains record little fluctuation in the composition of the dominant broad-leaved deciduous forest in the 1800s.

Population expansion and land policy implementation had a profound impact on vegetation in both the lowlands and alpine region of northeastern China. Arboreal pollen in the Songnen Plains declined from 1900 CE as marginal land was reclaimed, and agricultural activities significantly increased. Vegetation diversity increased as agricultural activities caused environmental disturbance, with pollen taxa indicating human disturbance including *Humulus*, *Polygonum* and *Xanthium*. Silt and organic content increased and C:N ratios declined after 1940 CE as erosion in the catchment and productivity in the lakes increased. In the Great Hinggan Mountains *Pinus* was selectively logged from 1900 CE and reached minimum values in the 1980s. Arboreal pollen declined from 1940 CE as timber harvesting increased, with *Betula* and *Quercus* increasing across the region from 1970 CE. Regional fire events in the mountains increased after 1970 CE, with a significant increase in microscopic charcoal occurring between 1990-2000 CE after a period of active fire suppression. Re-vegetation strategies and forestry protection in the late 1990s in northeastern China caused arboreal taxa and diversity to increase in the pollen records from the Songnen Plains and the Great Hinggan Mountains. This multi-proxy palaeoenvironmental study compares environmental change in the plains and alpine region of northeastern China and improves our understanding of natural and anthropogenic driven environmental change in the last 200 years

MIS 5a to MIS 4 climate transition in NE Poland—the palaeoenvironmental record

Barbara Woronko¹, Leszek Marks^{2,1}, Tomasz Karasiewicz³, Joanna Rychel², Mirosława Kupryjanowicz⁴, Magdalena Fiłoc⁴, Aleksander Adamczyk³

¹Warsaw University, Faculty of Geology, Warszawa, Poland. ²Polish Geological Institute – National Research Institute, Warszawa, Poland. ³Faculty of Earth Sciences, Nicolaus Copernicus University, Toruń, Poland. ⁴Faculty of Biology and Chemistry, University of Białystok, Białystok, Poland

Abstract

In central Europe the transition from MIS 5a (early Vistulian = early Weichselian) to MIS 4 (Lower Plenivistulian) is poorly understood in terms of feedback-mechanism relationships associated with climate shift and land-surface processes. The first Vistulian Ice Sheet advance reached northern Denmark and southern Sweden during the Late Pleistocene in MIS 4. Changeover dynamics during that turn remain a source of controversy in regards to eastern Poland, as that region's geomorphic history appears to be at variance with the rest of the country due to its higher continentality during warm interstadials and its decreased continentality during cold intervals. In example of this regional divergence numerous small shallow water bodies were present in northeastern Poland after MIS 6 (Saalian), which persisted until the end of MIS 5a (early Vistulian). In addition dry valleys are common landforms here, characterized by a distinctive hierarchical fourth-order tributary system, which in configuration have uneven longitudinal sections with numerous widening and narrowing valley floor. Also, in the upper parts of first-order tributaries and at dry valley bottoms there are in-abundance small depressions that once were either filled with open water or existed as bogs that accommodated peat, being independent of interconnection or intercommunication along their way. Northeastern Poland's MIS 5a to MIS 4 transition is marked by a drastic change in water body conditions, and correspondingly there is a geomorphic adjustment to dry and river valley system structure. During MIS 5a (middle Odderade Interstadial), the mean July temperature rose from about 12°C (the older Odderade Interstadial) to >13°C, which was accompanied by the spread of pine, spruce, and larch. Afterwards, both summer and winter temperatures gradually decreased as signalled by a further transformation of vegetation cover. That change in flora indicates the emergence of a cold continental climate with a lowering of both temperature and evaporation, which was accompanied by a rising water table. Some water bodies experienced a change in sedimentation from gyttja and organic mud accumulation to that of clayey-silty deposits. Pollen succession occurrences that extend into the Schalkholz Stadial are sporadic, their presence being limited to the occasional water body. Abundant small water bodies inside dry valleys then become drained for the first and only time, with contemporaneous erosion reaching the underlying MIS 5e (Eemian Inerglacial) deposits. Some dry valleys were transformed into rivulets that then drained the previously endoheiric depressions within them. Eemian Interglacial deposits formed along present river bottoms but are today rarely preserved on river valley slopes. Aeolian processes had activated in northeastern Poland, but any associated wind transport occurred on a small scale with limited aeolian deposition mostly occurring in valleys. A research was supported by the Polish National Science Centre (No. UMO-2013/09/B/ST10/02118).

Northern Cordilleran Ice Sheet displays a diachronous response to MIS 4 forcing, Yukon Territory, Canada

Brent Ward¹, Jeffery Bond², Derek Cronmiller³, Derek Turner⁴, John Gosse⁵, Britta Jensen⁶, Duane Froese⁶

¹Earth Sciences Simon Fraser University, Burnaby, BC, Canada. ²Energy, Mines and Resources, Yukon Geological Survey, Whitehorse, Yukon, Canada. ³Department of Earth Sciences, Simon Fraser University, Burnaby, BC, Canada. ⁴Earth and Environmental Science, Douglas College, New Westminster, BC, Canada. ⁵Earth Sciences, Dalhousie University, Halifax, NS, Canada. ⁶Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Abstract

Yukon Territory has been repeatedly affected by the northern Cordilleran Ice Sheet (CIS). This complex of coalescing ice lobes sourced from separate mountain ranges, produced irregular, digitate, horseshoe-shaped glacial limits on the plateau area of Yukon. Many of these ice lobes had separate source areas and dynamics but three broad, mappable, chrono-geomorphic regions have been defined that were thought to represent regionally coherent advances of the CIS. The intermediate mapped limits were thought to represent a single glaciation, but our results show in central Yukon it is MIS 6 while in SW Yukon it consists of 4 and 6.

Central Yukon was affected by west-flowing ice from the continental divide. Previous age estimates for the penultimate glaciation were MIS 6, largely based on an interglacial soil developed on these deposits. This MIS 6 age is confirmed by the presence of Old Crow tephra (124 ka) above deglacial outwash along the Pelly River. There is no evidence for a MIS 4 glaciation that is more extensive than MIS 2. The MIS 2 limit is >100 km to the east of the MIS 6 limit. Much older glaciations extended up to 115 km to the west of the MIS 6 limit.

SW Yukon was affected by north and eastward flowing ice from the Coast and St. Elias mountains, respectively. Near where the Coast Mountains and St. Elias ice coalesced, cosmogenic ¹⁰Be ages on boulders of 54-51 ka (n=4) on penultimate drift indicate this limit is MIS 4. This is the first confirmed MIS 4 glaciation in the Canadian Cordillera. Recent mapping in the area suggests that the MIS 4 advance was comparable in extent to the MIS 6 advance. This mapping also indicates that ice caps and cirques may have contributed substantially to the local extent of late Pleistocene limits and could account for the local all-time limit corresponding to MIS 4 advance.

Further west the chronology provided by tephtras from sections exposed near the all-time limit along the White River, confirms that the MIS 4 limit is nearly identical to that of the MIS 6 glaciation. Here the MIS 2 limit is 15-20 km further upstream.

Thus, there is a dichotomy between the extents of MIS 4 glaciation from different source areas for the northern portion of the CIS, indicating different glaciological responses to this climatic forcing. The northern CIS was a precipitation-limited system. We propose that variation in regional precipitation, specifically how moisture penetrates the coastal mountains, is a possible cause for the observed differences between glacial advances in different source areas. Causes for this regional variation in precipitation will be discussed.

Diverse records of Quaternary mammals, water isotopes and plant communities during MIS 4 across eastern Beringia

Duane Froese¹, Alberto Reyes¹, Britta Jensen¹, Kasia Staniszewska¹, Grant Zazula², Trevor Porter³

¹University of Alberta, Edmonton, Canada. ²Government of Yukon, Whitehorse, Canada. ³University of Toronto, Mississauga, Canada

Abstract

The penultimate cold stage, MIS 4, is well represented across the unglaciated region of interior Yukon and Alaska or collectively eastern Beringia. At sites from the Klondike to Fairbanks, the Sheep Creek-K tephra-K (SCt-K) and Dominion Creek tephra (DCt) are present, and mark the transition from MIS 5a to MIS 4 at ca. 70-80 ka BP. These tephra also provide a means to correlate paleoenvironmental records between sites. The most abundant sites are in the Klondike region, where SCt-K/DCt are preserved in syngenetic loessal silts (or yedoma-like deposits) that have been preserved in relict permafrost since deposition. These deposits include meteoric waters in pore ice and wedge ice, soils, and plant macroremains, along with diverse and abundant Quaternary mammals dominated by horse, bison and mammoth. Paleoenvironmental analyses of fossil arctic ground squirrel middens, in direct association with SCt-K/DCt indicate a cryoxerophilous (steppe-tundra) vegetation growing on well-drained substrates with deep active layers during MIS 4, functionally similar to MIS 2. Water isotopes from pore ice and wedge ice reflect meteoric precipitation, and have values of -215 to -235‰ (d2H) and -28 to -32 ‰ (d18O), suggesting temperature depressions of more than 10 degrees C relative to modern. The broad functional similarity between MIS 4 and MIS 2, reflected in water isotopes, sedimentation, faunal communities and vegetation suggests the regular appearance of the mammoth-steppe biome in eastern Beringia through cold stages of the late Pleistocene.

The Last Interglaciation and unique stature of MIS 4 in central North America

Ben Curry^{1,2}, Jeffrey Dorale^{3,4}

¹Illinois State Geological Survey, Champaign, USA. ²University of Illinois, Urbana-Champaign, USA. ³Department of Earth & Environmental Sciences, Iowa City, USA. ⁴University of Iowa, Iowa City, USA

Abstract

Continuous paleoecological records in kettle basins in Illinois, U.S.A., provide evidence of climate change during the waning of the penultimate glaciation (Illinois Episode) to the onset of the last glaciation (Wisconsin Episode). Traditionally, North American stratigraphers use the occurrence of loess and/or till as the basis for glacial episodes. At 38-42 °N, glacial episodes in the interior of North America are also marked in lake records by abundant *Picea* pollen and *Limnocythere friabilis* (ostracod) valves. Combined pollen and ostracod DCA analyses of three continuous records (Raymond, Bald Knob, and Pittsburg basins) have eigenvalues of 0.54 and 0.26 explained by temperature and relative moisture, respectively. Last Interglacial (Sangamon Episode) warm-wet periods feature abundant deciduous tree pollen and benthic ostracods, whereas Sangamon Episode warm-dry periods feature plant groups that tolerate drought and thrive on mudflats and nektonic ostracod species that crawled or swam amongst aquatic vegetation, indicating relatively shallow water. The nature of the contact between Illinois and Sangamon Episode deposits is abrupt, whereas the Sangamon-Wisconsin contact is gradual, characterized by increasing *Picea* and *L. friabilis* abundance beginning at about 55 ka.

The precise chronology of the Sangamon Episode biozones is based on wiggle matching of interval values of the 2nd DCA axis (moisture) from Raymond Basin with the well-dated $\delta^{13}\text{C}$ speleothem record of Crevice Cave, Missouri (located ca. 170 km SW of Raymond Basin). Not surprisingly, a notable “pacemaker” of changes in vegetation and relative moisture is insolation. In general, our wiggle-matching correlations are vetted by ages determined from fifteen SAR OSL analyses of quartz subsampled from outcrops and sediment cores from Raymond Basin.

The most striking result of the new chronology is that what would traditionally be interpreted as the wettest, warmest interglacial climate period (marked by abundant *Liquidambar* and *Fagus* pollen) occurred from 76-71 ka, with a peak in these conditions from 74-72 ka during early MIS4. The ostracod evidence for this period suggests winters were non-freezing, unlike modern climate. Additional evidence for warm winters are fossils of *Hesperotestudo crassiscutata* (an extinct large tortoise) at nearby Hopwood Farm. This paradox can be partly resolved by considering high winter insolation values during this time, but likely also requires that atmospheric circulation during this unique interval excluded incursions of arctic air into the region as occurs today. We suggest a strong southerly flow of air from the Gulf of Mexico that fed a rapidly growing ice sheet to the north, and bathed Illinois in moist and year-round warm conditions. These unique conditions lasted for about 5,000 years before climate shifted to a more continental mode and non-analog biotic assemblages from 71 to 55 ka, corresponding to the remainder of MIS4 and onset of MIS3.

“Patchwork” loess of Central Asia: A high-resolution spatio-temporal record of Pleistocene palaeoclimatic variability in piedmont loess along the Northern TienShan

Aditi Krishna Dave¹, Giancarlo Scardia², Lenke Lisá³, Charlotte Prud'homme¹, Kathryn Fitzsimmons¹

¹Max Planck Institute for Chemistry, Mainz, Germany. ²Instituto de Geociências e Ciências Exatas, Universidade Estadual Paulista (UNESP), Rio Claro, Brazil. ³Institute of Geology, Czech Academy of Sciences, Prague, Czech Republic

Abstract

Loess deposits are important terrestrial archives for palaeoclimatic reconstruction, especially in arid and semi-arid continental regions. The Central Asian loess deposits lie in a dynamic climatic zone under the influence of the mid-latitude westerlies and north-south shifting polar fronts, and at the peripheric influence of the Asian monsoon from the south. The loess deposits that blanket the piedmonts of the Asian high mountains in this region are relatively widespread and relatively thick, and therefore provide us with an invaluable archive for understanding the relationships between loess accumulation, palaeoclimate and topography within continental, arid and high terrain environments.

However, contrary to popular perception, the Central Asian loess deposits are neither evenly distributed along the piedmonts nor uniform in thickness, and vary in age and the timing of peak accumulation phases substantially. Here we present an integrated, high resolution chronostratigraphic record from seven loess sites from a 250 km east-west transect along the tectonically active piedmont of the Northern Tien Shan, southeast Kazakhstan, thus, demonstrating the importance of spatial as well as vertical palaeo-investigations of aeolian deposits in this region. Our dataset is based on grain-size analysis and magnetic susceptibility, set within a robust and absolute chronological framework using multiple luminescence dating approaches. We find that in addition to chronostratigraphic variability between the sites, the magnitude and peak of loess accumulation rates varies substantially along the Tien Shan range front. There is significant variation in the timing of loess deposition across the piedmont from west to east, with the western end dominated by late Pleistocene deposits contrasting with mid-Pleistocene deposits at the eastern end. These findings suggest non-uniform and asynchronous deposition of loess through time. Thus, the inter- and intra-variability between sites along the piedmont allow us to develop an integrated approach to study the influence of climate and topography on loess formation processes and accumulation.

Furthermore, we integrate our record with other existing loess datasets from the Ili basin in southeast Kazakhstan and China to develop a conceptual spatio-temporal model for aeolian dynamics along the loess piedmont of the Northern Tien Shan.

Unraveling residence time and migration history of aeolian deposits by combining cosmogenic nuclides and luminescence data into a unified model

Shlomy Vainer, Yoav Ben Dor, Ari Matmon
The Hebrew University of Jerusalem, Jerusalem, Israel

Abstract

Luminescence-based dating methods are usually applied to date episodic events in the history of aeolian sand deposits. These methods are restricted to the late Quaternary, and only reveal the last cycle of sediment burial. Burial ages modeled from cosmogenic nuclides, on the other hand, reach further back in time but are usually inferred as the minimum residence time of sand in the landscape. An approach that integrates luminescence dating and cosmogenic burial dating into a unified model was developed to reconstruct the migration history of sand and to constrain the timing of sand introduction to the landscape (Vainer et al., [Quaternary Geochronology, 2018](#)). The coupling of the two dating methods extends the time-scale and possible interpretation compared to their individual applications. Published luminescence ages from a large array of sand deposits are converted in the model to empirically-determined vertical displacement rates. These rates are consequently used to simulate migration of quartz grains through a sand column, simultaneously with the accumulation of cosmogenic nuclides. Each simulation is terminated when the modeled concentrations of ^{26}Al and ^{10}Be reach analytically measured concentrations of actual sand samples. Model results show that optically stimulated luminescence ages, which range in the order of 1-100 ka, only reflect the last cycle of sand migration, whereas cosmogenic nuclides indicate sand residence time over 1 Ma. The application of the model to samples collected from the Kalahari Erg in southern Africa indicates that most of the sand was introduced to the Kalahari during the Late Pliocene to Early Pleistocene, concurrent with the regional environmental framework. Furthermore, this empirical data-based approach allows quantifying migration-related processes such as the amplitude and periodicity of sand recycling. Our model reveals that since the Kalahari Sand was available for aeolian migration, it was exposed to the surface 22 times, on average. The presented model provides a powerful tool for estimating the emergence of sand in a given landscape, and also for understanding the dynamic evolution of any sand field and the mechanisms behind aeolian sand migration.

Past changes in erosion in antipodal active orogens – unsurprisingly, French and New Zealanders disagree

Anthony Dosseto¹, Alexander Francke¹, Samuel Toucanne², Matthew Ryan³, Sally Carney¹, Patrick Wilcox¹

¹University of Wollongong, Wollongong, Australia. ²IFREMER, Brest, France. ³Victoria University of Wellington, Wellington, New Zealand

Abstract

Mountains erode. A lot. And fast. But what happens in the context of Quaternary climate change is much less understood. This is mostly because of the lack of proxies for reconstructing past changes in catchment erosion. Uranium isotopes (^{234}U and ^{238}U) are sensitive to the mechanisms of hillslope erosion (shallow sheet wash vs mass wasting) and the rate of sediment transport. Thus, a high $^{234}\text{U}/^{238}\text{U}$ denotes deep hillslope erosion and rapid sediment transport. Applying this tool to sediment records could help us understand how catchment erosion responds to climate variability. We have applied this approach to two marine cores collecting sediment from two antipodal active orogens: the French and New Zealand Alps.

In the Mediterranean Sea, turbidite sequences record 75 kyr of erosion in the Var River catchment, which drains a portion of the southern French Alps. Uranium isotope ratios of these sediments show higher values during the Last Glacial Maximum, followed by a decrease in the Holocene. This suggests that glacial erosion was resulting in the production and rapid export of sediments, while during pluvial conditions shallower erosion and slower sediment transport were taking place.

A marine core of the west coast of New Zealand's South Island shows contrasting results. Here, the record spans the last 200 kyr, and the lowest uranium isotope ratios correspond to glacial stadials. In this case, this suggests that erosion was shallower and/or slower, compared to interstadials. While glacial cover was more extensive during these periods, it is possible that the sediment produced was not exported, only to be delivered to the Tasman Sea during the following interstadial. Taken together, these results show that rugby is not the only source of disagreement between French and New Zealanders. The response of mountainous catchments to Quaternary climate variability is complex, and the application of novel isotopic proxies, combined to other approaches, should shed the light on this complexity.

O-2221

Numerical tracking of cosmogenic nuclides during sediment erosion and transport in glacial landscapes

Dirk Scherler^{1,2}, David Egholm³

¹GFZ German Research Centre for Geosciences, Potsdam, Germany. ²Freie Universität Berlin, Berlin, Germany.

³Aarhus University, Aarhus, Denmark

Abstract

In steep mountain ranges, glacier surfaces often carry rocks and boulders that largely stem from erosion of ice-free bedrock hillslopes. Similar to river sediment, the concentration of cosmogenic nuclides, such as ^{10}Be , in supraglacial sediment can, in principle, be used to infer erosion rates. However, supraglacial sediment has been exposed to cosmic rays during its exhumation on the hillslope as well as during transport within and on top of the ice. Furthermore, cosmogenic nuclide production rates vary strongly with elevation, and glaciers do not mix sediment as efficiently as rivers. Therefore, sampling of supraglacial sediment and converting cosmogenic nuclide concentrations to erosion rates is challenging.

Here, we present a new approach for tracking cosmogenic nuclides during sediment erosion and transport in glacial landscapes. We implemented Lagrangian particle tracking (LPT) in the coupled ice- and landscape evolution model iSOSIA and applied the model to the Chhota Shigri Glacier in India. With each particle, we store its birthplace and its cosmogenic nuclide concentration, which gets altered during transport. This enables us to identify distinct source areas and cosmogenic nuclide production rates for sediment that is found in different parts of the glacier surface. Model results from transient simulations of the Chhota Shigri Glacier during phases of advance and retreat, reveal changing cosmogenic nuclide concentrations due to mixing of sediment from different source areas (with different production rates), despite uniform erosion rates. We furthermore used the model to test if different erosion laws for steep bedrock hillslopes produce distinct patterns in cosmogenic nuclide concentrations. Although our existing samples from the Chhota Shigri Glacier do not help distinguishing different erosion laws, because the limited altitudinal range of the source area, new samples from elsewhere on the glacier may do so. Our approach provides new ways to prepare a sampling campaign and helps interpreting measured cosmogenic nuclide concentrations in supraglacial sediment.

An empirically tuned simulation of the last British-Irish Ice Sheet: Comparison to evidence and implications for landscape evolution

Jeremy Ely¹, Chris Clark¹, Richard Hindmarsh², Sarah Bradley³, Edward Gasson⁴, Lauren Gregoire⁵, Niall Gandy⁵, BRITICE-CHRONO Consortium¹

¹The University of Sheffield, Sheffield, United Kingdom. ²British Antarctic Survey, Cambridge, United Kingdom. ³Delft University of Technology, Delft, Netherlands. ⁴University of Bristol, Bristol, United Kingdom. ⁵University of Leeds, Leeds, United Kingdom

Abstract

Palaeo-ice sheets provide us with a long-term record which enables us to better understand how ice sheets behave, influence the landscape and respond to climatic changes. The extent and dynamics of palaeo-ice sheets can be inferred by two methods: i) empirical reconstructions based on evidence left behind by an ice sheet; and ii) numerical ice sheet models based on the known physics of ice sheets. The ideal would be to reconcile these approaches, enabling empiricists to utilise model physics and modellers to compare to data. Here, we demonstrate an approach to simulating the last British-Irish Ice Sheet (BIIS) which draws upon empirically based knowledge of ice sheet extent. A novel climate forcing is used, which combines reconstructed palaeo-ice sheet surfaces with output from global climate models, to direct the simulation towards empirically reconstructed ice limits. The simulation takes output from a glacio-isostatic adjustment model, which is calibrated against relative-sea level records, as input for basal topography. To explore the uncertainty of ice-flow parameters we perform an ensemble experiment and consider different schemes for determining basal conditions. Members of the ensemble are compared to three sources of data, the particulars of which require three separate tools: i) geochronological data, recording the timing of ice-free conditions; ii) flowsets of subglacial bedforms, recording ice flow direction; and iii) the position of moraines, recording ice-margin position and shape. These comparisons enable us to quantify the fit between the simulation and data. For places or times where the fit is poor this could be a basis for questioning the empirical data or interpretations. Our best-fit simulation represents the dynamics of the BIIS as it grows, joins with the neighbouring Fennoscandian Ice Sheet and then deglaciates, capturing ice stream locations, potential ice-shelves and grounding-line positions. Furthermore, the simulation enables us to infer the likely glaciological conditions that existed during the deglaciation of the BIIS, which we would be unable to estimate from an empirical reconstruction alone. These enable us to better understand landform genesis, subglacial processes and landscape evolution during the operation of the BIIS.

First luminescence dating of flash-flood gravel clasts: Deposits from draining of glacial Lake Missoula, Montana, USA

Larry Smith¹, Reza Sohbati², Andrew Murray³, Mayank Jain²

¹Geological Engineering, Montana Tech, Butte, USA. ²Center for Nuclear Technologies, Technical University of Denmark, Risø Campus, Roskilde, Denmark. ³Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Risø Campus, Roskilde, Denmark

Abstract

Paleoflood deposits are used to reconstruct flood magnitudes and frequencies along streams for events that occurred in recent, historical, or ancient past. Paleoflood hydrology must include reliable ages of flood-transported deposits. Large floods commonly carry coarse clasts, such as cobbles and boulders where preservation of datable material requires unusual circumstances.

Here we test the applicability of infrared stimulated luminescence (IRSL) rock surface dating techniques to measuring burial ages of flash-flood transported gravel. A key requirement for the technique is that the luminescence signal, developed during exposure of fluvial cobbles to ionizing radiation, must have been bleached within clasts prior to burial. For short-term flood events, bleaching would likely occur only prior to entrainment. Examination of the IRSL-depth profile across the rock surface helps to discriminate those cobbles which were sufficiently exposed to daylight prior to entrainment thus providing the true burial age. Thus, this technique of measuring clast burial ages has the potential to both date flood events and to evaluate sediment routing during flood events based on the degree of prior bleaching.

Glacial Lake Missoula formed during Pleistocene glacial impoundment of the Clark Fork River in a bedrock canyon near the present border of Idaho and Montana in the northwestern United States. During one or more megafloods, a gravel bar with >10 m tall cross stratification and open-work fabric, formed on the downstream side of a bedrock hill. The gravel deposit is about 170 m above flood-eroded bedrock in the valley floor and about 250 m below the maximum water level attained by the lake. From a pit dug after sunset, cobbles were sampled and placed in light-tight bags. Eight oblate, subrounded clasts were selected, as these would tend to rest so as to expose one of the two sides.

Each of the flat surfaces was cored and sectioned into ~1mm-thick disks under darkroom conditions. IR₅₀ SAR protocol was used to measure the IRSL profiles. Two of 8 cobbles showed no light exposure, 4 showed limited light exposure, and at least one surface of 2 cobbles were sufficiently bleached before burial. Data from additional cores resulted in mean estimated doses of 58.5±2.5 Gy and 50.6±2.9 Gy. Environmental dose rates for the two cobbles and one matrix sample were measured using high-resolution gamma spectroscopy. Using two fading correction methods, field saturation-laboratory saturation ratio and g-values respectively, comparable burial ages were calculated for each cobble, 13.9 ±0.8 ka or 14.8±1.8 ka and 25.8±1.8 ka or 24.5±3.9 ka. The younger age is consistent with a late-stage catastrophic draining of the lake, whereas the older age likely represents an inherited age of a previously buried fluvial clast. These preliminary results suggest flash flood deposits are amenable to dating.

A centennial-scale cyclicity of flood events in the Peruvian Andes as recorded in fluvial deposits

Willem Viveen¹, Jorge Sanjurjo-Sanchez^{2,1}, Leonardo Zevallos-Valdivia^{3,1}

¹Grupo de Investigación en Geología Sedimentaria, Departamento de Ingeniería, Pontificia Universidad Católica del Perú, Lima, Peru. ²Universidad de A Coruña, A Coruña, Spain. ³Universidad Nacional de San Agustín de Arequipa. Facultad de Geología, Geofísica y Minas, Arequipa, Peru

Abstract

The Huancayo basin the Peruvian central Andes contains an extensive flight of fluvial terraces belonging to the Mantaro and Cunas Rivers. Terrace mapping revealed the presence of seven main levels and locally 11 terraces in the Cunas valley and five main levels in the Mantaro valley. The highest terrace level is located at 34 m above the local floodplain (+FP) level. A reconstruction of longitudinal profiles reveals that the terraces trend parallel to one another and made it possible to correlate the terraces of both river valleys. The Mantaro T5 level located at 34 m +FP is cut in lacustrine sediments indicating that at the time of terrace formation, the Huancayo basin was a lake. Twenty-two samples for luminescence dating were extracted from several terrace levels as well as eight samples for radiocarbon dating. The results showed that the lacustrine sediments were deposited between ~ 12.000 and 4418 ± 500 years ago, after which the Mantaro and Cunas Rivers incised and formed their terraces. The onset of valley incision and terrace formation is coeval with the onset of a higher frequency of South American Summer Monsoon (SASM) events, as evidenced by speleothem, lake and glacier records in the region. The other terrace levels, however, were formed after 2245 ± 217 years ago coinciding with an intensification of SASM events to heights that had not occurred since the early Holocene. Dating of the other terrace levels revealed that deposition of fluvial sediments occurred approximately every 250-300 years between 2245 ± 217 and 1188 ± 60 years ago. After that until the present the frequency of deposition increased to once every 150 years. The timing of fluvial sedimentation can be correlated to peaks in precipitation as registered by the aforementioned paleoclimatic archives. We postulate that the increases in precipitation resulted in large flood events in the region. A comparison with existing literature shows that the onset, frequency and timing of sedimentation events occurred synchronously in Peruvian river valleys extending from at least 10° to 18° S latitude. Those events were formerly attributed to the El Niño Southern Oscillation (ENSO), but since these are events with an interannual frequency, we dismiss ENSO as a controlling factor. Instead, we propose that changes in the temperature of the North Atlantic surface waters are responsible for the sedimentation events.

O-3000

Understanding the warm climates from past interglacials to the future

Qiuzhen Yin

Earth and Life Institute, Georges Lemaître Center for Earth and Climate Research, Université catholique de Louvain, Louvain la Neuve, Belgium

Abstract

Given the predicted future warming and that we presently live in an interglacial (the Holocene), past interglacials are of particular interest to understand better the climate processes characterizing the warm climate conditions. In my study, the climate response to insolation and CO₂ during the interglacials of the past 800,000 years are investigated by using climate models. My simulations show that the relative contributions of insolation and CO₂ to the intensity and duration of each interglacial vary from one interglacial to another. They also show that CO₂ plays a dominant role on the variations of the global annual mean temperature and of the climate in the Southern high latitudes, whereas, insolation plays a dominant role on the variations of monsoon precipitation, vegetation and the climate in the Northern high latitudes. Compared to the projected future climate, the past interglacials are cooler during boreal winter, but are warmer over the continents during boreal summer due to their much higher summer insolation. This suggests that the sensitivity of climate to the latitudinal and seasonal distribution of insolation must be kept in mind for the climatic projection at the century-millennium time scales. My results underline the diversity of the warm climates of the last million years and therefore the potential but also the difficulty to find exact analogues for our interglacial and its future. They show that the best analogue to the Holocene and its future depends critically upon the criteria used to select such an analogue.

O-3001

Geochronology of Late Pleistocene Paleohydrological Extreme Events in Upper and Middle Don River Basin

Ekaterina Matlakhova

Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

The relicts of large meandering palaeochannels (macromeanders) are found in the river valleys of the East European Plain. Channel widths of macromeanders are few times (sometimes up to 10-15 times) larger than the recent meanders of the same rivers. Such macromeanders are spread globally in the temperate climate zone of the Northern Hemisphere. Formation of large paleochannels is usually associated with Late Glacial (the end of MIS 2), however there are some evidences of formation of such landforms in earlier times (MIS 3).

The main aim of our study is establishing of absolute chronology of large paleochannels formation and periodization of the phase of extremely high river flow in Don River basin.

We studied a few key sites in Don River basin: Upper Don river valley near Epifan town (Tula region), Khoper and Vorona river valleys near Borisoglebsk town (Voronezh region) and Savala river valley near Savalskiy settlement (Tambov region, Russia). On these key sites rivers have wide floodplains with big paleochannels on their surface, which were the main subject of our study. These paleochannels are the signs of high flood activity epoch(s).

In our research we used a number of field and laboratory methods: hand and mechanical coring, examination of natural exposures, topographic profiling; radiocarbon (including AMS) and OSL dating, spore-pollen analysis. Also we made the reconstructions of paleo-discharges of the studied rivers based on paleochannels' parameters.

Data analysis shows that river incision was detected about 30-35 ka BP. Before LGM rivers had already been incised down to the modern river levels or deeper. LGM time was characterized by cryoaridic conditions, low runoff and accumulation in the river valleys. After LGM the high runoff epoch started, which was dated 13-19 ka BP. In that time large meandering palaeochannels (macromeanders) and modern wide high floodplains were formed in the river valleys. Our data shows that this epoch of high runoff was interrupted by a short low runoff period (~15-16 ka BP). So the Late Pleistocene epoch of high floods and large paleochannels formation had two periods – about 17-19 ka BP and 13-15 ka BP. Runoff in Holocene was lower than in Late Pleistocene.

This study contributes to the Russian Foundation for Basic Research (RFBR) Project № 18-35-00028 "Geochronology of extreme hydrological events in Don river basin in the end of the Pleistocene".

Stratigraphy proves scores of last-glacial Missoula jökulhlaups through high tracts of Channeled Scabland

Richard Waitt

Cascades Volcano Observatory, US Geological Survey, Vancouver, WA 98683, USA

Abstract

About 90 late Wisconsin Missoula-flood beds each separated by varved beds prove that each gigantic Missoula flood—peak discharge as much as 25 million m³/s—lays but one major graded bed. Critics have for many years billed the evidence for repeated Missoula floods as being only low-energy deposits confined to low routes. But stratigraphy of high-energy gravel bars and backflood deposits also show that numerous great floods swept down high scabland tracts such as the Cheney-Palouse.

At least 25 separate gravel-bearing floods backwashed from the Cheney-Palouse into Willow Creek. Rhythmic backflood beds in Tucannon valley also record at least 25 floods down the Cheney-Palouse. Rhythmic beds record at least 21 separate Cheney-Palouse débâcles backflooded far up Snake valley. Intercalated 16 ka Mount St. Helens ash shows these many Cheney-Palouse floods were the same as had backflooded lower-level Walla Walla and Yakima valleys.

At least 14 floods invaded high Priest valley. Pine Coulee exposes at least 12 flood beds near the upper limit of Missoula flooding into the Cheney-Palouse. Moses Coulee, whose high intake is hard to flood, passed at least 5 gigantic ones. At least 62 floods backflooded lower Yakima and Walla Walla valleys; at least 15 of them need at least 500 km³ of water hydraulically ponded behind kilometer-wide Wallula Gap. From Columbia gorge at least 17 floods swept far up John Day valley. At least 22 mighty floods swept from broad Portland basin over Lake Oswego trough into Tualatin valley. At least 40 débâcles via Portland basin backflooded tens of kilometers up Willamette valley.

Thickening Purcell Trench ice dammed early Lakes Missoula that released giant floods once every few to several decades. Farther west advancing Okanogan ice closed three huge floodways before recession reopened one. This changing geography shifted routings and discharges of successive floods down different distributaries. As Purcell Trench ice then dwindled over centuries, it held in smaller glacial Lakes Missoula that released smaller floods more often.

Earlier 1-D hydraulic modeling suggested 2500-km³ glacial Lake Missoula sufficed under different routing patterns to flood several main channels of the Scabland and Columbia valley. New 2-D models governed by shallow-water-flow equations largely concur that successive Missoula débâcles under changing geographic conditions flooded high scabland tracts. Stratigraphy, geomorphology, and modeling all together show that Missoula megafloods under the different settings swept the Channeled Scabland and Columbia valley nearly up to the limits of field evidence. Channels blocked in succession gave different channels peak discharges during different floods. No one Missoula flood, no matter how immense, could inundate all floodways at once up to the limit of evidence.

Chronology of Pleistocene ice-dammed lake outburst floods in the Altai Mountains, Siberia - first new data

Juergen Herget¹, Anna Agatova², Andreas Lang³, Roman Nepop²

¹Dept. of Geography, Bonn University, Bonn, Germany. ²Dept. of Geology, RAS, Novosibirsk, Russian Federation.

³Dept. of Geography, Salzburg University, Salzburg, Austria

Abstract

In the late Pleistocene, some of the largest floods in the world took place in the Siberian Altai Mountains. In the headwaters of the River Ob, advanced valley glaciers blocked the course of the River Chuya and formed ice-dammed lakes that repeatedly drained by catastrophic outburst floods. As discussed below, previous reconstructions resulted in more or less consistent scenarios of the timing and dynamics of the regional Pleistocene glaciation being the main trigger of the events. Methodological and technological progress in dating techniques have improved knowledge of the temporal dynamics but also increased the uncertainty due to an increasing number of contradictory data. This uncertainty has led some to doubt some previous findings of the chronology of the glaciation and related outburst floods in the Russian Altai Mountains. By the application of state-of-the-art techniques for different dating methods by experts in the field we want to improve the knowledge of the temporal and spatial dynamics of the outburst floods as indicators of the glaciation in the area, which might be seen as a key location for Central Asia.

Pleistocene megafloods in an incised-valley system. The lower Ebro River

F. Xavier Castelltort¹, J. Carles Balasch¹, Jordi Tuset², David Pino³, Mariano Barriendos⁴

¹Department of Environment and Soil Sciences, Universitat de Lleida, Catalonia, Lleida, Spain. ²Hydrology Group, Forest Sciences Center of Catalonia, Solsona, Solsona, Spain. ³Department of Physics (UPC) & Institute of Space Studies of Catalonia (IEEC), Barcelona, Spain. ⁴Department of History and Archaeology, University of Barcelona, Barcelona, Spain

Abstract

The Móra Basin is a small marginal sedimentary basin located near the south-eastern margin of the Ebro Basin formed during the Paleogene Alpine Compression in the domain of the Catalan Coastal Ranges. The Low Ebro River flows through the Móra Basin from north to south. Both the entrance to the basin and the outlet incise into Mesozoic carbonates which have originated two gorges, El Pas de l'Ase in the north and L'Estret de Barrufemes in the south. Every of both channel constrictions produces a significant backwater effect. The Comte Stream flows into the Ebro River from the left just before L'Estret de Barrufemes. At this point, the Ebro Delta is about 50 km far.

Just before the narrowing of L'Estret de Barrufemes there exist at least five Ebro River terraces. The aim is on the two lower units which are into the lower valley of the Comte Stream. Unit Two is made up of fluvial multistorey clast-supported, polygenic rounded conglomerates, and sandstones. The lower Comte Stream, near its mouth, incises into this unit which is at this point 17 m thick. Upstream, this unit forms the stream channel floor. It is incised and unconformably overlain by a multistorey layer 15 m thick of gravels and sands from the Unit One, preserved in the stream riverbank. The Unit stacks over the Unit Two. An outcrop of both units reaches until 3.5 km upstream from the Comte Stream mouth and near 40 m over the current Ebro River. At this point, slackwater deposits of cross-laminated sands and sandstones from both units finish the fluvial sediments into the Comte Stream channel.

The hydraulic behaviour in the Comte Stream mouth, influenced by flood waves of the Ebro River arriving at L'Estret de Barrufemes and their related deposits are the core matter of the research. The interpretation of the Comte Stream deposits is made on the basis of sequence stratigraphy. It comprises the analysis of deposits properties and textural features and their vertical and lateral relations. Therefore, on the one hand, the different units have been characterised to deduce fluid dynamics and sediment transport processes, and on the other hand, stratigraphical relations between units have been established. The analysis focuses on the two lower units which are those which flowed into the current Comte Stream channel but not dismissing the older fluvial units. It is significant to emphasise that the Lower Ebro River in the Móra Basin is an incised fluvial system influenced by marine base-level changes and the megaflood deposits were placed in a setting of the rising base level.

Morpho-stratigraphic characteristics and Late Quaternary environmental evolution of the Salado–Juramento fluvial megafan, Chaco Plain, Argentina

Belen Thalmeier^{1,2}, Daniela Kröhling^{1,2}, Ernesto Brunetto^{3,4}, Martin Iriondo¹

¹CONICET, Santa Fe, Argentina. ²Universidad Nacional del Litoral, Santa Fe, Argentina. ³CICyTTP-CONICET, Diamante, Argentina. ⁴Universidad Autónoma de Entre Ríos, Entre Ríos, Argentina

Abstract

Morpho-sedimentary data of one of the largest fluvial fans of South America, the Salado-Juramento megafan (ca.185,000 km²), are presented. It is one of the six megafans of the Chaco aggradational plain, representing part of the foreland basin along the eastern flank of the Central Andes. The applied methods combine assessment of landforms and processes and geomorphological mapping from remote sensing images analysis and field data. The lack of exposed stratigraphy across the flat megafan surface and the sub-environments complexity conducted to a program of research boreholes. Sedimentological analyses of cores were performed by laser diffractometry, optical microscopy and DRX; also geochemical data and OSL datings were obtained. The surface of the Andean basin of the formative transverse river of the megafan is 38,000 km². The river undergoes large seasonal fluctuations in discharge (from ca. 30 to 2,000 m³/s) that result from monsoonal precipitation (South American Monsoon System), with high sediment yields favouring an avulsive dynamic. The longitudinal profile of the megafan is upward concave, with gentle slopes (0.18–0.01°) and maximum width and length of 150 km and 650 km respectively. Aggradation and progradation have been conditioned by flexural and tectonic controls regulating the interaction between the megafan and its axial trunk river (Paraná). The defined nine morpho-sedimentary units of the megafan and the ten sub-units of its distal zone represent the complexity of subenvironment interactions produced by different processes. Fan-shaped depositional lobes and a radiating network of palaeochannel belts are typical landforms. Flexure and dynamic topography favoured subsidence, avulsion and accumulation, with high potential of preservation of swamp, channel, pond, soil, and loessic facies in the distal zone of the megafan. A Late Quaternary wetland (ca.29,000 km²) occupies this zone preserving high-resolution palaeoenvironmental data. Shallow cores and a 30 m depth borehole (29°10'28"S and 61°11'57"W) conducted to stratigraphic correlations. The representative Pleistocene sequence (19.5 to 6.5 m) is formed by clayey silts accumulated in temporary to permanent swamps with an interbedded hydric paleosoil. A sandy palaeochannel of the megafan was drilled on top of the wetland (6.5 to 5.5 m), covered by a loessic deposit (5.5 to 1.5 m). Late Holocene swamp sediments compose the upper part of the sequence. The palaeowetland deposits are lying on Plio-Pleistocene fluvial sands deposited by the Paraná system (30 to 19.5 m). First geochronological data and regional correlation indicate that Chaco megafans would have reached their maximum development during the MIS 3 and the first part of the MIS 2, and experienced aridity in the LGM. The recent expansion of deforestation and agricultural land on the megafan increased its vulnerability to flooding events. Megafan evolution information is the key to support socio-economic decisions on aquifer exploitation, land uses and infrastructure planning.

Catastrophic Flood Events During Late Pleistocene-Holocene in the Tropical Narmada River Basin, Western India

Alpa Sridhar

The M. S. University of Baroda, Vadodara, India

Abstract

High-energy catastrophic flood events are recorded in response to the abrupt deglacial intensification of the monsoon. Information on long term frequency, magnitude and causes of large floods is necessary for estimation of future floods. The occurrence of floods in the rivers of western India is related to monsoon rainfall intensity and cyclonic activity. The study highlights the geologic record of high-energy discharges in the bedrock reaches of the Narmada River basin. The flood deposits are preserved as huge gravel bars, now incised by small tributaries arising from the nearby drainage divides. The area comprises highly dissected Deccan Trap basalt with plugs of Carbonatite and numerous NE-SW trending lineaments and fractures. Gravel sequences ranging from 5-30m are seen exposed on either side of the tributary, the Banganga. The sequence comprises clast supported gravel (Gcm) overlain by couplets of coarse sand (Sp, Sh) and gravel (Gp, Gh) capped by a thin calcretized fine silt layer. Overlying this are units of coarse massive gravel (Gm), thick calcretized silt, upward graded gravel - sand unit and horizontally stratified sand-gravel couplets (Sh, Gh). The clasts are largely sub angular to sub rounded and up to 50cm in intermediate axis in the basal part of the sequence indicative of short distance transport. The sediment facies assemblage suggests that the deposition of gravel occurred due to hyperconcentrated flood flows followed by vertical accretion of sand deposits during low flow conditions. The rhythmic layering in the upper sequence suggests episodic flooding and rapid recession. The thickness of these units is seen to vary; the maximum being in the central part of the basin as compared to the upper and lower reach. OSL chronology on the silt units that cap the gravel sequences from the central part have provided ages of 12 ± 1 ka, 7.5 ± 1 ka, 3.5 ± 0.3 ka suggesting three distinct episodes of sediment deposition under high-energy discharge conditions. Since the Banganga river itself is short (~10km in length), narrow, with limited catchment and remains dry during non-monsoon months, it is unlikely that such huge pile of sediments could have been transported and deposited by the present-day stream. However, Narmada is a large river and has records for high magnitude flooding characteristics. The post-glacial high energy discharge in the Narmada River could have scoured pathways along the lineaments that run almost perpendicular to the channel in the tectonically active basalt terrain. These scours were then filled with sediments during the spill over during large scale flooding events related to intensified monsoon ~12, 7.5 and 3.5 ka and later on incised by the Banganga River.

A 10,000-year flood record of Sant Maurici Lake, Central Pyrenees

Miquel Angel Calero¹, Lothar Schulte¹, Blas Valero-Garcés²

¹Department of Geography, Barcelona, Spain. ²Instituto Pirenaico de Ecología, Zaragoza, Spain

Abstract

Studies of high-mountain lakes contribute to high-resolution information about the catchment flood dynamics. These catchments respond sensibly to hydrological extreme events because of altitudinal environmental and climatic gradient. Local mountain communities are vulnerable to hydrological extreme events such as flash floods, debris flows and flooding of the valley bottom.

The aim of this study is to identify hydrological extreme events and their provenance through the geochemical and sedimentological imprint of flood layers of the Sant Maurici Lake (42°34'54" N, 1°0'15" E, 0.22 km², 1924 m a.s.l.) located in Escrita Valley, on the southern slope of the Central Pyrenees. The catchment surface is 15.91 km² and the highest elevation is 2950 m a.s.l. at the Subenuix Peak. This study is part of a regional project that focuses on the reconstruction of the climatic variability in the Pyrenees during the Holocene. With the paleoflood data inferred from the Sant Maurici sediments, we expand the information provided by other nearby paleoclimate studies (e.g. lakes Estanya, Enol, Bassa de la Mora).

An 865 cm-long core was retrieved from the Sant Maurici Lake, which covers ~12,000 years. Sedimentological and geochemical analysis include lithology, color, elemental composition, XRF and smear slide observation. Three index are used in order to identify hydrological extreme events: $(Sr + Rb + Zr) / Ca$; $(Sr + Rb + Zr) / Ti$; and $(Ca + Zr) / Ti$. The second index $((Sr + Rb + Zr) / Ti)$ allows us to identify both, the siliciclastic and carbonate flood layers, which were deposited during 10.000 – 10.500 cal years BP (Preboreal) and 3600 – 4000 cal years BP (Subboreal). These two flood episodes show a similar duration ~ 350 years, both separated by ~ 6000 years hiatus and ~45 years mean return periods. We attribute these pulses of increased flooding and deposition in the San Maurici Lake to pulses of storm activity which were reported by several paleoenvironmental studies (fluvial, lacustrine, marine sequences) focused on the Iberian Peninsula and NW Mediterranean Sea. These stormy episodes (~ 1500-year cycle) are related to the displacements of the Westerlies Stream. To conclude, regional changes in the atmospheric circulation system affected environmental conditions of the Sant Maurici catchment.

Abstract

The assessment of seismic hazards along subduction zone coastlines provides important information regarding the frequency and magnitude of earthquakes and tsunamis that can be expected to impact coastal communities in the future. Unlike many subduction zone coastlines that involve one tectonic plate subducting under another, seismic hazard assessments in the Tokyo Region are complicated due to the presence of a nearby triple junction, where one continental (CON) and two oceanic plates (PHS, PAC) collide. The CON/PHS and CON/PAC boundaries are recognized earthquake sources. However, until now, historical and geological evidence of a PHS/PAC earthquake has been lacking. Here we show that two unusually large tsunamis are evidenced by sandy deposits preserved along ~50 km of coastline in the Tokyo Region. The oldest of them, deposited about 1,000 years ago, contains evidence consistent with tsunami deposits reported elsewhere in Japan (e.g., marine foraminifera, rip-up clasts, pebbles, erosional base) and represents a previously unknown prehistoric earthquake. In computer simulations, this earthquake deposited sand that extended too far inland to represent earthquakes originating from the CON/PHS and CON/PAC boundaries. Rather, the greater inland penetration requires interplate thrusting along the PHS/PAC boundary, a previously unconsidered source for earthquakes. This previously unconsidered source has the potential to generate tsunamis that could result in damaging consequences for the Tokyo Region as well as other Pacific Ocean coastlines.

O-3009

Subduction zone paleoseismology in northeast Japan

Yuki Sawai

Geological Survey of Japan, Tsukuba, Japan

Abstract

After 2011 Tohoku disaster, the Japanese government decided to incorporate not only written record-based but also geology-based paleoseismology into long-term forecast of subduction zone earthquakes. In this presentation, I review the recent progress of subduction zone paleoseismology in northeast Japan (Hokkaido and Tohoku regions) and how they have been applied for the long-term forecast.

Along the Pacific coast of eastern Hokkaido, a historically unknown tsunami, so-called “17th-century tsunami”, was revealed by Nanayama et al (2003). Nanayama’s report modeled its source as having both offshores of Tokachi (western Hokkaido) and Nemuro (eastern Hokkaido). Such multi-segment earthquakes were initially considered to recur every 500 years, but the intervals later were reevaluated by Sawai et al. (2009) to vary ranging from 200 to 800 years. The most recent long-term forecast published in 2017 by the government incorporated the variation of the recurrence intervals and recalculated occurrence potentials for subduction zone earthquakes in southern Kuril trench.

In Tohoku region, paleotsunami research began using lacustrine deposits along the coastal area of Japan Sea in the 1980s. After that, in early 1990s, research groups of Tohoku University and Tohoku Electric Power Company identified a tsunami deposit associated with 869 Jogan tsunami, one of the oldest historical tsunamis in Japan. However, National Seismic Hazard Maps for Japan (2005) did not include this tsunami because its source had not been modeled yet. Building on their works, Geological Survey of Japan later proceeded further geological research and modeled its source as having an offshore Sendai source, with a moment magnitude (M_w) of greater than 8.4-8.6, using numerical computer simulations. The government was scheduled to apply this estimation for long-term forecast for subduction zone earthquakes in Japan trench, but the serious disaster occurred about one month before their disclosure.

Megathrust earthquakes at subduction boundaries: Their isotopic signature in remobilized sediment

Cecilia McHugh^{1,2}, Leonardo Seeber², Troy Rasbury³, Michael Strasser⁴, Toshiya Kanamatsu⁵, Ken Ikehara⁶, Kazuko Usami⁷

¹Queens College, City University of New York, Flushing, NY, USA. ²Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA. ³Stony Brook University, Stony Brook, NY, USA. ⁴University of Innsbruck, Innsbruck, Austria. ⁵Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan. ⁶Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, Tsukuba Central, Japan. ⁷Atmosphere and Ocean Research Institute, The University of Tokyo, Chiba, Japan

Abstract

The 2004 Sumatra (Mw9.3) and the 2011 Tohoku-Oki (Mw9.0) megathrust earthquakes and associated tsunamis were close to the upper size limit for such events and had devastating societal consequences. These events are rare so that few are known e.g., M9.4 Alaska 1964, M9.6 Chile 1960, Cascadia 1700 AD. A major objective of submarine paleoseismology is to characterize location, time, and size of large tsunamigenic megathrust earthquakes from their sedimentary record.

Submarine studies of recent well-resolved earthquakes provide precious ground truth, especially post-2011 surveys of the Japan Trench. Short-lived radioisotopes including those from the Fukushima nuclear reactor (excess $x\text{s}^{210}\text{Pb}$, ^{137}Cs and ^{134}Cs) and Sr, Nd and Pb isotopes have permitted to document the thickness and spatial distribution of the sediment remobilized in the 2011 event and by prior earthquakes. Three main sediment transport facies were recognized turbidites, mass-flows (debris flows, slides and slumps) and “homogenites”. Homogenites have been associated with earthquakes in other tectonics settings and have also been documented for the 2011 Tohoku event. In the Japan Trench, “homogenites” are acoustically transparent and they are isotopically homogeneous.

During the *R/V Natsushima* 13-02, 13-19 and *R/V Sonne* 251 expeditions we obtained up to 10m long sediment cores, multibeam bathymetry and subbottom PARASOUND profiles from the upper forearc slope, from a prominent quasi-continuous terrace on the forearc slope and from the Trench. The 2011 sedimentation event is unusually thick and widely distributed from 600 to 8000 m of water depth. The sediment remobilized during the 2011 event is characterized by a large enrichment in $x\text{s}^{210}\text{Pb}$. Revealing that sediment remobilization was restricted to the upper few centimeters To accumulate ~2m thick deposits such as those recovered from the Japan Trench, surficial sediment remobilization had to occur over large areas. Up to 7m thick acoustically homogeneous deposits in other trench cores likely resulted from M~9 paleoearthquakes. The Sr, Nd and Pb isotopic ratios within these acoustically transparent deposits have a narrow range in composition. A similar process, as that of the 2011 event, in which surficial sediment derived from large areas of the seafloor was remobilized seems necessary for such thick and isotopically homogeneous deposits to accumulate. In contrast, the Sr, Nd and Pb ratios of smaller, younger and older turbidites reflects a wide range in isotopic composition as expected from diverse sources. Turbidites and “homogenites” recovered from the Japan Trench also reveal along-trench variability in isotope ratios that can be used to identify sediment sources and thus areas of strong shaking close to earthquake ruptures. These combined results may potentially reveal not only the occurrence of mega-quakes but also the segmentation of the boundary.

O-3011

Earthquake-triggered remobilization of surficial slope sediments: Advancing turbidite paleoseismology in the marine and lacustrine realm

Ariana Molenaar¹, Jasper Moernaut¹, Maarten Van Daele², Marc De Batist², Nathalie Dubois^{3,4}, Michael Strasser¹
¹University of Innsbruck, Innsbruck, Austria. ²Ghent University, Gent, Belgium. ³Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland. ⁴ETH Zürich, Zürich, Switzerland

Abstract

Turbidite paleoseismology aims for improved understanding of earthquake recurrence by studying records of earthquake-induced turbidites in marine or lacustrine basins. However, good process understanding of turbidity currents and turbidites is crucial to reliably evaluate the records' quality and compatibility with other paleoseismological archives. Most studies up to now have assumed submarine landslides and subsequent flow transformation into turbidity currents as the main sediment remobilization process. This raised doubt considering the continuity and sensitivity of turbidite records as landslides only form after critical sediment mass accumulation on an inclined potential sliding surface.

Recent research on turbidite records of Chilean lakes and the Japan Trench suggested the existence of a different remobilization process: earthquake-induced removal of the upper few centimeters at the sediment-water interface (i.e. surficial remobilization) as opposed to sliding of thick (meter-scale) sediment packages. This process may provide for continuous earthquake records as surficial remobilization is less dependent on critical 'recharging' of slope sediment before seismic shaking. Our study is the first to directly investigate the slope where the process takes place.

Here we present first evidence of surficial remobilization on the slopes of the Japan Trench and two Chilean lakes. Our data shows centimeter-scale gaps in slope sequences of both settings, which can be linked to the strongest historical earthquakes of the two regions. Therefore, we suggest surficial remobilization plays a significant role in sediment transportation upon seismic shaking. Also, several individual slope cores contain multiple gaps indicating that evidence of surficial remobilization can be preserved within slope sequences. Moreover, we find surficial remobilization-related gaps from slope gradients $>2.2^\circ$, whereas no gaps are observed on flatter slopes. Our data suggests a linear relationship between total remobilization per site and slope angle (maximum 4.3°). Both findings point towards gravitational downslope stress as a controlling factor on surficial remobilization depth. Furthermore, gaps could only be observed from M_w 8 in the Japan Trench suggesting that a minimum shaking duration, as this is directly related to magnitude, is needed for surficial remobilization to occur. The study of 25 more Chilean lake cores will further constrain the effect of different slope and seismological characteristics.

Sediment in both Chilean lakes and Japan Trench mainly consists of diatoms making their geotechnical characteristics comparable. Therefore, the Chilean lakes function as a natural laboratory where data acquisition is cost-effective and where well-laminated unbioturbated background sediment allows for precise stratigraphic correlation. Observation of surficial remobilization gaps on the Japan Trench slopes suggests global significance of the process.

O-3012

A disturbance from the 1700 AD earthquake identified by radiocarbon dating from Lower Squaw Lake, Oregon, USA

Ann Morey

Oregon State University, Corvallis, USA

Abstract

Accurate identification and dating of earthquake deposits are essential for the development of chronologies, models of fault behavior and stress linkages, and to calculate probabilistic assessments used to inform hazard maps. Cascadia lakes are increasingly being used for paleoseismic investigations because they are sensitive recorders of disturbances and can produce continuous records that span the Holocene. This is particularly important in Cascadia because there are no instrumental or written records of megathrust earthquakes given the most recent event occurred in 1700 AD. Identifying a deposit that can be confidently attributed to the ~M9 1700 AD Cascadia earthquake in lake sediments is important because the deposit characteristics can be used to identify similar deposits from past earthquakes downcore.

To determine if Cascadia earthquake deposits can be uniquely identified in sediments from Lower Squaw Lake, OR, I compared the historic portion of the record to the sequence of historic events, including the ~M9 1700 AD Cascadia and ~M7 1873 AD intraplate earthquakes. Initial deposit attribution was based on timing and relative position, then deposits were described and compared. Deposits attributed to intraplate and subduction earthquakes were different from each other but have the same structure: an initial unit composed of lake-margin, failure-prone schist becoming increasingly organic-rich upward, followed by a fine-grained, watershed-sourced unit suspected to result from liquefaction of the lake's large, coarse-grained subaerial delta. This silt unit grades upward into a long, organic-rich tail. Deposits attributed to floods did not have organic tails. The organic tail is composed primarily of lake phytoplankton, diatoms, bacteria and degraded organic matter, suspected to have formed as a result of flocculation which resulted from the mixing of fine particles and electrolytes released during liquefaction with lake water.

A sample taken from the organic tail of the lower portion of the deposit attributed to the 1700 AD earthquake was dated at 110 ± 25 RCY BP, similar to simulated radiocarbon distributions for a calendar age of 1700 AD (OxCal Program, version 4.3; C. Bronk Ramsey, 2017). Simple calibration produced two possible ranges: 1682-1736 cal AD and 1805-1935 cal AD, typical for this unusual section of the radiocarbon production curve. A radiocarbon age from a detrital sample between the deposit attributed to the 1700 AD earthquake and the tailed deposit attributed to the 1873 AD earthquake make the younger range impossible. A detrital sample from below the deposit attributed to the 1700 AD earthquake constrains the sequence from below. The figure below shows the results of a depositional sequence which constrains the timing of the deposit to ~1680-1740 AD. This is strong evidence that this deposit was formed in direct response to the 1700 AD Cascadia earthquake.

Intra- and inter-site reconstructions of coseismic subsidence during the great 1700 CE earthquake in southwest Washington USA

Andrea Hawkes¹, Niamh Cahill², Simon Engelhart³, Benjamin Horton⁴, Jason Padgett³, Isabel Hong⁵, Marie Bartlett¹, James Arnuk¹, Ellis Kalaidjian¹, Scott Adams^{1,6}

¹University of North Carolina Wilmington, Wilmington, USA. ²Maynooth University, Maynooth, Ireland. ³University of Rhode Island, Kingston, USA. ⁴Nanyang Technological University, Singapore, Singapore. ⁵Rutgers University, New Brunswick, USA. ⁶Tampa Bay Estuary Program, Tampa Bay, USA

Abstract

Coseismic subsidence was estimated during the great 1700 CE earthquake at the Cascadia subduction zone (CSZ) using a foraminiferal-based Bayesian transfer function. To test intra-site reproducibility subsidence was reconstructed in three cores within 25 to 600 m at two sites; one in eastern Willapa Bay, WA and one in western Grays Harbor, WA. Estimates of paleommarsh elevation prior to the earthquake differed by 10s cm, likely representative of the variations in marsh surface elevation seen in modern salt marshes at the sites today. At both locations, reconstructed subsidence estimates ranged from ~0.50 to 1.00 m, although the difference in intra-site subsidence estimates were not statistically significant at the 95% level. The similarity (<0.20 m difference) in intra-site subsidence supports the transfer function technique in reconstructing subsidence within a single marsh location, to some extent irrespective of paleommarsh elevation differences and location within the saltmarsh. Further, the addition of quantitative subsidence estimates at Grays Harbor partially fills a spatial gap in the central part of the CSZ that runs from southern Washington through Vancouver Island, British Columbia. Overlapping inter-site subsidence estimates between eastern Willapa Bay and western Grays Harbor, which are ~40 km apart in the strike direction, provides no evidence of plate segmentation between the two locations which agrees with the present earthquake rupture models.

The current distribution of quantitative coseismic subsidence estimates for the 1700 CE earthquake are unable to limit the width of rupture as the majority of sites are located directly at the coast. As a result of this limited distribution and in the absence of additional evidence, the earthquake modeling community uses the 450 C isotherm as the down-dip rupture boundary. Here, we attempt to address this limitation by using subsidence estimates from an additional site (eastern Grays Harbor), ~30 km down-dip of the western Grays Harbor site. A statistically-significant difference in coseismic subsidence estimates between western and eastern Grays Harbor may provide insight on rupture width at this location. Greater (lesser) subsidence at eastern Grays Harbor than western Grays Harbor may indicate a wider (narrower) rupture, although further estimates would be required.

Pioneering multi-proxy palaeotsunami research along the Pacific Coast of Ecuador

Gloria I. López^{1,2}, Kervin Chunga^{3,4}, Williams Mendez³, Carlos Martillo⁵

¹CENIEH, Burgos, Spain. ²University of Haifa, Haifa, Israel. ³Escuela Técnica de Manabi, Portoviejo, Ecuador.

⁴Universidad Estatal de la Península de Santa Elena, Santa Elena, Ecuador. ⁵Escuela Superior Politécnica del Litoral, Guayaquil, Ecuador

Abstract

The complex environmental, vegetative, geological, geographical, and tectonic setting of Northern South America can set the stage for an elaborate and heterogeneous compilation of different marine extreme event signatures within the coastal sedimentary record. The Pacific Coast of Ecuador, between Esmeraldas and the Bay of Guayaquil has been the focus of the first multi-disciplinary palaeotsunami investigations ever conducted in the country since 2016, targeting multiple sedimentary environments from fluvial-dominated plains to sandy beaches, in both natural settings and urban areas.

Important historical earthquakes have been recorded in Ecuador since 1896, all triggered by $M_w > 6.9$ earthquakes associated to the Nazca Subduction Zone, each producing extensive and critical damage to both the natural environment and human-made structures. Even though some of them have triggered tsunamis, very few have been evidenced geologically as not all tsunami-generated sediments are preserved due to the complex depositional settings encountered along this coastline.

The aim of this on-going investigation is to identify marine extreme event signatures in different types of sedimentary environments using a multi-proxy approach, including detailed lithostratigraphic descriptions, particle size analyses, petrophysics, mineralogy (i.e., heavy mineral assemblage characterization), analysis of morphoscopic features of sediment grains, bio-stratigraphy, dating by means of both ^{14}C and Optically Stimulated Luminescence (OSL) and luminescence signal analyses. For the latter, two novel approaches were implemented to help distinguish between tsunami and storm events: a) measurement of bulk samples using a Portable OSL Reader (PPSL) to create luminescence profiles in order to elucidate variances in stratigraphic continuity; and b) Single Grain Over-Dispersion (SG-OD) OSL analyses which allow to characterise the degree of sedimentary chaos within a deposit.

Presence of multiple potential tsunami and possible storm deposits was found throughout the numerous large trenches excavated and on exposed coastal/fluvial outcrops found along the coast, varying in thickness and sedimentological features depending on the environmental setting. On-going luminescence analyses (both PPSL and OSL) seem to be a key identification proxy to distinguish between palaeostorm and palaeotsunami units, besides the more conventional analytical techniques, also allowing to narrow the time-window for the chronology of the different events found along this coast.

O-3015

Late Quaternary environments in the Nile Basin

Martin Williams

University of Adelaide, Adelaide, Australia

Abstract

Late Quaternary climates in the upper Nile Basin have fluctuated between two extremes: cold and dry or warm and wet. Episodes of very high Nile flow coincide with intervals of sapropel accumulation in the E Mediterranean, the most recent having ages of 81 ka (S3), 55 ka (S2) and 13.5-6.5 ka (S1). Between 75 ka and 15 ka the regional climate was mostly dry (apart from moist phases at 55-50 ka and, perhaps, 38-30 ka) with active dunes encroaching on the Nile. In the Ethiopian headwaters of the Atbara and Blue Nile, ³⁶Cl exposure ages for glacial moraines range from 70 to 15 ka, after which the ice melted as the climate grew warmer.

In the Red Sea Hills of Egypt and the Sinai Peninsula, moist air masses from the Mediterranean extended as far south as latitude 24°N between 31.2 ka and 22.5 ka, which is when lakes in the Blue and White Nile headwaters of Ethiopia and Uganda were drying out.

During the Last Glacial Maximum (24-18 ka), temperatures in the Ethiopian Nile headwaters were 4-8°C lower than today. Periglacial processes were active down to 3000 m, slopes were unstable, and the tree line was 800-1200 m lower than today. The Blue Nile was then a highly seasonal river with a bed-load of sand and gravel, much of which was deposited by the main Nile in northern Sudan and southern Egypt. The ecotone between savanna and desert extended 300-500 km further south and the Atbara ceased to flow for much of the year. The abrupt return of the summer monsoon at 14.5 ka caused the hitherto closed lake basins in the Ugandan headwaters of the White Nile to fill and overflow, creating a shallow seasonal lake up to 25 km wide and over 400 km long south of the Blue and White Nile confluence of that time.

The Blue Nile and Atbara provide most of the sediment and flood discharge, but the White Nile provides most of the water during the time of minimum annual flow. When flow in the White Nile was cut off, as it was during 25-15 ka, winter floods from the Red Sea Hills would have helped sustain Nile flow.

Until 14.5 ka, sand-bearing Blue Nile distributary channels radiated across the surface of the Gezira alluvial fan to join the White Nile up to 120 km south of its present confluence. Later Blue Nile incision beheaded these channels, reduced seasonal flooding, and caused desiccation of the wetlands along the Nile and its major tributaries. Episodic late Pleistocene channel incision along the main Nile converted former flood plains into alluvial terraces suitable for prehistoric occupation.

Continental records for the 'African Humid Period': lake sediment archives from the Ounianga Basin and the Tibesti Mountains, N Chad

Michèle Dinies^{1,2}, Philipp Hoelzmann¹, Jens Karls³, Martin Melles⁴, Volker Wennrich⁴, Martin Claussen^{5,6}, Reinder Neef², Stefan Kröpelin³

¹Freie Universität Berlin, Institute of Geographical Sciences, Berlin, Germany. ²German Archaeological Institute (DAI), Scientific Department of the Head Office, Berlin, Germany. ³University of Cologne, Institute of Prehistoric Archaeology, Africa Research Unit, Cologne, Germany. ⁴University of Cologne, Institute of Geology and Mineralogy, Cologne, Germany. ⁵Max-Planck-Institut für Meteorologie, Hamburg, Germany. ⁶Universität Hamburg, CEN, Hamburg, Hamburg, Germany

Abstract

Triggered by orbital forcing via increased summer insolation, an intensified and northward shifted African/Indian monsoon resulted in a re-greened early and middle Holocene Sahara. During this phase – often named 'African Humid Period' – a wooded savannah is documented for the Central Sahara at least up to 19°N. Since the mid-Holocene, as a response to monsoonal weakening, the Sahara has turned into today's largest hot desert. The timing, magnitude and progression of the ecological responses to this shift – especially the de-greening of the Sahara – are discussed contrarily.

The volcanic Tibesti Mountains and their forelands in Northern Chad are a key region for palaeoclimate research due to their inner-continental position and diversity of ecological habitats. We present records from ecologically related, but topographically different settings in elevated craters and in the lowland oases of the Ounianga Basin.

Lake Yoa provides a unique continuous, high-resolution and well-dated sedimentary record for the Tibesti's eastern foreland since the onset of lacustrine deposition around 10,500 cal BP. The distinct dominance of grasses and sporadic occurrence of dry-adapted Sudanian elements in the basal pollen spectra indicate an already established thorn savannah pointing to a prior onset of humid conditions. The successive spread of more humidity demanding, deciduous Sudanian trees about 1000 years after the lake formation suggest a continued slow wetting in the Central Saharan plains, culminating in an extensive savannah with abundant Combretaceae – a tropical plant family with a recent distribution in the Sahel and southwards.

During the 5th millennium cal BP a distinct ecosystem change from a deciduous Combretaceae savannah to a thorn savannah is documented within a few hundred years, possibly triggered by trespassing climatic thresholds, whilst the main biomass-producers display a gradual change. The grass proportion decreased slowly over several millennia, while the goosefoot proportion – dominating the desert vegetation together with grasses – increased successively.

¹⁴C dating of micro-charcoals and pollen concentrates reveal an onset of lake formation in the Tibesti Mountains around 9500 cal BP, distinctly later in comparison to the surrounding plains, probably a consequence of the exceptional hydrological settings of the crater lakes. Pollen-analytical results show the persistence of sagebrush-grass-formation vegetation during the 'African Humid Period', indicating a less pronounced vegetation change in the high mountains.

Our results indicate a stepwise re-greening and de-greening of the Central Sahara. The mid-Holocene rather sudden, definitive retreat of a Combretaceae savannah is followed by a gradual decline of vegetation cover as indicated by the slow decrease of grasses – thus not connected to prompt aridification with vast vegetation-free areas.

Local environmental context of the Howiesons Poort sequence at Klipdrift Shelter, South Africa

Turid Hillestad Nel¹, Karen van Niekerk¹, Christopher Stuart Henshilwood^{1,2}

¹Centre for Early Sapiens Behaviour (SapienCE), University of Bergen, Bergen, Norway. ²Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa

Abstract

The Late Pleistocene Middle Stone Age (MSA) in southern Africa displays variations in technological and cultural mechanisms and shifts in anthropogenic ecological niches. An essential question is the role of climatic and vegetation changes as potential catalysts for human adaptability, changing mobility patterns and increased cultural complexity. To what extent did global and regional climatic fluctuations affect local vegetation and precipitation patterns, and could potential local variations have influenced human settlement and subsistence strategies?

Past local vegetation and climate can be reconstructed by analyses of micromammal species that become incorporated into archaeological sediments. Their suitability as palaeoenvironmental indicators is a result of small home ranges, precise ecological requirements and being primary consumers in the food chain. In this study, micromammals recovered from the Howiesons Poort (HP) sequence at Klipdrift Shelter (KDS), located on the southern Cape coast of South Africa, have been analysed to provide proxy data for palaeoenvironmental reconstruction. The HP is a prominent techno-cultural period characterised by blade-based industries and complex material culture (i.e. geometric engravings on ostrich eggshell and worked ochre). At KDS, the HP dates to c. 51-64 000 years ago, corresponding with Marine Isotope Stages (MIS) 4 to 3. Anthropogenic material from the sequence includes HP typified stone tools, modified ochre pieces, engraved ostrich eggshell, *in situ* hearths, and consumption of both terrestrial and marine fauna. Our study aims to provide an environmental context for human utilisation of the shelter while addressing the need for site specific testing of potential (a)synchronous changes in behavioural-environmental proxies.

Taxonomic identification of 20 micromammal species from 19 layers have ensured reconstruction of a detailed palaeoenvironmental sequence. Taphonomic analysis also sheds light on post-depositional processes and provides information regarding non-human and human site utilisation. The results of biodiversity indices, taxonomic composition and habitat weighting create a detailed picture of local environmental conditions during MIS 4 to 3 and contributes new insights to the palaeoenvironmental conditions at the Cape coast.

Zoogeomorphic agency and geoarchaeological interpretation of the dust increase over North Africa at the termination of the African Humid Period

Kathleen Nicoll¹, Andrea Zerboni²

¹University of Utah, Salt Lake City, USA. ²Università degli Studi di Milano, Milano, Italy

Abstract

Several investigations suggest that the termination of the African Humid Period is marked in North Africa by increased dust fluxes to the Atlantic Ocean. The rapid rise of dust supply to the sea as preserved in offshore core records around 5 ka BP is generally interpreted as the consequence of a rapid diminishment of the monsoon system and immediate aridification. However, the study of new zoogeomorphological features discovered in dryland landscapes of Northern Africa reflect early human-animal agency acting since prehistory on surface processes, and enable further interpretations regarding the origin of African continental dust fluxes to oceans. Studying the geoarchaeological record of ancient domestication of cattle, sheep, and goats, we recognize that activities related to animal husbandry (transhumance, pastoralism, and herding) were disturbances that significantly affected surface processes like erosion and dust mobilization, as well as reduced vegetation and ecosystems productivity. We argue that the spread of human activities and intensive husbandry of cattle and caprines in this region significantly influenced the geomorphic stability, ecosystem and landscape sustainability in a comparable manner of overuse observed in present-day arid and marginal environments, where pastoral overgrazing pressure increases erosion processes and enhances dust mobilization. We thus reinterpret the increased dust emission from North Africa at the end of the African Humid Period as due to human/animal induced soil erosion and dust mobilization in the context of a drying environment. We suggest that human/animal activities have amplified dust generation from the North African continental interior since ~7 ka BP. This strong evidence of prehistoric human impacts on surface processes in North Africa supports arguments for an early beginning of the Anthropocene.

Northeast Africa and the Eastern Desert of Egypt with its relevance for Modern Human dispersal in the Late Pleistocene

Felix Henselowsky¹, Karin Kindermann², Nicole Klasen³, Philip Van Peer⁴, Rene Eichstädter⁵, Andrea Schröder-Ritzau⁵, Norbert Frank⁵, Christian Willmes³, Olaf Bubenzer¹

¹Institute of Geography and Heidelberg Center for the Environment, Heidelberg University, Heidelberg, Germany.

²Institute of Prehistoric Archaeology, University of Cologne, Cologne, Germany. ³Institute of Geography, University of Cologne, Cologne, Germany. ⁴Prehistoric Archaeology Unit, Institute of Geo-Sciences, University of Leuven, Leuven, Belgium. ⁵Institute of Environmental Physics, Heidelberg University, Heidelberg, Germany

Abstract

Northeast Africa is one of the key regions for understanding human dispersal “Out-of-Africa”. Only this region provides a full terrestrial route along the natural bottleneck of the African continent and into southwest Asia. During the late Pleistocene, Northeast Africa has experienced fundamental environmental changes. However, in this area little is known on how humans were affected by these changes as could be deduced from the analyses of complementary archaeological and environmental archives. Instead, palaeoenvironmental information often derived from marine records or global climate models, representing an over-regional climate reconstruction without any direct correlation to archaeological sites. Interdisciplinary geoarchaeological research of the Collaborative Research Centre 806 “Our Way to Europe” at the limestone hogback of Gebel Duwi in the Eastern Desert of Egypt, where the sites of Sodmein Cave, Sodmein Playa and Saquia Cave are located, fills this gap with new results from on- and off site investigations, linking palaeoenvironmental information with archaeological evidence of human presence to the overall landscape setting. This is achieved by three methodological approaches, delivering the following key results.

First, geomorphic mapping at Gebel Duwi by the use of high-resolution satellite imagery and digital elevation models integrated with field investigations at Gebel Duwi shows the coexistence of young and active geomorphic features directly next to presumably old wadi terraces with stable surfaces, which are often covered with Middle Stone Age artefacts. Based on this landscape mosaic, the integration of information from open-air surface sites and the comprehensive stratigraphy of human occupation debris in Sodmein Cave serves as a spatial-temporal background to investigate human occupation in this area.

Second, first optically stimulated luminescence (OSL) age estimates from the archaeological stratigraphy Sodmein Cave range from late MIS 5 to early MIS 4. Th/U based dating of speleothem growth at the nearby Saquia Cave indicate for the first time wetter climatic conditions derived from a single terrestrial archive during all interstadials of MIS 5 in Northeast Africa. This seems to confirm the presumption that humans have been present during multiple wet-phases of the Last Interglacial in the Eastern Desert and thus strengthen the importance of this area, apart from the Nile Valley, as an important region on the northern migration route of modern humans.

Finally, a GIS-based PalaeoMap of the Last Interglacial environment of Egypt sums up palaeo-climate, ecozones, water availability and appropriate raw material sources as primary needs of hunter-gatherer societies on an over-regional scale and thus expands the regional field investigations to the overall context of Northeast Africa. This multi-scale research approach allows us to integrate socio-environmental interactions from distinct site regions in the Eastern Desert to the overall context of Egypt and derive its relevance for modern human dispersal Out-of-Africa.

Late Pleistocene palaeoenvironment in southwest Ethiopia – insights from geoarchaeological investigations at different spatial scales

Elena A. Hensel¹, Olaf Bubenzer², Martin Kehl¹, Ralf Vogelsang³, Oliver Bödeker⁴

¹Institute of Geography, University of Cologne, Cologne, Germany. ²Institute of Geography & Heidelberg Center for the Environment, Heidelberg University, Heidelberg, Germany. ³Institute of Prehistoric Archaeology, University of Cologne, Cologne, Germany. ⁴Department of Geoscience, University of Cologne, Cologne, Germany

Abstract

The reconstruction of palaeoenvironmental changes requires multidisciplinary investigations, using different scales of consideration. Geoarchaeological research allows using these different angles - from geoscientific analyses to archaeological observations. The interdisciplinary project A1 “Out of Africa - Late Pleistocene Rock Shelter Stratigraphies and Palaeoenvironments in Northeastern Africa”, as part of the Collaborative Research Center 806 “Our Way to Europe”, focuses on the usage of various research approaches to reconstruct Late Pleistocene rock shelter stratigraphies and the palaeoenvironment at sites in Northeastern Africa.

The southwestern Ethiopian Highlands, one of the projects research areas, holds valuable archaeological sites. According to the Mountain Refugium Hypothesis, prehistoric hunter-gatherer might have frequented these high elevated areas trying to cope with environmental stress. Rock shelters like Mochena Borago and the Sodicho Rockshelter, at Mt. Damota and Mt. Sodicho, preserved complex and heterogeneous sediment stratigraphies with comprehensive archaeological sequences of the Late Pleistocene. The poster displays initial results of research in the area, mainly focusing on geoarchaeological work at the Sodicho Rockshelter. Research topics, e.g. site formation or the preservation of archaeological remains, can be addressed by using different scales of investigation. The methodological approach comprises a local scale, using high resolution Pléiades 1A and ASTER GDEM* satellite images as a tool for landscape analyses. A selection of sedimentological and geochemical field and lab analyses are applied to clarify site stratigraphy. The smallest scale of investigation is done by micromorphological observations to record microscopic changes in fabric and characteristic features.

The first results suggest, that the actual area is influenced by highly dynamic hydrological systems of radial and dendritic drainage networks with temporal swamp formation. Open-air sites and obsidian raw material outcrops are threatened by active gully erosion. A better preservation is given in the rock shelters, such as Sodicho. Several occupation sequences, with Later Stone Age lithic assemblages, alternate with thick volcanic ash layers. Environmental changes are indicated not only by the abrupt volcanic fallout but also a sterile clayish horizon – referring to the African Humid Period. In the future the obtained geoarchaeological data will help to improve the knowledge of human-environmental interactions in Northeastern Africa.

Abstract

Palaeoenvironmental records from high-altitude sites in eastern Africa are few in number relative to the numerous records from the rift valley, so knowledge of Late Pleistocene-Holocene environmental dynamics at higher altitudes is somewhat limited. Here we present a 16,000-year diatom and XRF-derived geochemistry record from Garba Guracha (3950 masl), a ~5 m-deep cirque lake in the Bale Mountains, Ethiopia. Key research questions include: i) Can we identify environmental changes equivalent to those known from lower altitude sites? ii) How does the diatom stratigraphy record changes in the lake and its catchment, and how are these changes related to climatic variations?

Diatom productivity was low during the Pleistocene-Holocene transition, the assemblage being dominated by shallow-water, ice-tolerant taxa. These conditions continued during the African Humid Period (11,700 - 4,250 cal. BP), but with increased organic productivity. Dominant taxa were the facultatively planktonic Fragilarioid species (*Staurosirella pinnata* and *Staurosira construens* var. *venter*). After ~4,500 BP the diatom assemblage changed to dominance by *Pseudostaurosira pseudoconstruens*, apparently in response to a reduction in woody *Erica* vegetation cover in the catchment, and drier climate. Benthic and aerophilous taxa also increased during this period, with a further increase in the last 150 years, probably reflecting reduced lake depth and increased aquatic macrophytes. Overall, the Garba Guracha record shows more subtle responses to Holocene climatic change than records from low-altitude sites.

Heavy metal contamination of Northern Norwegian Younger Stone Age Seafood c. 4300 - 1900 BCE.

Hans Peter Blankholm, Nikola Kovačević
UiT The Arctic University of Norway, Tromsø, Norway

Abstract

Prehistoric human seafood is generally considered safe and healthy. The analysis of a c. 2400 year deep time-line (c. 4300 – 1900 BCE) of the heavy metal toxins cadmium, lead and mercury in the Younger Stone Age human food chain in Arctic northern Norway suggests that this was not always the case. Investigations of the Atlantic cod (*Gadus morhua*) and harp seal (*Phoca groenlandica*) bone component of the marine food dominated diet indicate, at times, highly elevated levels of cadmium and lead and, to some extent, mercury. On average, those levels of cadmium and lead contamination were three to four times higher than today's recommended limits. The levels of mercury were generally below the presents recommended limit but still of considerable magnitude. This shows that human marine food in the Younger Stone Age of northern Norway, although almost certainly unknown to the prehistoric societies, was surprisingly unhealthy if not unsafe and may have had detrimental effects on individuals and society alike. This paper presents the data, methodology and results followed by a discussion of probable, global climate change driven, causes for the contamination including changes in temperature, sea-level change, erosion and melting permafrost.

A paleoenvironmental perspective on human-environment interactions during the Iron Age in the Lofoten Islands, Norway

Stephen Wickler¹, Nicholas Balascio², William D'Andrea³, R. Scott Anderson⁴

¹Tromsø University Museum, Tromsø, Norway. ²Department of Geology, College of William & Mary, Williamsburg, VA, USA. ³Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA. ⁴School of Earth Science & Environmental Sustainability, Northern Arizona University, Flagstaff, AZ, USA

Abstract

In the North Atlantic region, early human settlements were established in marginal agricultural environments and were susceptible to various environmental stressors. The Lofoten Islands have had an important role in the history of this region, particularly during the Iron Age (500 BC-AD 1050), when Lofoten developed from pioneering agricultural settlements to a prominent node of power and trade under Viking chieftains. Iron Age developments in Lofoten were concurrent with significant natural environmental changes, including variations in climate and sea level, which likely influenced early settlements. Our project involves an integrated archaeological and paleoenvironmental investigation of human-environment interactions on the island Vestvågøy. We are developing sedimentary records from isolation basins to reconstruct relative sea-level history, and from lakes in the main agricultural valleys to reconstruct early human-landscape impacts. These data are coupled with archaeological evidence that we have compiled from published literature as well as local cultural history archives. Here we present data from several sedimentary records that span the late Holocene from Vestvågøy. Reconstructions from two isolation basins show sea-level lowered ~4 m over the last 4.1 ka and provide perspectives on how coastal environments and harbor locations changed, particularly during the Viking Age (AD 800-1050) when maritime activity increased. We also infer spatial changes in landscape impacts based on the analysis of bulk organic geochemical data, pollen, and molecular biomarkers. Preliminary data indicate significant changes c. 2.5 ka, likely coinciding with early agricultural settlements, and after which the number and types of archaeological sites discovered increases. Overall, this project contributes a better understanding of how people have interacted with the environment in Lofoten in the past and how humans and landscapes have evolved through time.

O-3024

Long-term settlement on islands of SW Norway

Christin Jensen

University of Stavanger, Stavanger, Norway

Abstract

Development-led archaeological excavations are the main providers of information about synchronic prehistoric human practices. In applying a cross-disciplinary approach combining archeological and paleoecological research strategies, new knowledge about the dynamic relations between humans and a changing environment, as well as a more profound understanding of long-term landscape change is achievable.

The settlement history and landscape development of the mainland of southwestern Norway is well documented by discrete archaeological, geological and palaeobotanical records, while there have been fewer studies in the island region. Recent archaeological excavations connected with the planning of a new coastal highway, bridging islands of the outer Boknafjord region, has however given access to new information about landscape and settlement. The archaeological objects and sedimentary records of the outer islands reveal a settlement history going back until at least the Middle Mesolithic. The sites were probably part of a settlement pattern based on logistic mobility, taking advantage of the variability in natural resources. The botanical analyses of an organic structure sealed under a raised beach, possibly remains of a human construction like a bark mat, and radiocarbon dated to the Middle Mesolithic period show the presence of mixed forest on the island during that time. High terrestrial biodiversity may have been an important attribute to the marine resources, and a reason why these coastal sites eventually were chosen for more permanent settlement. Although scarce availability of soil substrate on the islands, a farming practice with animal husbandry and cereal cultivation is evidenced from the Late Neolithic onwards until present day, comparable with the more well suited agricultural districts on the mainland.

⁴Geography and Environment, University of Southampton, Southampton, United Kingdom. ⁵Poznan Radiocarbon Laboratory, Poznan, Poland

Abstract

Mortensnes (*Ceavccagead̥ge* in Sami) is a well-investigated archaeological site in northern Norway. It is also close to the eastern colonization corridor of Northern Norway, both in botanical and human terms, and is expected to provide a signal of early human interaction with vegetation in the past. Using sedimentary ancient DNA from Nordvitatnet at Mortensnes, we reconstructed temporal changes in the plant species composition of vegetation in this area for the first time. We also analyzed the sediments for loss on ignition (LOI), and other non-biological proxies. The sediment chronology covers the entire Holocene and part of the late Pleistocene. We identified about 40% of the taxa each to species and genus level, and about 20% of the taxa to tribe, subfamily, and family levels. Our results show a relatively species poor Late Glacial and Younger Dryas period, dominated by arctic taxa like *Dryas*, *Papaver*, and *Saxifraga oppositifolia*. The total plant species richness increased rapidly in the early Holocene, concurrent with increasing LOI, indicating a generally higher biological productivity. Nitrogen demanding species such as *Anthriscus sylvestris*, *Chamerion angustifolium*, and *Filipendula ulmaria* likely indicating anthropogenic activity in the vicinity of the lake, appear from around 11 000 cal. BP, the same time as the oldest dated archeological records from Mortensnes. The occurrence of pioneer species indicative of past climatic episodes suggests that the historical climate strongly affected vegetation in northern Norway, particularly during Late Glacial-early Holocene transition. During the Holocene, several ruderals and human activities appear concurrently suggesting anthropogenic factors as an important driver of vegetation change despite the anticipated low human impact in this region. Linkages in time between these compositional changes in vegetation and archeological events will be made in order to explore possible interactions between humans and vegetation development.

Late Holocene insect faunas and human impact in Greenland

EVA PANAGIOTAKOPULU¹, Bjarne Grønnow², Kim Vickers³

¹School of GeoSciences, Edinburgh, United Kingdom. ²SILA, National Museum of Denmark, Copenhagen, Denmark.

³independent researcher, sheffield, United Kingdom

Abstract

The impact of hunter gatherers on their environments has been the topic of lengthy debates and palaeoecological investigations with the emphasis on understanding specific signals which tie back to particular activities. In Greenland human impact of hunter gatherers in relation to a changing climate has been less studied, although there has been much discussion of the role of climate in the demise of Norse farming communities and the disappearance of pre-Inuit hunting groups. Palaeoecological research on hunter gatherers in Greenland has tended to concentrate on bone assemblages with limited research on other aspects of the flora and fauna. There has been some research on fossil insect assemblages from pre-Inuit (Saqqaaq) and Thule Inuit Greenlandic sites but there is need for more detailed study, expanding the groups identified to provide further information about the taphonomy and interpretation of the relevant assemblages. A large number of samples from Saqqaaq Qeqertasussuk at Disko Bay from around 4400 BP spanning around a thousand years are discussed in relation to previous work from the site and the cultural record of site use and abandonment. In addition, comparative results from a Thule Inuit midden near Nuuk at Kangeq dating from the 14th century onwards provide information from a period which overlaps with the demise of Norse farms in the inner fjords of the Western Settlement. Presence and abundance of taxa are considered as they may relate as much to seasonal activities by the hunters as to taphonomic processes. Results provide information for seasonal use and different modes of exploitation of materials. Data from different periods of occupation are examined and compared in order to understand better hunter gatherer subsistence, changes over time and abandonment. These hunter gatherer sites are discussed in the context of natural Greenlandic insect faunas examining human impact as a driver of change. A comparison with assemblages associated with Norse pastoralists indicates the different nature of human impact on their environments and provides information on the ecological footprints of different groups, which may have broader relevance in terms of understanding the development of man made environments. A number of species of insect are common to both hunter gatherer and Norse farming communities but several disappear with their unwitting hosts in the late Norse period and not all are re-introduced with renewed European occupation, farming and enforced sedentism in the last three centuries.

The role of fire in scrub clearance during the Norse *landnám*, Greenland

James E Schofield¹, Kevin J Edwards^{1,2}, Paul M Ledger³

¹University of Aberdeen, Aberdeen, United Kingdom. ²University of Cambridge, Cambridge, United Kingdom.

³Memorial University, Newfoundland, St John's, Canada

Abstract

The Norse *landnám* (Old Norse: 'land-taking') of Greenland began around AD 985 with the supposed arrival of 14 ships from Iceland. At the outset of colonisation, a potential obstacle to the establishment of Norse farmsteads was the birch-willow scrub that covered substantial areas of southern Greenland. Typically, pollen diagrams demonstrate that clearance of the scrub vegetation began at *landnám* and that this process was completed shortly thereafter. Burning has often been advocated as the main method of clearance used by the Norse settlers. This idea largely developed from the evidence of a small number early studies conducted in the Western Settlement. These reported visible charcoal horizons positioned stratigraphically prior to the palynological signal for human activity. A more substantial number of pollen and microscopic charcoal profiles are now available from different sedimentary contexts across southern Greenland. Many of these include detailed palaeoenvironmental records with high temporal resolution which can now be presented collectively, allowing a thorough and critical examination of hypotheses relating to the use of fire in Greenland by the Norse settlers.

Relative and accumulation rate (influx) microscopic charcoal data from the Eastern and Western Settlements of Greenland encapsulate not only the critical *landnám* horizon and the settlement period (~AD 1000-1400), but also provide information for the preceding centuries and those following the abandonment of the colony. Thus they provide baselines for the accumulation of microscopic charcoal particles in a sub-Arctic environment over substantive periods when there was no demonstrable regional human presence. The results show that elevated microscopic charcoal influx to lakes and mires was not restricted to the immediate years following *landnám*. High charcoal accumulation rates were sustained throughout the four centuries of settlement, over much of which time the pollen records indicate that scrub coverage had been reduced to a minimum. The data suggest that the case for widespread clearance of scrub vegetation by the Norse in Greenland through burning has perhaps been overstated. It would seem that a substantial proportion of the microscopic charcoal seen in sedimentary records was more likely to be derived domestically from fires used in heating and cooking.

Reconstructing landscape change at Cerro Benitez, Patagonia (52°S): new insights for megafaunal extinctions and human occupation.

Robert McCulloch¹, Claudia Mansilla², Fabiana Martin³, Luis Borrero⁴

¹Centro de Investigación en Ecosistemas de la Patagonia, Coyhaique, Chile. ²Centro de Investigaciones Gaia Antártica (CIGA), Universidad de Magallanes, Punta Arenas, Chile. ³Instituto de la Patagonia, Universidad de Magallanes, Punta Arenas, Chile. ⁴CONICET-IMHICIHU, Buenos Aires, Argentina

Abstract

During the Last Glacial Maximum, a coterminous Patagonian ice sheet extended from ~38° to 55°S which would have posed a considerable geographical barrier to the colonization of the region by early hunter-gatherers. During the Late glacial, warmer climatic conditions drove rapid landscape changes characterized by retreating glaciers and the spread of vegetation that strongly reflected the regional east-west precipitation gradient and latitudinal movements in the southern westerly winds (SWWs). The region of Cerro Benitez, Ultima Esperanza, Chile (52°S) was successfully colonized by a rich fauna, including *Mylodon*, *Hippidion*, *Lama gracilis* and other camelids and carnivores such as *Smilodon* and *Panthera*. Archaeological evidence for sites of early occupation by *Homo sapiens* along the Andes is limited but a key site in southern Patagonia where human occupation has been extensively recorded is within a cave system on the flanks of Cerro Benitez. Human occupation has been established at Cueva del Medio at c. 12.6 ka, with signals of ephemeral human interaction with *Hippidion* and camelids.

To better understand the changing landscape during the Late glacial and the Holocene an 11m core was retrieved from a basin mire on Cerro Benitez. The record suggests deglaciation from the area sometime before c. 18 ka followed by relatively stable open grassland conditions that would have favoured a food chain dependent on large herbivores. A brief period of expansion of southern beech (*Nothofagus*) woodland at c. 13.8 ka suggests a response to more humid-temperate conditions before the contraction of tree cover during a return to colder conditions coeval with the Antarctic Cold Reversal and the apparent cessation in human occupation of Cerro Benitez. The rapid expansion of southern Beech forest at c. 12.1 ka indicates the onset of Holocene-like conditions and a dramatic change in resources and their accessibility provided by the landscape. The increase in southern beech forest and greater fire activity also coincided with the disappearance of the mylodonts. It is probable that the rapid loss of open grazing led to the local extinction of the large herbivores. During the Holocene the forest cover fluctuated, probably in response to latitudinal shifts in the focus and intensity of the SWWs. The early Holocene human occupation of the region may have been the result of exploration by a new community of hunter-gatherers adapting to the increasingly forested environment around Cerro Benitez. They targeted small rockshelters for habitation, diversified their diet by adding some coastal and forest subsistence resources and made a more informed use of the regional lithic raw material sources. Cueva del Medio itself was only revisited by hunter-gatherers c. 4.5 ka contemporary with an opening of the forest cover.

Simulating the mid-Holocene 'Green' Sahara and the potential relationship with future precipitation change

Peter Hopcroft¹, Paul Valdes²

¹University of Birmingham, Birmingham, United Kingdom. ²University of Birstol, Bristol, United Kingdom

Abstract

The early to mid-Holocene in North Africa is a fascinating example of a fundamental natural environmental change. During this time much of the present-day Sahara was transformed by an expansion of vegetation and lakes. This transition was caused by a substantial increase in precipitation that resulted from the change in insolation that resulted from variations in Earth's orbit through time. However, simulations with a range of climate models have repeatedly failed to reproduce an adequate precipitation response for the mid-Holocene, raising questions about their underlying skill, and reinforcing concerns about the currently wide uncertainties on precipitation in future projections.

In this work we use a Bayesian methodology to optimise one of these general circulation models HadCM3. Simulations of the mid-Holocene with this model produce a relatively weak precipitation response over North Africa, with a minimal expansion of grass plant functional types. Following our optimisation which is based on a 150-member perturbed parameter ensemble, HadCM3 is able to reproduce the precipitation increase inferred from pollen samples for the mid-Holocene without any significant degradation of the present-day model simulation skill. We also investigate the role of moisture stress in shaping the coupled dynamic vegetation response. Based on an ensemble of present-day and mid-Holocene simulations, we find that a modest improvement in the simulation of present day arid region vegetation dynamics, also improves the vegetation response during the mid-Holocene.

Finally, we employ a statistical emulator to compare the simulations of the mid-Holocene with an equivalent ensemble of future-like simulations in which atmospheric CO₂ is doubled. We use these to identify how an improved simulation of North Africa in the mid-Holocene impacts the uncertainty distribution on precipitation in the 'future-like' state. We discuss processes that may contribute to the realism of this.

How blue was the 'Green Sahara'? Reviewing Saharan megalakes evidence for wetter environments

Jay Quade¹, Elad Dente^{2,3}, Moshe Armon², Yoav Ben Dor², Efrat Morin², Ori Adam², Yehouda Enzel²

¹University of Arizona, Tucson, USA. ²The Hebrew University of Jerusalem, Jerusalem, Israel. ³Geological Survey of Israel, Jerusalem, Israel

Abstract

The proposed paleoclimatic change in the Sahara based on shallow lakes and discharge deposits, flowing streams, and minor vegetation changes, is dwarfed by the suggested presence of very large (mega) lakes, ranging in surface area from 3000-350,000 km² at 15-35°N. We review the physical and biological evidence for these proposed megalakes, especially during the African Humid Period (11-5 ka). We point to the lack of evidence supporting the existence of such megalakes, including the absence of paleoshorelines, and of near-shore remodeling of adjacent ancient alluvial fans and bajadas. Outside the core of the Sahara, there is ample evidence in support of the existence of the vast Megalake Chad (10-18°N) during the African Humid Period. However, this lake system drains large areas of the tropics 5-10°N that experiences 1000-1500 mm yr⁻¹ of rainfall even today. An approximate shift of the rain belt by 5 degrees to the north would have increased dramatically the area of the watershed that experiences such precipitation amounts. A simple hydrologic model of the proposed megalakes areas requires mean annual rainfall 1000 mm yr⁻¹ or much more, and therefore, a northward displacement of the tropical rain belts by ≥1000 km. Such a profound shift is not supported by a range of other paleoclimate proxies nor by modeling efforts, therefore challenging the existence of such megalakes in the Sahara. In our view, published evidence for perennial water bodies in the Sahara is more consistent with the presence of isolated wetlands, discharging springs, and small shallow lakes (<50 km²), and hence no conjecture on tropical paleoclimate in the Sahara during the African Humid Period can be supported. In conclusion, pale-green, discontinuous, patchy wetter environments did exist in the Sahara, but their exact spatial distribution and magnitude should be reevaluated.

Abstract

Eastern African hydroclimate became significantly drier in the mid-Holocene at the termination of the African Humid Period (AHP; ~15 to 5 ka). This aridification resulted in the desiccation of many lakes and may have pressured hunter-gather societies to move towards concentrated pastoralist settlements at the shores of the few remaining lake areas or river valleys. During the AHP, Lake Chew Bahir, in the East African Rift System, was presumably expansive with a paleo-shoreline ~30 m higher than present day, and likely served as an important freshwater source and refugia. Today it is a predominantly dry playa mudflat with ephemeral swamps in the deltaic areas. Strontium (Sr) isotope ratios (⁸⁷Sr/⁸⁶Sr) preserved in carbonate-rich lacustrine strata provide regionally-specific records of past variability in weathering and regional drainage patterns. During humid episodes, the Chew Bahir catchment expands northwards to include the Chamo and Abaya catchments. As these catchment are dominated by younger volcanic lithology, with low Sr isotopic ratios, additional water inflow from here can potentially change the overall Sr isotope ratio of the lake water in Chew Bahir in a measurable way.

This study aims to reconstruct the hydrobalance of paleolake Chew Bahir using a three-step approach. We first establish the Sr isotope ratio of the input end members by sampling modern waters from the Chew Bahir and adjacent catchments, including groundwater, lakes, springs and rivers. We then analyse the Sr isotope ratios of microfossils from the time period of the most recent AHP lake level high-stand from three short cores (CB05, CB06 and CB03) along a transect from the centre to the western margin of the Chew Bahir basin. Finally, we use the paleo Sr isotope record over the last 15 ka to develop an isotopically-enabled hydrobalance model to quantify past lake levels. Over the last ~15 ka ⁸⁷Sr/⁸⁶Sr ranges from 0.7059 to 0.7066, with higher values during the start of the AHP, decreasing towards the termination. This suggests a larger input of water entering paleolake Chew Bahir from the northerly catchments and paleo-connectivity of these lake systems during humid periods. This study provides valuable data for reconstructing millennial-scale change in hydrobalance and freshwater availability, in a highly-sensitive climate region, over a key time period for the transition from hunter-gather societies to pastoralism.

Quaternary dune generations on northern Fuerteventura

Christopher-B. Roettig¹, Thomas Kolb², György Varga³, Daniel Wolf¹, Ludwig Zöller⁴, Dominik Faust¹

¹Dresden University of Technology, Department of Geography, Dresden, Germany. ²Justus-Liebig-University Giessen, Department of Geography, Giessen, Germany. ³Hungarian Academy of Sciences, Geographical Institute, Budapest, Hungary. ⁴University of Bayreuth, Department of Geography, Bayreuth, Germany

Abstract

Aside the long lasting research history concerning the origin of the Canarian archipelago, also the carbonate sands aroused interest since the first investigations by Humboldt in 1779. Especially the Eastern Canary Islands (Lanzarote, La Graciosa and Fuerteventura) show huge deposits of dune generations (the oldest are dated to >450 ka) intercalated by reddish layers. Generally, these archives consist of I. carbonate sands, II. dust deposits and III. material of volcanic origin (tephra, lapilli and basaltic debris). The studied sequences reveal a recurring pattern, starting with a) deposition of carbonate sands, followed above by b) deposition of dust accompanied by weak soil forming processes, lowering the sediments resistivity against c) water induced relocation, finalising one sequence.

The supply of carbonate sands depends on sea level changes. We assume highest sand supply to occur right after sea-level maxima during periods of falling sea level (Fig. 1). Whereas during periods of rising sea level the sand supply is decreased to the benefit of dust imprint. The southward shifting of the Westerlies during glacials goes ahead with extending ice volume (and falling sea level, by implication). Consequently, during sea level low stands, the Canarian archipelago is effected by more moisture conditions induced by the increased influence of the Westerlies. These conditions favour the deposition of dust, enable weak soil forming processes and initiate water induced relocation.

For some decades, features of reddened silty layers were interpreted as results of strong soil formation. In contrary, our analytical findings support the assumption that these reddish layers are mainly related to aggrading iron loaded dust deposits since the in situ soil forming processes seem to be restricted to slight de- and recalcification processes and some oxidation of iron and manganese.

Finally, we want to focus on the site-specificity within these archives and the influence of the local volcanism completing the complexity of the investigated dune archives, making them both challenging but so much interesting in the same way.

Modelling late Quaternary surface hydrology changes and climate feedbacks over African drylands

Joy Singarayer¹, Charlie Williams^{2,1}, Sifan Koriche¹, Simon Dadson³, Sallie Burrough³

¹University of Reading, Reading, United Kingdom. ²University of Bristol, Bristol, United Kingdom. ³University of Oxford, Oxford, United Kingdom

Abstract

Historical and Quaternary palaeoenvironmental archives from northern and southern Africa indicate phases of extreme wet/dry conditions of much greater amplitude than the variability seen in recent observations. Such variability of hydroclimate has also been strongly linked to ancient human adaptation and migration. The most well documented wet phase is the African Humid Period (AHP; ~14,000 to 6000 years ago), during which North Africa experienced expansion of wetlands, river systems, and lakes. This occurred as a response to orbitally driven changes in the seasonality of insolation, leading to strengthened summer monsoons. Similar wetter conditions have been documented at various times for southern Africa, including the expansion of mega-lake Makgadikgadi. Recent studies suggest that African wet-dry phases may have resulted from small changes in the magnitude of hydroclimate variability and/or more persistent conditions. African dryland regions have been found to have some of the strongest land-atmosphere coupling strengths in the world, where surface hydrology feedbacks significantly amplify small changes in precipitation. Yet, interactive feedbacks with variable lakes/wetlands are missing from most climate models.

Here, we investigate simulating changes to surface hydrology over African dryland regions during the late Quaternary, and whether including feedbacks with lakes/wetlands enables improved simulations of large swings in palaeohydroclimate. We will present results from two components of the study. Firstly, idealised AHP climates (based on palaeoclimate data) were used to drive the JULES land surface model, a statistical overbank inundation model, and a surface hydrological model to simulate river discharge, wetland inundation and inland lakes. The distribution of inland water bodies at the AHP and present-day were compared to palaeo and modern hydrological data. Secondly, we incorporated surface water area changes into the new UK climate model, HadGEM3.1, both as prescribed changes during the AHP, and subsequently interactively using the land surface/hydrology models. We will compare simulations of the AHP with and without interactive inland water bodies to examine the impacts of the introduced feedbacks.

Revisiting the palaeohydrology of the Nama Karoo – late Pleistocene lake high stands and associated archaeology in the South African interior

Andrew Carr¹, Brian Chase², Peter Holmes³, Tebogo Makhubela⁴, Mulalo Rabumbulu⁴, Brian Stewart⁵

¹University of Leicester, Leicester, United Kingdom. ²Institut des Sciences de l'Evolution-Montpellier, Université de Montpellier, Montpellier, France. ³University of the Free State, Bloemfontein, South Africa. ⁴University of Johannesburg, Johannesburg, South Africa. ⁵University of Michigan, Ann Arbor, USA

Abstract

In the 1970s and 1980s several late Pleistocene palaeo-lakes were proposed to have existed within the South African interior. In particular, the ~44 km² Alexandersfontein pan, south of Kimberley, in the central interior summer rainfall region, was identified as providing evidence for major lake phases at 19 and 17-13 ka. The presence of Middle Stone Age (MSA) and Later Stone Age (LSA) artefacts within stratified deposits, rather than as surface lags, was also noted. In the context of a broader study considering geomorphic evidence for palaeohydrological change across the interior of South Africa, we present new results from Alexandersfontein, as well as from two large pans, Swartkolkvloer and Grootvloer, which are part of the Fish and Sak River catchments to the west. Our aims are to: 1) provide much more robust constraints on the timings of palaeohydrological change and, where possible, first age constraints on stratified archaeological materials; 2) provide more detailed descriptions of the character of the archaeological materials (and their contexts) across these sites. The dating programme encompasses new radiocarbon dating, the application of single grain luminescence dating, and preliminary attempts to apply cosmogenic dating and U-Series methods.

At Alexandersfontein radiocarbon dating of lacustrine clays exposed at the northern margin of the site implies the existence of a late Pleistocene high stand ~14 m above the modern pan at ~32,100 cal yr BP. OSL ages indicate the overlying colluvial sediments are all younger than 10-12 ka. A key locale identified within the Alexandersfontein system is the Mauritsfontein site, where recent aeolian sands (luminescence age ~2.7 ka) overly a sequence of lacustrine silts and a well-developed calcrete, which can be traced across the site. The latter contains *in-situ* MSA lithics and is the subject of U-series dating analyses. At Swartkolkvloer an impressive double shoreline system (at +5 and +10 m) dates to between ~27,400 and ~40,500 cal yr, BP, while at the southern margins of Grootvloer (to the north), freshwater mussels have now been dated to ~20,600 cal yr BP.

Additional radiocarbon, luminescence and U-Series results from all of these sites will be presented. The results thus far imply the existence of several substantial (potentially >120 km² in the case of Swartkolkvloer) lake systems during late MIS 3 and during MIS 2. This is broadly consistent with recently identified evidence for more humid conditions during late MIS 3/early MIS 2 elsewhere in the western interior. The potential causes will be considered. Of particular significance is the identification of stratified MSA lithics. Given that this is a rare occurrence in the interior, where the archaeological record is largely surficial, these sites also present opportunities to provide numerical age constraints on human occupation(s) of this region.

Abstract

Williams Point is an iconic late Quaternary sedimentary sequence exposed at the margin of Madigan Gulf at Kati Thanda – Lake Eyre, Australia's largest lake. The 15 m high cliff outcrop is capped by ~ 5 m of the Williams Point Aeolian Unit (WPAU), which overlies a thin (< 0.5 m) beach/shoreline facies, and 5 – 6 m of fluvio-lacustrine facies. Previous researchers (Magee et al., 1995; Magee et al., 2004) have used this sedimentary sequence as critical evidence of hydrological change throughout the last glacial cycle over a large proportion of Australia’s arid interior. We present a revised chronology using single-grain optically stimulated luminescence within a Bayesian modelling framework. We evaluate the evidence of prolonged pedogenesis in the upper parts of the fluvio-lacustrine facies and we re-examine the WPAU, which contains abundant eggshell of large flightless birds (*Dromaius novaehollandiae* and the extinct putative *Genyornis newtoni*).

Our new data highlights that the lacustrine facies at the base of the cliff (interpreted to represent shallow, but oscillating lake water levels) were deposited 130 ± 16 ka to 113 ± 20 ka. An unconformity separates the overlying fluvio-lacustrine phase with all eight samples indicating fluvio-lacustrine deposition at 85.9 ± 3.3 ka. An erosional unconformity separates this unit from the overlying Coxiella beach facies which itself dates to 70.4 ± 4.4 ka ($n = 2$ samples). This beach facies is interpreted to represent a regressional shoreline with a water level ~ 12 m deep. The overlying WPAU dates to 48.1 ± 6.1 ka ($n = 3$ samples), slightly younger than previously identified. Importantly the WPAU has formed at the same time (within errors) of the last megalake phase of Lake Eyre at 48 ± 2 ka (Cohen et al., 2015). The topographic position of the WPAU and the new chronology demands that this gypsiferous aeolian unit has formed as Lake Eyre has receded as it underwent a hydrological transformation. This would suggest that the putative *Genyornis newtoni* has indeed become extinct at a time period of extreme hydrological change. These results bring a fresh perspective to a site that has had a big influence on previous views of the Quaternary history of Australia’s arid zone.

Abstract

Santorini volcano (Eastern Mediterranean Sea) has been violently explosive active over the last ca. 360 kyrs, producing thick pumice and scoriae deposits in the proximal area from twelve major Plinian and numerous interplinian eruptions. However, tephra chronological information is sparse and the distal tephra record is incomplete mainly due to the lack of glass chemical data sets that enable proximal-distal tephra correlations and the difficulty of obtaining reliable numeric age dates from proximal deposits. This gap in knowledge has several implications for both volcanological and palaeoenvironmental studies. On the one hand, eruption frequencies, magma volumes and tephra dispersal directions of this high-risk volcano are difficult to estimate; on the other hand, the present uncertainties in tephra assignments yield serious constraints for the independent dating of palaeoclimate records in the Eastern Mediterranean region.

In this study, we present new proximal geochemical glass data of all major and some minor Santorini eruptions. We use this dataset in order to establish precise correlations with numerous visible and non-visible (crypto) tephra layers of Santorini provenance in three marine sediments cores from the SE Aegean Sea. Cores M40/4-65 (KL49), LC21 and M40/4-67 (KL51) form a 250 km medial-distal to distal transect SE of Santorini and span the last ca. 80 kyr, 160 kyr and 200 kyr, respectively. Their chronologies have been established by combining tephrochronology and new age estimates of sapropel boundaries via orbital chronology (KL49, KL51) as well as alignment of foraminiferal oxygen-isotope data with the Soreq speleothem $\delta^{18}\text{O}$ curve calibrated via U/Th disequilibrium dating (LC21; Grant et al., 2012). These age models enable the precise dating of marine tephra layers and, through geochemical correlation with proximal Santorini deposits, provide more reliable time constraints of all Plinian and some interplinian Santorini eruptive events than previously obtained numeric ages of proximal deposits (e.g., Druitt et al., 1999).

Our new tephrostratigraphic record from the SE Aegean Sea furthermore allows for a more detailed reconstruction of tephra dispersal directions for the last 200 kyrs of Santorini volcanic activity. Both the proximal and marine tephra glass chemical and chronostratigraphical datasets provide a basis for future distal tephra correlations that can help to facilitate the correlation of marine and terrestrial palaeoclimate proxy data in the Eastern Mediterranean region.

Tephrostratigraphic insights from Lake Ioannina, North West Greece

Amy McGuire¹, Christine Lane¹, Katherine Roucoux², Ian Lawson², Paul Albert³

¹University of Cambridge, Cambridge, United Kingdom. ²University of St Andrews, St Andrews, United Kingdom.

³University of Oxford, Oxford, United Kingdom

Abstract

The palaeoenvironmental record of Lake Ioannina (NW Greece) is an important archive of Quaternary climate and ecological change in the Mediterranean region. The pollen record from Ioannina is argued to contain a clearer representation of vegetation response to millennial-scale climate variability than other eastern Mediterranean records, due to the persistence of tree populations in nearby refugia, allowing a rapid ecological response to abrupt changes in climate (Tzedakis, 2002). Developing an independent chronology for the site to allow the study of these millennial-scale changes, particularly the comparison of their timing and impacts to those identified in other regional records, has proved challenging. These challenges arise from low organic content of the material and older ages associated with radiocarbon dating of sediments from karstic environments, where the underlying geology adds 'old', inert carbon to the system. Tephrochronology offers a key means of building age-depth-models for such sites.

Here we present the findings of tephrostratigraphic investigations of the 38 metre I-08 core from Lake Ioannina, which spans the last ~50 kyrs BP. Both visible and crypto-tephra horizons have been detected in the core. Geochemical analysis has been used to identify tephra layers associated with explosive volcanism at Italian volcanic sources, including Campi Flegrei, Pantelleria and the Aeolian islands. The identification of multiple layers associated with the eruption of Campi Flegrei following the 38 ka BP Campanian Ignimbrite super-eruption provides an exciting challenge and raises important questions about the detection of reworked material both prior to and following tephra layer deposition in the lake. These tephra horizons provide a chronology for the I-08 core, as well as facilitating the direct correlation of this record with other Mediterranean pollen records such as Lago Grande di Monticchio (S Italy), Lake Ohrid (Albania), and Tenaghi Philippon (NE Greece).

New major element analyses of proximal tephras from São Miguel confirm a link between the Azores and mainland Europe

Stefan Wastegård^{1,2}, Hans Johansson^{1,2}

¹Dept. of Physical Geography, Stockholm University, Stockholm, Sweden. ²Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden

Abstract

The Azores archipelago is one of the most active volcanic areas in the North Atlantic region. Approximately 30 eruptions have been reported over the last 600 years with some major VEI5 eruptions further back in time, e.g. the Fogo A eruption, 5600 cal yr BP. The geochemical composition of associated tephra-derived glass, however, is not well characterized. An Azorean origin of cryptotephra found in distal areas such as North Africa, the British Isles and Greenland has been suggested, but proximal data from the Azores are scarce and the correlations have been tentative at best. These tephra have a trachytic composition which excludes an Icelandic origin. Johansson et al. (2017) presented major element analyses of proximal tephra-derived glass from five Holocene eruptions on the Azores Islands. There is a striking geochemical similarity between trachytic tephra from volcanoes on the São Miguel island and cryptotephra found on Ireland (e.g. Chambers et al., 2004; Reilly & Mitchell, 2015), and especially with eruptives from the Furnas volcano. New EPMA analyses of samples taken in 2018 confirm and strengthen the link between Furnas and Irish cryptotephra, e.g. between the Furnas AD 1440 eruption and the Irish MOR-T2 tephra (e.g. Chambers et al., 2004). We also suggest a correlation between a previously unsourced tephra found in a Swedish bog with an eruption of the Sete Cidades volcano ca 3600 cal BP. We conclude that trachytic tephra erupted from explosive eruptions on São Miguel have a potential to contribute to the construction of a European-wide tephrostratigraphic framework.

Abstract

Volcanic ash is useful for helping us understand records of past environmental change. It provides us with independent marker layers in sediment from which the timing of key environmental and climatic changes can be assessed and geographically disparate sites in different settings can be linked (oceans, peat bogs, lakes, ice cores). It also provides us with a means by which to test the robustness of other chronological techniques and can help us refine age estimates obtained using methods such as radiocarbon dating. In the historical time frame, many ash layers have uncertainties of only a year or less, and throughout the Holocene many can provide ages on sequences with less than +/-100 year uncertainty. Cryptotephra was first identified in the UK in Caithness, Northern Scotland (Dugmore, 1989), with the recognition of Icelandic ash within peat. The subsequent 30 years have seen a significant rise in the number of researchers employing this technique and as a result of methodological and analytical advances we are now able to characterise very low concentrations of ash in sequences in areas remote from volcanic centres.

The application of tephra analysis to the peatlands of southwest England represents a much more recent spatial extension of the technique. Hall and Pilcher (2002) first reported that there are 'extremely sparse tephra layers on Dartmoor'; however, at that time, they were unable to characterise them. This was followed up by Matthews (2008) who's work on Roman Lode, Exmoor identified and characterised 3 ash layers (Hekla 1947, Hekla 1510 and OMH-185) covering the period back to c. 2700 cal yrs BP. Subsequently, Fyfe et al. (2016) identified five distinct ash layers on Dartmoor, and Watson et al., (2017) reported on the identification and chemical characterisation of two ash layers on Bodmin Moor, Cornwall (likely the AD 860 A and B ash layers), demonstrating that far-travelled ash is able to reach this region of the UK.

Here we report a more in-depth study of tephra in peat sequences on Exmoor and Dartmoor which was borne out of the Exmoor Mires partnership (<http://www.exmoormires.org.uk>). This has identified considerably more volcanic ash layers in the south west extending back to over 9000 cal yrs BP and originating from a number of volcanic centres. This provides us with an exciting opportunity to study the timing of key environmental changes in southwest England and also to assess how these compare to other parts of the UK, Ireland and Northern Europe.

Initiating cryptotephra research in Iceland

Maarit Kalliokoski^{1,2}, Esther Ruth Guðmundsdóttir¹, Bergrún Arna Óladóttir^{3,4}, Hreggviður Norðdahl³

¹Nordic Volcanological Center, Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland. ²Department of Geography and Geology, University of Turku, Turku, Finland. ³Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland. ⁴The Icelandic Meteorological Office, Reykjavik, Iceland

Abstract

Icelandic tephrochronology is the result of a long line of research and consists of geochemically well characterized and well dated tephra horizons. However, there is no one site in Iceland which would hold a complete record of all the silicic major tephra marker layers, which traditionally form the core of the chronology. Because the extent (of the dispersal area) of a visible tephra layer is determined both by the intensity and the length of the eruption as well as the prevailing wind directions during the eruption, most of the marker layers in Iceland are visible only within a certain sector extending away from the source volcano. Additionally, the tephra preservation potential may vary through time in any one site due to changing environmental conditions, which contributes to gaps in the tephra stratigraphy of a single site. Some amount of tephra grains is, however, expected to be deposited over a larger area and to be preserved as a cryptotephra layer.

We therefore suggest that initiating cryptotephra research in Iceland would increase the chances of constructing a more complete tephra stratigraphy for any single site, as well as help to strengthen the dialogue between tephrochronological frameworks of Iceland and distal areas. For an example, the cryptotephra findings in Northern Europe indicate that surprisingly many silicic tephra layers may yet be missing from the Icelandic tephrochronology. These tephras could possibly be present as cryptotephra layers in Iceland as well.

The focus of our research is in improving the early Holocene tephrochronology of North, East and Northeast Iceland by using both visible and cryptotephra layers. We conducted a systematic cryptotephra search in six sites by taking the following steps: 1) continuous high-resolution subsampling of peat cores and organic-rich soil sections 2) sieving accompanied by density separation where necessary 4) electron probe microanalysis of tephra geochemistry 5) constructing tephra stratigraphy for each site and 6) establishing between-site correlations of tephra layers by using both major element biplots and correlation coefficients.

Our preliminary results reveal the presence of at least six separate geochemically confirmed cryptotephra deposits between the Hekla 5 and the Saksunarvatn tephras in the inspected soil and peat sequences. For example, the silicic Fosen/Reitsvík tephra (ca. 10,200 BP) which was detected as a visible layer in just one of our sites, forms a cryptotephra layer in the five others, and can therefore be used as a secure tie-point between all our sites. So far our results suggest that cryptotephra method works well in the Icelandic conditions, at least in the organic-rich soils and peatlands, and holds great promise for future tephrochronology projects.

Establishing (crypto-)tephrostratigraphic frameworks: a case study of the Last Glacial-Interglacial Transition in the British Isles (c. 16-8 ka BP)

Rhys Timms¹, Ian Matthews¹, John Lowe¹, Simon Blockley¹, Alison MacLeod², Adrian Palmer¹, Dorothy Weston¹, Shuang Zang¹

¹Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, United Kingdom. ²Department of Geography and Environmental Science, University of Reading, Reading, United Kingdom

Abstract

The use of cryptotephra deposits as time-synchronous markers has become an important tool in the investigation of Quaternary records. When reliably identified, cryptotephra offer improved chronological control for records in which they can be traced, in turn helping to build a better understanding of the spatial and temporal complexities of environmental, geological and archaeological change. However, the use of cryptotephra for this purpose can be hampered by issues relating to: i) stratigraphic integrity; ii) chemical composition; and iii) chronological precision. Here we present the collective results of cryptotephra investigations conducted on more than 50 sites in the British Isles which span the Last Glacial-Interglacial Transition (LGIT; c. 16-8 ka BP). This collective evidence represents one of the most detailed studies of tephra deposition for this interval anywhere in the world, revealing that as many as 26 tephra fall deposits may be represented, with the great majority originating from the Icelandic province. These tephra are ranked as to their potential to serve as isochronous tie lines, based on the robustness of available evidence with respect to stratigraphic consistency, glass analytical data and chronological control. Currently, 15 of the 26 candidates are considered useful isochronous markers, while the data obtained from the remaining 11 are considered insufficiently robust. The issues encountered in the development of this framework are not unique and we hope that the approach applied here will find relevance in the wider tephra community. We also present preliminary results from on-going research that aims to extend and improve this tephrostratigraphical framework for the LGIT interval in the British Isles.

The Greenland tephra repository: uncovering the source and timing of distant eruptions

Siwan Davies¹, Paul Albert², Anna Bourne³, Eliza Cook⁴, Anders Svensson⁵, Takehiko Suzuki⁶, Vera Ponomareva⁷, Britta Jensen⁸

¹Swansea University, Swansea, United Kingdom. ²University of Oxford, Oxford, United Kingdom. ³Queen Mary University of London, London, United Kingdom. ⁴University of Copenhagen, Copenhagen, Denmark. ⁵University of Copenhagen, Copenhagen, United Kingdom. ⁶Tokyo Metropolitan University, Tokyo, Japan. ⁷Institute of Volcanology and Seismology, Petropavlovsk-Kamchatsky, Russian Federation. ⁸University of Alberta, Alberta, Canada

Abstract

Polar ice-cores have long been recognised for their value as repositories of volcanic activity. Unsurprisingly, tephra deposits from local eruptions dominate these records. However, improvements in micro-sampling and analytical techniques have uncovered a range of cryptotephra erupted from exceptionally distant eruptive sources. For instance, in the Greenland ice-cores, tephras from five different volcanic regions (Japan, Kamchatka, Cascades, Alaska and Iceland) have been identified during a short mid-Holocene window. This highlights the pivotal position of the Greenland ice-cores to capture deposition from the convergence of several far-travelled ash clouds. Their position in the ice provides high-precision age estimates from known eruptions such as Hekla 4, KS-2, Mazama and Mashu (-f-j), which can be employed as chronological constraints for other proxy records where these deposits are also preserved. Moreover, major and trace element signatures afford an opportunity to explore the distinct nature of tephra compositions originating from different tectonic settings. This is especially important for constraining the origin of unidentified sulphur peaks in ice-cores and optimise our quest to identify tephras from low-latitude eruptions. We present our micro-analytical approach to analyse small, fine-grained ash particles extracted from the ice and scrutinise the process of pinpointing eruptive sources.

O-3043

The geomorphology, controls and dynamics of southern African dust sources.

Frank Eckardt

Univesrity of Cape Town, Cape Town, South Africa

Abstract

This presentation examines the landforms of southern Africa associated with contemporary dust emissions. These sources include dunes, soils, rivers and pans from across Botswana, Namibia and South Africa. Emissions are examined considering sand/silt and clay composition and include abrasion and saltation processes. Supply settings and availability dynamics are determined by both climatic and anthropogenic factors and are varied in both space and time. Particular focus is placed on the dunes of the Kalahari, Namibian west coast dunes, coastal sabkhas, rivers and gravel plains, inland playas of the Namib and Kalahari, large ephemeral basins of Etosha and the Makgadikgadi as well as South Africa's Arenosols.

O-3044

Intersections between wind regimes, topography and sediment supply: Perspectives from Central Asian dunes and dust

Abstract

The widespread aeolian deposits of the Central Asian steppes and piedmonts offer great potential to better understand the dynamics of, and interactions between, the major northern hemispheric climate subsystems of Eurasia over Quaternary timescales. However, there is a problem with established assumptions linking climate processes with dust generation and aeolian deposition in the arid Central Asian context. Emerging datasets from the Tien Shan piedmont suggest that 1) hypotheses assuming a connection between increased loess accumulation and cold glacial conditions do not hold for this region, and 2) mass accumulation rates, and the timing of peak dust flux, are highly variable from one site to another. These results raise questions as to the nature of the relationship between loess accumulation, aeolian flux and palaeoclimate.

Here we investigate the relationship between wind regimes and the distribution, morphology and timing of dunes and dust in the Ili Basin, spanning southeast Kazakhstan and western China. Our findings, based on GIS and geomorphic mapping, wind trajectory reconstruction, geochemical provenancing and loess chronostratigraphy, indicate that:

- Dominant wind strength and aeolian transport capacity varies strongly across the basin, most likely in response to the obstructing influence of the Tien Shan mountain ranges;
- Ripples overlying linear dunes in the central basin directly correspond to short-term wind-storm events;
- Linear dunes preserve variable orientation across the basin, reflecting variability in the vector of dominant sand-shifting winds, over timescales where sand supply was plentiful;
- Dust sources for loess deposits vary across the basin depending on wind regime and supply, indicating more dominant local supply in the east, and increasing distal contributions to the west;
- The timing of loess accumulation varies substantially across the basin; there is no uniform, contemporaneous draping of dust along the piedmont.

Our integrated approach provides more nuanced information about aeolian processes in relation to wind regimes not otherwise available from site-specific case studies, and highlights a need to interrogate climate-driven models for aeolian deposits.

O-3045

Loess, dust, parna: unravelling the conceptual continuum in Australasia for improved paleoenvironmental reconstruction in the Quaternary.

Carol Smith¹, Stephen Cattle²

¹Lincoln University, Christchurch, New Zealand. ²University of Sydney, Sydney, Australia

Abstract

There are a variety of both mechanisms and geomorphic processes which generate, sort and concentrate silt-sized grains: entrainment by wind, then deposition by aeolian processes follow. This can occur in semi-arid to temperate to periglacial geomorphic units. Loess is an accepted term in New Zealand for aeolian, silt-sized deposits of glacial origin. In Australia, a varied terminology ranging from parna, to dust to lithogenic fluxes are all employed to describe aeolian silt sized deposits, generally accepted to be sourced from semi-arid environments.

This range of terminology can be a source of confusion and has likely arisen from historical constructs during the development of loess research world-wide. But what we do know is that aeolian sediments and their associated soils in both Australia and New Zealand encompass a wide range of particle size, mineralogy and geochemistry. This reflects differences in the dust source of the contributing regional geomorphic units, dynamics of dust emission from the differing geomorphic units as well as post sedimentary changes to the dust deposits (pedogenesis) driven by gradients of aridity and weathering.

We aim to demonstrate that despite these differences, loess, dust, parna also exist on a continuum, influenced by gradients of aridity, weathering and particle size. We will do this by deconstructing some specific examples in Australia and New Zealand. We compared the different provenance, formation pathways, mineralogy and geochemistry for these sediments using a range of techniques including optical micromorphology, granulometric analysis and QEMSCAN[®] analysis.

In Australia (southern NSW), microfabric analysis demonstrated a continuum of pedogenesis of the associated parna soils along gradients of aridity and weathering. In New Zealand, the transport pathway for the loess mantled landscape in the Manawatu district (North Island) is generally accepted, but the morphological and chemical difference between the soils developed on the drier terraces (Tokomaru) compared to those on the moister terraces (Dannevirke) is still not fully understood. On comparing the mineralogy and geochemistry, the dust / parna in Australia is dominated by quartz and clay, and little plagioclase feldspar. While in New Zealand (Manawatu), the grain size distribution of the two soils are very similar. The Dannevirke soil mineralogy is dominated by kaolinite and chlorite while the Tokomaru soils have a greater proportion of weatherable mineral grains.

We discuss the results in terms of the conceptual differences in the transport pathways and pedogenesis of loess and how this can inform our ability to reconstruct Quaternary paleoenvironments, and ultimately contribute to improved numerical models of the dust cycle.

New Zealand as a potential source of mineral dust to the atmosphere and ocean during glacials

Bess Koffman^{1,2}, Steven Goldstein², Gisela Winckler², Michael Kaplan², Louise Bolge², Merry Cai², Toby Koffman², Cristina Recasens³

¹Colby College, Waterville, USA. ²Lamont-Doherty Earth Observatory, Palisades, USA. ³Almac Group, Craigavon, United Kingdom

Abstract

The geochemical composition of sediments and dust can be used to trace their provenance, thereby providing insights into a range of Earth surface processes. During past glacial climates, much of New Zealand was blanketed by temperate erosive glacier systems, which produced significant volumes of sediment. To trace the extent of subsequent aeolian and oceanic transport of this material, and thus its potential impact on climate and ecological systems, we characterized the geochemical composition of sediments. We present geochemical analyses, including Sr-Nd-Pb isotopes and major/trace elements, of more than 20 fine-grained (<5 μm diameter) sediments from the major dust- and sediment-producing regions of the South Island. We find that sediment composition strongly reflects local lithology. The central South Island, including the Canterbury Plains and Mackenzie Basin, has a relatively homogenous isotopic composition, with $^{87}\text{Sr}/^{86}\text{Sr} = 0.7095\text{-}0.7165$, $\epsilon\text{Nd} = -6.5$ to -4.0 , $^{208}\text{Pb}/^{207}\text{Pb} = 2.470\text{-}2.485$, and $^{206}\text{Pb}/^{207}\text{Pb} = 1.198\text{-}1.215$. The southern South Island, including Southland and Otago, has an isotopically younger and more variable composition, reflecting the presence of Paleozoic volcanic complexes. Here $^{87}\text{Sr}/^{86}\text{Sr} = 0.7041\text{-}0.7140$, $\epsilon\text{Nd} = -4.0$ to $+5.3$, $^{208}\text{Pb}/^{207}\text{Pb} = 2.463\text{-}2.483$, and $^{206}\text{Pb}/^{207}\text{Pb} = 1.196\text{-}1.208$. We make comprehensive comparisons to available isotopic data from other Southern Hemisphere mid-latitude dust sources, finding that while isotopic fields often overlap, the combination of Sr, Nd, and Pb isotopes offers improved ability to discriminate between potential source areas. We estimate the expansion of glacial outwash plains based on a sea level lowering of 130 m at the Last Glacial Maximum (LGM), and find that the Canterbury Plains likely covered an estimated 38,500 km^2 while the Southland/Otago Plains may have extended to 50,500 km^2 . Considering New Zealand's extreme uplift and erosion rates (~ 10 m kyr^{-1}), we suggest that the South Island, though limited in extent compared to larger Southern Hemisphere landmasses, may have served as an important dust source to the high-latitude atmosphere and ocean during glacial periods.

O-3047

Automated static image analysis technique to identify Saharan dust particles within unconsolidated eolianites on Fuerteventura

György Varga¹, Christopher-Bastian Roettig²

¹Geographical Institute, Research Centre for Astronomy and Earth Sciences (MTA) , Budapest, Hungary. ²Institute of Geography, Dresden University of Technology, Dresden, Germany

Abstract

The identification of windblown dust in regions located relatively far from major dust source areas is an intriguing problem of sedimentary studies. The identification of external mineral particles is rather challenging, however, in certain cases the geological-geomorphological environment provide suitable conditions. The island of Fuerteventura is free from quartz and just bears basaltic rocks and carbonate sands originating from the shallow shelf. Therewith the islands dune sequences are placed best to serve as a natural laboratory for our investigations of quartz-rich, silt-sized Saharan dust deposits.

An automated static image analysis method completed with Raman spectroscopy was applied in this study to identify and separate Saharan mineral particles from Upper Pleistocene sedimentary units.

The captured high-resolution grayscale images of ~50,000 individual mineral particles per samples allowed us to apply different independent approaches. Beside bulk grain size and grain shape characterization, (a) sedimentary subpopulation partition by parametric curve-fitting, (b) Raman spectroscopy based quartz particle identification, and (c) grayscale intensity mean values of particles (relatively high values were used as a proxy for quartz grains due to the finding of a strong correlation between light transmissivity of grains and chemical identity) were used.

The presented set of methods provided new data on the granulometric character, the depositional mechanisms and the admixture of dust material to sandy units. Joint applications of several size, shape and grayscale intensity values and mathematical techniques allowed the separation of quartz grains from other mineral particles.

Support of the National Research, Development and Innovation Office NKFIH K120620 (for G. Varga) is gratefully acknowledged.

Loess deposition and remobilization in an ice-marginal landscape

Randall Schaetzl¹, Garry Running², Phil Larson³, Tammy Rittenour⁴, Douglas Faulkner², Jarrod Knauff¹, Christopher Baisch¹, Samantha Kaplan⁵

¹Michigan State University, East Lansing, USA. ²University of Wisconsin - Eau Claire, Eau Claire, USA. ³Minnesota State University, Mankato, USA. ⁴Utah State University, Logan, USA. ⁵University of Wisconsin - Stevens Point, Stevens Point, USA

Abstract

Considerable loess research has focused on systems of silt generation and eolian transport, and their ties to paleoclimate. In our study area in western Wisconsin, USA, just outside the Last-glacial margin, most of the silt was derived from broad outwash valleys and transported on westerly winds, often assisted by saltating sand. Normally, such systems lead to continuous blankets of loess downwind from the source area. Across the hilly, sandstone landscapes of western Wisconsin, this initial phase of loess deposition probably began shortly before the last glacial maximum and continued through the early period of glacial recession, ca. 23-18 ka. Across this ice-marginal landscape, much of this loess was deposited on ground rife with permafrost. We will argue that the landscape underlying this initial loess deposit was later destabilized by thawing permafrost, leading to widespread slumping and mass movement of loess across steep hillslopes, exposing loess deposits to strong winds and saltating sands. Our data will show that this combination of events and circumstances led to widespread landscape instability, facilitating reentrainment of this "initial" loess during a secondary period of silt transport. Much of this loess, which we refer to as "secondary" loess, was deposited at sites farther downwind. Because of the hilly topography and assumedly strong winds at this time, transport and deposition of much of this secondary loess was strongly influenced by the bedrock topography. Thick deposits of secondary loess, often burying "primary" loess below, formed in protected sites on the lee (SE) sides of the highest hills. These deposits approach thicknesses of 7 m. Conversely, the northwest-facing hillsides were windswept and are today loess-free. Ventifacts are commonplace on this landscape, attesting to a period of strong winds and widespread erosion. The result of these eolian depositional-erosional events is a loess cover that is highly spatially variable, and in places, of two distinct ages.

We report on stratigraphic data from one of the thickest loess sites in the region, where >5 m of loess cap a hilltop. Western and northwestern flanks of this hill are loess-free. Our down-core data on texture and geochemistry, as well as OSL ages, clearly indicate a stack of younger, sandier loess overlying a siltier, older unit. The broader implications of this loess "stack," all of it entirely postglacial in age, will be the focus of this paper.

O-3049

A tale of two dune fields: dust emission processes from White Sands, New Mexico and Monahans, Texas, USA

Mark Sweeney¹, Steven Forman², Eric McDonald³

¹University of South Dakota, Vermillion, USA. ²Baylor University, Waco, USA. ³Desert Research Institute, Reno, USA

Abstract

Research focusing on dust emissions from eolian dunes has recently increased as researchers recognize the importance of improving global emissions estimates and detailed characterization of dust sources. The well-sorted nature of eolian sand has precluded dunes from being considered as major sources of dust because most dune fields contain a very low percentage of dust-sized material. However, dust emission potential of dune fields can be quite variable on a landform scale, related to grain size distribution, mineralogy, and processes contributing to grain abrasion during saltation transport. We used the Portable in situ Wind Erosion Lab (PI-SWERL) to measure the PM-10 dust emission potential from a variety of geomorphic units comprising two dune fields: the White Sands dune field in New Mexico, dominated by gypsum, and the Monahans dune field in West Texas, dominated by quartz. These dune fields contain landforms with variable sedimentologic properties, including large active dunes, protodunes and sand sheets, stabilized and vegetated dunes, and fine-grained interdunes. Deflation of playa at White Sands leads to low-relief protodunes to well-developed dunes. The eolian sand is well sorted and contains <1.5% fines. The Monahans dunes are sourced from the Pecos River and transition from low relief vegetated sand sheets with >10% fines, to vegetated parabolic dunes, to active and partially stabilized dunes containing <3% fines at the dune field core. PI-SWERL tests reveal that Monahans sand sheet would be a prolific dust emitter if the vegetation was destabilized ($1.21 \text{ mg m}^{-2} \text{ s}^{-1}$ PM-10). Vegetated parabolic dunes are moderately emissive ($0.31 \text{ mg m}^{-2} \text{ s}^{-1}$), while active dunes have relatively low dust fluxes ($0.03 \text{ mg m}^{-2} \text{ s}^{-1}$). White Sands dunes are moderately emissive ($0.36 \text{ mg m}^{-2} \text{ s}^{-1}$), with fluxes comparable to vegetated parabolic dunes of the Monahans. Dust emissions from the Monahans sand sheets and parabolic dunes are largely driven by the liberation of resident fines during saltation. Dust emissions from the dune field core are likely driven by abrasion of sand that removes grain coatings, as well as minor chipping and spalling. White Sands dust emissions are likely driven by significant chipping and spalling of soft gypsum grains that become more equant downwind. Active dunes likely contribute to high ambient dust concentrations in desert environments, but with persistent drought or landscape disturbance by the growing oil and gas industry in West Texas, sand sheets could become significant dust producers in the future. White Sands occasionally generates large dust storms that cause visibility and respiratory problems for nearby populations. Conditions during the 1930s Dust Bowl drought may have resulted in wide-scale deposition of White Sands-derived dust. Our results indicate that dust emissions from dune fields can be highly variable, highlighting the importance of landscape-scale properties in dust emission estimates.

Pleistocene –Holocene depositional rhythms in clastic successions of the Caspian Sea under climatic control

Elmira Aliyeva^{1,2}, Dadash Huseynov¹, Elnur Amirov³

¹Geology and Geophysics Institute of Azerbaijan National Academy of Sciences, Baku, Azerbaijan. ²Scientific - Research and Project Institute of oil and gas, SOCAR, Baku, Azerbaijan. ³Halliburton, Baku, Azerbaijan

Abstract

The Lower Pleistocene (Absheron stage), Middle Pleistocene (Khazar stage) exposures on the Absheron Peninsula, and Holocene sediments from the Kura river delta located in the western flank of the South Caspian depression have been studied via integration of different geological and analytical methods -sedimentology, paleontology, isotope and trace elements geochemistry. Lithologically Pleistocene sediments are represented by shelly sandstones, coarse- to medium - grained sandstones, silts and silty shales. Holocene succession is dominantly composed of muddy sediments with some sand intervals. The Caspian Sea level fluctuations were recorded in the Pleistocene succession as depositional environment changes within shoreface -offshore settings, and in Holocene sediments – in facies variations within deltaic- fluvial environment.

A high resolution time series geochemical analyses of carbon and oxygen isotopes and

elemental ratios (Mg/Ca and Sr/Ca) in ostracod shell carbonate demonstrate a close correlation between Caspian Sea level fluctuations, climatic variations, and faunal assemblages, depositional environment changes.

The shallowing and decrease of salinity of the basin on the Plio-Pleistocene boundary caused the formation of a poor and stressed faunal complex in the Early Absheronian time. Subsequent the mid-Absheronian transgression accompanied with the increased of salinity created favorable conditions for flourishing of fauna. In Holocene Kura river delta retreat and realignment brought salinity variations in the 10-12‰ range, and rapid changes in the hydraulic conditions. Consequently, fresh and brackish water species dominance was recorded.

Based on the $d^{18}O$, $d^{13}C$ and Ca/Mg, Sr/Ba ratio variations we can testify to significant climatic and basin salinity variations during Pleistocene-Holocene that provided us by unique opportunity for characterizations of short-term climatic cyclicality in this geological interval that was, probably, the major Caspian lake-level control, governing depositional processes in the basin. We can report tens of climatically driven small scale depositional rhythms in the Caspian Quaternary succession. Thus, the Caspian Sea level drop and accumulation of the low stand sediments took place during cool stage of the climatic cycles. In contrast, deposition of high stand sediments was more common during warm stages.

Absolute chronology of Caspian sea Late Quaternary basins

Redzhep Kurbanov^{1,2,3}, Andrew Murray⁴, Tamara Yanina⁵

¹Moscow State University, Faculty of Geography, Moscow, Russian Federation. ²Institute of Geography, Moscow, Russian Federation. ³Institute of Deserts, Ashgabat, Turkmenistan. ⁴Nordic Laboratory for Luminescence Dating, Department of Geoscience, Aarhus University, Aarhus, Denmark. ⁵Moscow State University, Faculty of Geography, Москва, Russian Federation

Abstract

The stratigraphy and palaeogeography of the Northern Eurasian Pleistocene is recorded in Caspian Sea sediments. They contain a unique record of major regional and continental phenomena (e.g. glacial-interglacial cycles of the Russian plain, the Caucasus and Central Asia, and links to the oceans during marine high-stands), as well as of global climate change. To fully understand this record there is an urgent need for an accurate numerically-based chronology for the marine history. During the Late Quaternary dramatic changes in relative sea-level are known to have occurred in the Caspian Sea. However, all previous attempts at resolving the uncertainty associated with the timing of these transgressive/regressive events using standard dating methods have produced inconclusive or controversial results. For the last 5 years series of reference sections of Caspian sea Late Quaternary in Lower Volga valley (Kosika, Raigorod, Cherny Yar, Srednyaya Akhtuba, Leninsk, Batayevka, Seroglazka, Bykovo, Selitrennoye), Manych Depression (cores from central and eastern parts of the depression), Dagestan coast (Turali section, Darvagchai-zaliv Paleolithic site), Mangyshlak peninsula, Gorgan river valley, Kerch and Taman peninsula (Tuzla and Eltigen sections), Western Turkmenistan (Cheleken peninsula) were dated using radiocarbon and OSL. High-resolution luminescence dating results correlated with biostratigraphical chart based on Caspian sea Didacna Eichwald mollusks and radiocarbon dating allowed to re-evaluate the existing understanding of the chronology of Caspian Sea transgressions. We will present newest results based on more than 200 OSL dates from main Late Quaternary stratigraphic layers, describing main palaeogeographic events: Novocaspien, Early and Late Khvalynian; Hyrcanian and Late Khazarian transgressions; Atelian, Mangyshlak and Enotaevka regressions.

O-3052

Variability of the chocolate clays deposition during the Late Pleistocene in the Lower Volga Region

Radik Makshaev, Tamara Yanina, Alexander Svitoch
Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

Chocolate clays are one of the most common facies of the Lower Khvalynian deposits in the Lower Volga River valley. They were deposited during the Early Khvalynian transgression of the Caspian Sea. These clays consist mainly of clay with lenses sand and silt that contains mollusc shells.

Here we present the results of 69 radiocarbon ages of chocolate clays derived from mollusc shells (*Didacna*, *Monodacna* and *Dreissena* species). Radiocarbon ages were calibrated to calendar years using the CALIB 7.0.4. (IntCal13) program (Stuiver and Reimer, 1993). The materials were collected from the key sections (Svetly Yar, Raigorod, Sr. Akhtuba, Cherny Yar, Tsagan-Aman, Kopanovka, Enotaevka, etc.) in the Lower Volga region.

Radiocarbon dates of chocolate clays reveal ages between 20-11 cal ka BP. 28 of these ages lie between 14,1-13,5 cal ka BP. The ages at the base of the chocolate clays are 16-14,5 cal ka BP and at the top are 14-12,5 cal ka BP. Few dates correspond to 11 and 20 cal ka BP. The radiocarbon ages of the bottom part of the chocolate clays in the southern key sections are 16,5-14,8 cal ka BP, meanwhile in the Northern sections they are 14,1-13,8 cal ka BP.

The results suggest that the sand layers with mollusc shells in the bottom of the chocolate clays were deposited between 16,2-14,7 ka BP, which correspond to the Oldest Dryas cold event, while during 14,5-14,1 ka BP chocolate clays with massive structure were accumulated. This time corresponds to the Bølling warm period. The ages of upper and middle sand horizons that contain molluscs *Didacna ebersini*, *Dreissena polymorpha* are estimated between 14,1-13,8 ka BP, which correspond to the Older Dryas cold event. Deposits of sandy clay sediments that contain molluscs of *Dreissena polymorpha* reveal the ages of 13,8-12,8 ka BP and correspond to Allerød warm period.

The results show that the variability of the litho-facial composition of the Early Khvalynian region sediments in the Lower Volga could potentially depend on the Late Pleistocene climatic regimes. The abundance of molluscs prevailed during the cold events when sandy layers were deposited. In the Bølling warm period when massive chocolate clays were deposited the molluscs disappeared.

Correlation of the paleogeographic events in the Caspian sea and on the East European Plain during the glacial epoch

Tamara Yanina, Nataliya Bolikhovskaya, Redzhep Kurbanov, Valentin Sorokin
Lomonosov Moscow State University, Moscow, Russian Federation

Abstract

The problem of correlation between transgressive-regressive oscillations in the Caspian and glacial events on the Russian Plain is of great importance in Pleistocene paleogeography. It has been thoroughly studied previously by a number of researchers, but at the present moment, there is no unequivocal opinion on the problem. This work presents new data obtained by the authors during the last years. They allow us to specify relationships of events in the Caspian Sea and on the Plain. The authors have carried out analyses of the sections from the Lower Volga Region and boreholes cores from the northern Caspian Sea. The complex studying included lithologic, faunistic, palynological and geochronological analyses. Paleogeographic evidence on glacial events on the Plain is based on published sources. The conclusion is made the events during the last glacial epoch (MIS 4-2) left their distinguishable imprint on the Caspian Sea environment evolution. During MIS 4 and the first part of MIS 3 the Atelian regression developed in the Caspian Sea. The dating obtained for the Atelian deposits testifies to the formation of them from 68 to 45 ky. The horizons of the soil (MIS 5) is broken by frost cracks and wedges that are filled with the Atelian sediments. Palynological materials indicate periglacial vegetation in the basis of the Atelian deposits and moderately warm in their upper part. The early stage of the Khvalynian transgression of the Caspian Sea developed during the second half of MIS 3. The radiocarbon dates (31.5-28.5 ky) of deposits are comparable with the OSL dates. Judging from the shell composition the water temperature was moderately warm. Pollen data confirm it. It was the interstadial epoch. The level rising was interrupted during maximum cooling and aridization at MIS 2 and resumed when the ice sheet was decaying. The events known as warm phases of Bølling and Allerød promoted the ice sheet melting along with thawing of permafrost, the latter having been widespread in the Volga drainage basin. All the above contributed to the Khvalynian transgression. The 'chocolate' clays were accumulated in the Volga estuary and in depressions in the Pre-Khvalynian relief. Phases of a cooling known as the Oldest, Older and Younger Dryas marked by a decrease in the runoff volume from the Caspian drainage basin are correlatable with regressive stages in the Khvalynian basin history. The best pronounced of them corresponded to the Younger Dryas. The Khvalynian came to its end at the first sharp warming that resulted in the rise of the Caspian level. The Mangyshlakian regression is dated to the Holocene and was essentially a response to the increase in the climate continentality. The work is supported by the Russian Foundation for Basic Research (Grant 18-00-00470).

The Late Pleistocene history of the Manych Strait (new data)

Redzhep Kurbanov¹, Tamara Yanina¹, Andrew Murray², Vladimir Belyaev¹, Olga Borisova³, Daria Semikolennykh¹, Mikhail Svistunov¹

¹Moscow State University, Moscow, Russian Federation. ²Aarhus University, Roskilde, Denmark. ³Institute of Geography RAS, Moscow, Russian Federation

Abstract

Manych-strait connected Black sea and Caspian Sea in Pleistocene is a great event in the history of the Ponto-Caspian region. The strait located within such geological structure as Manych Depression which is extended sublatitudinally from the west coast of Northern Caspian to the north-west of the Azov sea. The existence of the Manych-strait is essentially for the stratigraphy and paleogeography. There were several stages when marine waters spilled over from Black sea to Caspian and alternatively. Due to the alternation of sedimentary layers it is possible to correlate pleistocene deposits and paleogeographic events. Nowadays there are a lot of materials and data about the history of Manych-strait. In the profile are distinguished interbedding marine deposits with lacustrine and alluvial formations and subaerial deposit on top. The main question is the paleogeographical reconstruction and chronological timeframe of main events of Late Quaternary. We try to solve this problem using our new data and elaborating available information.

The preliminary scheme of the sequence of paleogeographic events in Pleistocene is complied. The beginning of Late Pleistocene is marked by the penetration of marine water deep within the Manych Depression during the Black Sea interglacial transgression (Karangat Trangression, MIS 5e). The character trait of marine water through this period is relatively high salinity (18-20 ‰), that favors the development of Black Sea mollusks. During the transition to the glacial epoch (MIS 5d-a) the marine waters oh Karangat bay had begun retreated back into the Black Sea basin. In the end of this stage there was a strait called Hirkanian, which had desalted brackish waters (8-10‰) of the Caspian sea. The marine epoch in the central part of the Manych depression changed to the durable lacustrine phase of development in the second half of Late Pleistocene (MIS 4-3), Burtass lake existed there. In the beginning of its existence it was flowing through (it so because of the major of fresh- and calmwater mollusks in the base of the layer).

During the continental stage there was an active erosion damage of the burtass deposits. Through this period were formed specific landscape forms – extended ridges – which finally formed in the epoch of degradation of the last glaciation and Khvalynian water removing to the Black Sea basin. After the closing of the Khvalynian strait began the continental epoch, through this time there were forming the subaerial stage, which is continuous nowadays.

New data on stratigraphy of late Holocene deposits of the Sea of Azov (Eastern Europe)

Gennady Matishov, Galina Kovaleva, Vladimir Polshin, Kristina Dyuzhova, Vadim Titov
Southern Scientific Centre RAS, Rostov-on-Don, Russian Federation

Abstract

Over the last 15 years we were studying bottom sediments and coastal outcrops of the Azov Sea. A regular sample of cores in different parts of the sea implemented, as well as drilling on the coast. The combination of lithologic, seismoacoustic, micropaleontological (spore-pollen, diatom) data with radiocarbon dating made it possible to clarify several aspects of the Holocene history of this internal marine basin.

The summary of radiocarbon dating from 25 cores with the results of micropaleontological analysis made it possible to clarify the age and thickness of bottom sediments of the Azov Sea. It has been established that the upper 2-3 m of the sedimentary thickness are consisted of by deposits of the New Azovian age (last 3.1 thousand years) usually. A decrease of their thickness (less than 1 m) is noted in the east of the open sea area, as well as in the central and eastern parts of the Taganrog Bay.

The time intervals of transgressive-regressive phases' existence were corrected; several stages of sea level rise and fall were traced, which affected at the change of diatoms' species composition. These stages do not coincide with the Black Sea basin ones, and reflect regional features and relative isolation of the Azov Sea from the Black and Caspian Seas. It was shown that changes of the Azov Sea level occur with a delay compared with regional landscape-climatic phases. The obtained data confirm the interrelation of sea and land processes occurring in the Azov Sea basin: general humidization in the region preceded the transgressive phases, and the regressive ones, on the contrary, are associated with aridization of the climate. The results of the diatom analysis confirm the existence of the Fanagorian and Korsunian regressions, as well as the Nymphaean transgression. The humidization of the climate at the beginning of the Subboreal period coincides with the transgressive phase. The initial stages of the New Chernomorian and Nymphaean transgressions also coincide in time with the period of humidification of the climate.

It is shown that the water area of the Taganrog Bay was significantly expanded by intensive abrasion processes, which proceeded at the general background of transgressive sea level rise in the Late Holocene. As a result, over the past few thousand years, the size of the bay, its depth, the configuration of the shores changed, the outlines and location of the Don River Delta were transformed. At the stage of the Fanagorian regression, the dried seabed was actively denudated. It has been established that the accumulative bodies of the sand tails at the southern coast of the Taganrog Bay have been formed over the past 5,000 years.

Caspian sea Late Khvalynian transgression and its role in development of human population during Epipaleolithic in Western Turkmenistan

Svetlana Shnaider¹, Redzhep Kurbanov², Margarita Shangina², Alisher Saltanat³

¹Institute of Archaeology and Ethnography of the Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation. ²M.V.Lomonosov Moscow State University, Moscow, Russian Federation. ³Novosibirsk State University, Novosibirsk, Russian Federation

Abstract

During Quaternary period, unstable sea-level regime of the Caspian Sea resulted in vast transgressions and deep regressions which played an important role as a natural barrier and influenced past migration routes of human populations. Because of its central geographic location, the area also channeled culture, technology, and other forms of exchange between adjoining regions from the first modern human occupation into Eurasia and up to the present day.

Unfortunately, not all areas of Caspian region are studied evenly, and at the present time the ancient human history of the Eastern Caspian is very poorly understood. Previous investigations of the prehistory of the region were conducted in the middle of 20th century by A.P.Okladnikov (Okladnikov, 1953) and later by G.E.Markov (Markov, 1966), and published in Russian. These studies suffer from the absence of absolute chronology and the results of modern multidisciplinary analysis. The reexamination of old Okladnikov's collections is ongoing and focusses on the multilayer rockshelter sites named Dam-Dam-Cheshme 1, Dam-Dam-Cheshme 2 and Jebel, which are located in the Great Balkhan (Uly Balkan) region, and two other sites located in the Krasnovodsk peninsula – Kuba-Sengir and Kaylu.

In 2018, we conducted an archaeological survey at Krasnovodsk peninsula in Turkmenistan, during which we identified the exact location of Kuba-Sengir and Kaylu sites and described their geomorphological position and collected samples for luminescence dating.

The latest data on the age of the largest Late Quaternary Khvalynian transgression of the Caspian Sea (Yanina, 2017) allow us to reconstruct the paleogeographic situation in the region. About 13-15 thousand years ago, the level of the Caspian reached maximum of +46-48 m, i.e. 76 meters above the modern level. During that time, the seawater filled located to the south-east Western-Turkmen lowland with, forming a deep gulf and penetrated along the Uzboy valley for 100-120 km to the east, while flooding and extending the Kemal lowland (Fedorov, 1978). Located on the altitude of +60 meters Cuba-Sengir cape site was outside the flooding zone and could be populated for a longer time. The waters of the Caspian Sea at this time approached as close as possible, and the shell material from the beach close to the site could be a source for production of the beads. This fact is also indicated in the numerous finds of fish bones, including sturgeon. It is unlikely that the ancient population used shells from deposits of older Caspian transgressions, since the horizons containing them are located substantially lower.

Results of science work will be cartographic materials of the levels dynamic of the Caspian Sea and revealing the influence of the levels evolution of the Caspian Sea on archaeological objects in the Holocene.

Source-to-sink processes and their response to hydroclimatic variability in tropical Lake Towuti, Indonesia

Marina A. Morlock¹, Hendrik Vogel¹, Martin Melles², James M. Russell³, Satria Bijaksana⁴

¹Institute of Geological Sciences and Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ²Institute of Mineralogy and Geology, University of Cologne, Cologne, Germany. ³Department of Earth, Environmental, and Planetary Sciences, Brown University, Providence, USA. ⁴Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung, Bandung, Indonesia

Abstract

Humid tropical landscapes are subject to intense weathering and erosion, which strongly influence sediment mobilisation and deposition. Over longer timescales, these processes are altered by climatic and environmental changes, as well as other factors, e.g. tectonics, giving rise to complex, dynamic landscapes. In this setting, we aimed to understand how hydroclimate and geomorphology altered the style and intensity of erosion and sediment composition in a tropical lake and its tectonically active catchment. Lake Towuti (2.75°S, 121.5°E) is one of the oldest and deepest lakes in Indonesia, with uninterrupted lacustrine sedimentation over several glacial-interglacial cycles. We present results from a source-to-sink analysis of Lake Towuti's modern catchment, and apply this understanding of modern processes to a 100-m-long, continuous lacustrine sediment record, spanning the last ~1 million years.

We find that the overall composition of modern sediments across the lake is strongly influenced by tectonic disturbance of river courses, which enhances bedrock abrasion and promotes slope instabilities in some of the river catchments. The two large and most tectonically influenced rivers Mahalona and Loeha, together with material from the lateritic catchment soils, are identified as the three dominant sediment sources to coring location TDP-Site 1. Geotechnical analyses from Lake Towuti's catchment show that the lower laterite horizons have lowest stability and can function as slide planes to mobilise the entire soil package during mass movement events. Across the 100-m-long Pleistocene sediment record, variability in sediment composition reflects the interplay between these three sources, which in turn can be related to hydroclimatic variability in the region. In addition, long-term tectonic basin evolution, post-sedimentary sediment alteration, and changes in lake productivity are important factors that shape sediment composition through time. Preliminary results of the high-resolution geochemical sediment record suggest that hydroclimate at Lake Towuti is sensitive to changes in orbital parameters, as well as higher-frequency climate variability.

The detailed study of the modern catchment and associated processes provides an important contribution to defining the baseline status and variability of ecosystems and landscapes in Central Sulawesi in the recent past and on glacial-interglacial time scales. In combination with the long sediment record, this enables a comprehensive reconstruction of changes in depositional environments and hydroclimate from the Southeast Asian humid tropics through large parts of the Pleistocene.

Forest-fire-climate dynamism in the lowland tropics of Wallacea over 30,000 years

Rebecca Hamilton¹, Janelle Stevenson¹, Sarah Ivory², James Russell³

¹The Australian National University, Canberra, Australia. ²Penn State University, State College, USA. ³Brown University, Providence, USA

Abstract

The lowland tropics of Wallacea in south-east Asia represent some of the most diverse, biogeographically significant forests globally. Long-term ecological data for this region are, however, scarce, making it difficult to predict vegetation response to future drivers of change, including an increase in the intensity and frequency of precipitation extremes. Emerging palaeoclimatic data suggest that marine isotope stage 2 (MIS 2) within Wallacea was significantly drier and more seasonal than either MIS 3 or the Holocene, and that the Holocene was characterised by a series of lower-amplitude hydroclimatic shifts. Examining floristic response to these shifts can provide insight into the acclimation thresholds of forest taxa to hydroclimatic drivers of different magnitudes, and illuminate the dynamism of the tropical landscape over millennia.

This research presents palynological records from two sites within lowland Sulawesi, Indonesia – Lake Lantoa (16,500 yrs BP to the present) and Lake Towuti (30,000 yrs BP to the present) – that, respectively, capture local and regional floristic change from that start of MIS 2 to the present. Our results show that closed forest has persisted in the local and regional landscape over the assessed time period in spite of being subject to drier climates and heightened fire activity prior to the Holocene. However, there are notable intra-forest compositional shifts evident in the records in response to glacial scale climatic forcing and changing patterns of landscape disturbance (including burning). These include contraction of tropical coniferous forest between 31,000 and 17,000 yrs BP in response to heightened seasonality, the replacement of seasonal forest taxa with rainforest species with increased humidity (at the Bølling-Allerød interstadial and the MIS 2-Holocene boundary), and a slight return of seasonal/ secondary forest types in response to late-Holocene anthropogenic activity. These findings demonstrate the stability of the tropical forest biome in Wallacea to key drivers of change, but highlight intraforest compositional dynamism in the landscape in response to these drivers.

The origin of variability present at Lynch's Crater, northeastern Queensland (Australia), across the period 40 - 10 ka

Susan Rule^{1,2}, Peter Kershaw¹, Chris Turney³, Simon Haberle²

¹Monash University, Melbourne, Australia. ²Australian National University, Canberra, Australia. ³University of New South Wales, Sydney, Australia

Abstract

The presence and timing of Heinrich (H) events have been well-established in the north Atlantic region (H1, H2, H4 and H5) and associated with rapid temperature, precipitation and ocean circulation changes due to iceberg discharge events linked to the Hudson Strait/Hudson Bay region while the more minor H3 and H6 are associated with European ice-sheets. In the Southern Hemisphere and the tropics it has been suggested that warming and/or wetter conditions likely due to the southward movement of the ITCZ are associated with Heinrich events. Studies undertaken at Lynch's Crater, northeastern Queensland have resulted in conflicting conclusions of conditions present during Heinrich events with the suggestion that the presence of inorganic phases indicate wet H events (Muller et al. 2008) while Turney et al. (2004) suggest that H events coincide with 'warm' (dry) ENSO activity based on sediment humification and the Cyperaceae/Poaceae pollen ratio. A more recent high resolution palaeoecological study shows across the period 40 – 10 ka conditions are highly variable and that both 'wet' and 'dry' conditions coincide with H events. It is suggested that local insolation and the degree of continentality (Australia and New Guinea being one landmass), which may impact the circulation of ocean surface currents such as the Indonesian Throughflow and the extent of the Indo-Pacific Warm Pool, may be influential in the determination of the extent of the southward migration of the ITCZ and therefore whether 'wet' or 'dry' conditions coincide with H events.

Abstract

Located in the eastern part of Brazil, the Atlantic forest is one of the most diverse forests of the world, encompassing high levels of endemism along a latitudinal gradient from 3°S to 30°S. Pollen Analysis of the last 120 kyr BP has shown that the Atlantic forest was sensitive to glacial-interglacial cycles reflected in changes in forest composition together with contraction and expansion phases. However, the drivers for these changes are still poorly known. Yet, long-term datasets are very useful to observe how the succession of different cycles impacted the Atlantic forest, which can lead to predicting future responses of ecosystems to drastic climatic changes.

In Southeastern Brazil, where the Colônia crater is located, the influence of the Atlantic Ocean, polar air masses, and monsoon circulation make the area a unique place for regional and global paleoclimatic research. Here we present new pollen, diatoms, biomarkers, charcoal and geochemical results from the sediment core CO14 (14 meters length) retrieved from the bog. Pollen interpretations are based on the presence of the cold-moist related taxa (*Araucaria*, *Ilex*, *Podocarpus*), and warm moist related taxa (Anacardiaceae, Euphorbiaceae, *Myrsine*, Myrtaceae) indicators. The sediment and geochemistry analyses showed that the site was previously a lake until ca.120kcal yr BP when it was progressively filled in. Our results reveal that during the last 160 kyr BP, the Atlantic forest responded differently to the last 2 glacial periods. High frequencies of arboreal vegetation were detected during MIS6, MIS5, MIS3 and MIS1 stages and high fire activity was found during MIS6, MIS4, and MIS3. During cold and dry periods such as MIS4, MIS3b and MIS2 an open landscape was covering the area. The interplays between monsoon and polar air system dominances are inferred to explain the different responses of the tropical forest to global changes.

Abstract

Madagascar is well known as a biological hotspot with a unique flora and fauna regarded as ones of the earth's biologically richest, but also most endangered terrestrial ecoregions. Assessing its future development under changing climate, but also increasing human impact, requires a profound understanding of its natural dynamics over long timescales. Related to past climatic variability studies on vegetation dynamics in Madagascar are rather scarce. Thus, this new project, launched in 2018, is focusing on forest resilience to climatic and anthropogenic impact. In this context, we aim to provide high-resolution reconstructions of past vegetation and climate changes, based on a multi-proxy approach applied to multiple lowland and mountain sites in northern Madagascar. Preliminary results from the investigation of several lacustrine sediment records, continuously covering the past 25 ka cal BP, reveal distinct vegetation dynamics, which can be linked to climatic variability. At ca. 15 ka cal BP a remarkable increase in sediment accumulation rate, increased minerogenic input, coarser particles together with enhanced organic carbon content most likely reflect the onset of the African Humid Period in Madagascar. Contemporaneously, reduced charcoal and montane rain forest occurrence suggest moister conditions with forest expansion from mountain to lowland environments. Moist conditions were intensified during the Early Holocene until ca. 5 ka cal BP. Thereafter, distinctly increase in charcoal indicate drier conditions in northern Madagascar, most likely caused by insolation driven shifts in the southern position of the Intertropical Convergence Zone and monsoon duration in northern Madagascar. Further, our records clearly indicate human impact on the vegetation during the past ca. 1000 years (commonly regarded as one of the trigger for the megafauna extinction) through a tremendous increase of charcoal. Our studies in northern Madagascar will increase the understanding of past vegetation dynamics in tropical regions and especially help to distinguish between climatic and anthropogenic drivers for ecosystem changes in this highly vulnerable region.

The changing tropical landscape in the Lake Victoria Basin, East Africa

Charles Twesigye

Kyambogo University, Kampala, Uganda

Abstract

The impacts of human activities and climate change in the Lake Victoria Basin (LVB) was assessed using Remote Sensing Technologies, DNA analysis of fish populations and water quality analysis techniques. In the LVB, wetlands are part and parcel of many water bodies where they are hydrologically and ecologically linked through the supply of water, nutrients and organic matter. In the upper reaches of the LVB, many wetlands have been formed by spring water draining into valley bottoms where the gradient is low and hence water accumulates, supporting characteristic biota. Other wetlands are formed as a result of shallow water table in depressions, though most of these are seasonal and their area fluctuates depending on the prevailing weather conditions. Tropical wetlands are known to be very productive, providing water and primary productivity upon which large numbers of plants and animal species depend for survival. They are also important locations of plant genetic diversity and support large numbers of bird, mammal, reptile, amphibian, fish and invertebrate species. However, the human population explosion in the LVB, coupled with unsustainable exploitation, have led to a decline in wetland goods, particularly fisheries. Human activities in the LVB have accelerated the rate of ecological change and increased threats to the existing natural resources. A substantial natural resource base is thought to be one of the many reasons that led European powers to scramble for Africa during the 18-20th century, where economic ventures was the main agenda. The explorers found that the entire catchment of Lake Victoria was already a vibrant civilization center with structured indigenous governance systems to regulate the utilization of resources around the lake. Today, Lake Victoria, the world's second largest fresh-water lake, stands as the most critical economic resource that links its three riparian countries of Kenya, Tanzania and Uganda, as well as Rwanda and Burundi, which form its drainage basin. The lake and its basin is the single most valuable shared natural resource in the region and the lifeline to the downstream countries of Sudan, South Sudan and Egypt. This paper examines the impact of human activities and climate change on the LVB changing landscape based on remote sensing and GIS analysis combined with DNA and water analysis. The quality of the effluent generated by the industries found within the study sites and their effects on downstream discharge was also determined. The physical and chemical analysis of water quality revealed high levels of phosphates and nitrates along the agricultural zones of River Nzoia Basin. The satellite images revealed that in all the three study sites land vegetation cover has continuously reduced in size. The extent of ecological change and increased threats to the existing natural resources in the LVB is discussed.

O-3063

Island life – the biogeography of South Pacific chironomids

Peter Langdon, Catherine Langdon, David Sear, Mary Edwards, Sandra Nogue-Bosch
University of Southampton, Southampton, United Kingdom

Abstract

Little is currently known about the biogeography and biodiversity of chironomid faunas from islands in the South Pacific. There are various theories regarding the distributions of insect faunas across these widely spaced islands, including dispersal associated through human colonisation. Chironomids are typically abundant fossils from lake sediments and provide valuable palaeoenvironmental information, and hence analyses of their distribution (in space and time) in South Pacific islands will likely yield important data regarding biogeographic processes and past environmental change. There are no known surveys of chironomids from the freshwater lakes of the South Pacific.

This project is focused on assessing chironomid communities from Holocene lake sediment sequences in Vanuatu, Samoa, and the Cook Islands, an increasing distance gradient from major biological centres such as Australia, New Zealand and Indonesia. The island locations will allow us to assess the biogeography and diversity of chironomid communities in space and time, including the potential impact of human colonisation. Furthermore, independent palaeoclimate and vegetation proxies exist for some of the sequences, allowing us to test the response of chironomids in the South Pacific to major hydroclimate and vegetation change. Initial results indicate that both hydroclimate and human colonisation are important factors in controlling chironomid communities, and these will be discussed in depth during the presentation.

Environmental change through the last glacial cycle at Fraser Island, subtropical Australia

Justine Kemp¹, Henk Heijnis², Maureen Longmore^{3,4}, Patricia Gadd², Nigel Spooner³, Daniele Questiaux³

¹Griffith University, Nathan, Australia. ²Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia. ³University of Adelaide, Adelaide, Australia. ⁴The Australian National University, Canberra, Australia

Abstract

Recent programs to extract detailed and longer records of Australia's Pleistocene environments have produced a number of efforts to analyse long sedimentary sequences in the subtropical sand islands of Australia's east coast. Echo Lake is a perched fen within ancient dune sands on Fraser Island at 25° S that provides a record of precipitation change over ~100 ka. A 12 metre core into the (now) ephemeral swamp revealed lacustrine sedimentation in a period of higher precipitation, followed by a transition to swamp sedimentation as water levels fell. The chronology, based on ¹⁴C and OSL ages, suggests parts of the record may be interrupted or lost owing to drying or burning of the surface. Here we present an updated OSL chronology together with pollen analysis and ITRAX-XRF proxies for palaeoenvironmental change over the last glacial cycle in subtropical Australia.

Palaeochannels of Australia's Riverine Plain - Reconstructing past environments and vegetation across the Last Glacial Maximum and Holocene.

matt forbes¹, Tim Cohen¹, Nathan Jankowski¹, Michael Bird², Simon Haberle³, Felicitas Hopf³, Daniela Mueller⁴, zenobia jacobs¹

¹University of Wollongong, Wollongong, Australia. ²James Cook University, Cairns, Australia. ³Australian National University, Canberra, Australia. ⁴Albert-Ludwigs Universitat, Freiburg, Germany

Abstract

A series of palaeochannel facies throughout the Riverine plain of southeastern Australia reflect environmental conditions spanning the Late Pleistocene and Holocene. The Gum Creek (41-29 ka) and Yanco (29-18 ka) palaeochannels both provide evidence of significant late Pleistocene fluvial activity, likely connected to increased spring snow melt from the south east Alpine region. This paper attempts to broaden the palaeoenvironmental record of these palaeochannels via investigations of the finer silt sediments that both underlie and cap the coarser-grained channel sands. New OSL ages for the overlying silty channel fill from four separate sedimentary cores/sites indicates that the rate of sediment infill/accumulation varies between sites. $\delta^{13}\text{C}$ analysis in conjunction with pollen and elemental investigations suggests that the vegetation landform mosaic also varied through space and time. $\delta^{13}\text{C}_{\text{TOC}}$ data is predominantly a C3 vegetation signature ranging between -28‰ and -22‰. However, C4 vegetation calculations, taking into account the effects of SOM decomposition and the varying accumulation rates between sites, point to a pulse in C4 vegetation across the Riverine Plain post LGM fluvial activity. In turn, there is an increased dominance in C3 trees and grasses in the mid to late Holocene. A shift in *Eucalyptus/Poaceae* ratios from <1 to >2 in the upper 200cm of the Gum Creek facies sediments supports a shift from a landscape with greater grassland representation to a more closed wooded mosaic. In contrast, the pollen within the sediments of the Yanco palaeochannels, although limited in numbers, identifies a consistent contribution from *Poaceae* (70%) between the surface and 200cm depth, despite the C4 estimations from $\delta^{13}\text{C}$, also indicating a distinct shift to C3. We interpret this particular Yanco site as representing a consistently open vegetation mosaic through the Holocene with a shift from C4 to C3 grasses, and no major increase in wooded vegetation. Elemental ratios derived from XRF analysis of bulk sediments imply fluctuating environmental conditions during the deposition of the upper and lower silt units, with a distinct period of wetter conditions around 2ka cal BP, which followed fluctuating wetting and drying phases. A lack of pollen and low TOC (<0.05%) values in the older silt units below the channel sands makes understanding changes in the vegetation mosaic more challenging. Despite this, $\delta^{13}\text{C}$ for both TOC and TIC indicate a dominance of C3 vegetation prior to the commencement of fluvial activity.

An Integrated study of aeolian, lacustrine and fluvial geoarchives in the Murray-Darling Basin, Australia; reconstructing LGM hydro-climate variability

Sara Brandolese¹, Samuel Marx¹, Jan-Hendrik May², Tim Cohen¹, Jessica Reeves³

¹University of Wollongong, Wollongong, Australia. ²University of Melbourne, Melbourne, Australia. ³Federation University, Ballarat, Australia

Abstract

In this study we present new records for Australia's Murray Darling Basin (MDB), a vast (>1 million km²), predominately semi-arid basin. These new records obtained by the study of mostly unexplored lake-lunette systems chiefly preserve records of LGM palaeoenvironmental change, that is, hydro-climate variability.

Lakes and adjacent lunettes are semi-closed systems where the material composing the lunette is mainly deflated from the lake basin, consequently, in combination lake-lunette records potentially allow a more refined reconstruction of changes in the basin hydrologic conditions through time. Lunettes evolutionary models developed for semiarid areas worldwide have identified discernible sedimentary facies associated with dry and drying conditions as well as lake full phase, e.g. as implied by Bowler's (1973) classic lunettes model. Using this approach, lake-lunette systems can provide extremely valuable palaeohydrologic data, which in isolated systems (fluvially disconnected), have been interpreted as corresponding to major climatic fluctuations.

In the Southern MDB lake-lunette systems are however mostly connected to major river systems. Therefore in this setting, the development of both lunette and lake facies has been highly dependent on fluvial dynamics. This adds complexity when interpreting the palaeoenvironmental significance of these records.

Reconstruction of lakes-lunettes stratigraphy within different systems in the MDB has revealed a high degree of variability in sedimentary facies between sites (and within sites), implying facies assemblages are dependent on i) river dynamics (essentially connectivity) and ii) hydrogeology (groundwater dynamics).

Despite variability in facies between sites, the overall results support a scenario of high discharge for both the Murray and the Darling Rivers, contemporarily to enhanced aeolian activity and therefore lunettes building through the Last Glacial Maximum.

In combination the results of this study imply that boundary conditions influence lunettes facies, however, lunettes accretion phases may be linked to broad-scale hydro-climatic conditions. The possible palaeoenvironmental scenarios developed by the study of lunettes sedimentary sequences include wet conditions in the lower Darling during the LGM, supporting the hypothesis on moisture available from the Coral Sea or a northern migration of Westerlies; on the Murray River, lunettes facies records point towards a more enhanced seasonality although implying the lack of extremely dry conditions throughout the glacial stage.

In addition, the deglacial has resulted in the cessation of lunettes accretion and corresponding dominance of pedogenetic processes within the lunettes, possibly implying reduced winds strength or change in their position and sediment supply limitations extended at broad scale, which might relate to the change from mixed to suspended load systems affecting all major rivers within the basin.

Abstract

Global climate variability during the late Quaternary is commonly framed in terms of the ‘bipolar seesaw’ pattern of asynchronous temperature variations in the northern and southern polar latitudes. However, the terrestrial hydrological response to this pattern in south-eastern Australia is not fully understood, as continuous, high-resolution, well-dated proxy records for the hydrological cycle in the region are sparse. Here we present a well-dated, highly resolved record of moisture balance spanning 30000 – 10000 calendar years before present (30 – 10 ka BP), based on x-ray fluorescence and organic carbon isotope ($\delta^{13}\text{C}_{\text{OM}}$) measurements of a sedimentary sequence from Lake Surprise in south-eastern Australia. The data provide a locally coherent record of the hydrological cycle (Fig. 2). Elevated Si (reflecting windblown quartz and clays), and relatively high $\delta^{13}\text{C}_{\text{OM}}$, indicate an extended period of relative aridity between 28 – 17.5 ka BP, interrupted by millennial-scale episodes of decreased Si and $\delta^{13}\text{C}_{\text{OM}}$, suggesting increased moisture balance. Peak aridity was reached between 21 and 17.5 ka BP, possibly representing the expression of the global Last Glacial Maximum. This was followed by a rapid deglacial shift to low Si and $\delta^{13}\text{C}_{\text{OM}}$ at 17.5 ka BP, indicative of wetter conditions. We find that these changes are broadly coeval with similarly high-resolution records from south-eastern Australia and New Zealand. We also supplement our high-resolution record with discrete clumped isotope measurements on freshwater gastropods from Blanche Cave, also in south-eastern Australia. Temperatures either side of the Last Glacial Maximum were slightly cooler than those of the modern day, with the hint of a decrease from 40 to 30 ka BP. We did not find gastropods within the 28-17.5 ka BP interval in this cave, but identify this as a period for urgent attention.

Together, our analyses suggest that drivers of the regional hydrological cycle have varied on multi-millennial time scales, in response to major shifts in global atmosphere-ocean dynamics during the last glacial-interglacial transition. Southern Ocean processes were the dominant control on hydroclimate during glacial times, via a strong influence of cold sea surface temperatures on moisture uptake and delivery onshore. Following the last deglaciation, the southward migration of cold Southern Ocean fronts likely resulted in the establishment of conditions more like those of the present day. These conclusions will be tested in future work, focused on quantitative rainfall estimates from clumped isotope of land snail shells.

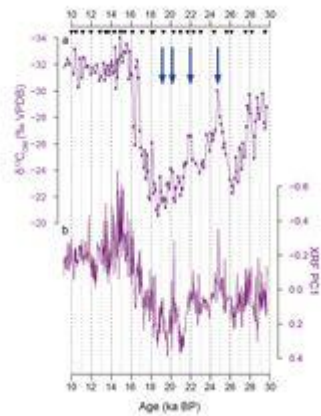

Figure 1. Selected data from the Lake Surprise record: **a)** Bulk sediment carbon isotope ratios ($\delta^{13}\text{C}_{\text{OM}}$), interpreted to reflect plant moisture stress; **b)** First principal component (PC1) of the calibrated scanning XRF dataset, interpreted to reflect aeolian deposition of Si. Arrows indicate periods of increased effective moisture within the relatively arid LGM. Triangles denote ^{14}C age control points.

Low altitude periglacial activity in south eastern Australia during the late Pleistocene

Timothy Barrows^{1,2}, Stephanie Mills¹, Keith Fifield³

¹University of Wollongong, Wollongong, Australia. ²University of Portsmouth, Portsmouth, United Kingdom.

³Australian National University, Canberra, Australia

Abstract

Glaciation of Australia during the late Pleistocene was restricted to Tasmania and the Snowy Mountains. Ice occupied the highest areas of mainland Australia briefly four times between ~59,000-16,000 years BP based on exposure dating. Periglacial processes dominated at lower altitudes and produced a wide variety of landforms ranging from large-scale block fields to smaller-scale solifluction deposits at the lowest elevations. These landforms hold considerable potential to shed light on the magnitude of cooling during glacial periods. However, few periglacial deposits in Australia have been dated because of difficulty in finding dateable material. In this paper we present a new study of block deposits in Victoria and of low altitude (~600 m) scree slopes in New South Wales. We review the likely modes of formation of these deposits and their environmental setting. We then present trial ages from cosmogenic nuclide exposure, optically stimulated luminescence, and radiocarbon dating and weathering rind measurements to provide dating information for these deposits. Although each method has advantages and disadvantages, a combined approach provides limiting ages for the periglacial deposits we studied. We find that the apparent ages of formation extend over a longer period than just the last glacial maximum. These ages constrain maximum cooling of south eastern Australia during the last glacial cycle.

Southeast Australian palaeofloras of the late Pleistocene and their implications for glacial palaeoclimate reconstructions

Kia Matley¹, Kale Sniderman¹, Andrew Drinnan¹, Nicholas Porch², Quan Hua³

¹The University of Melbourne, Melbourne, Australia. ²Deakin University, Melbourne, Australia. ³Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia

Abstract

The climatic extremes of the last glacial period (approximately 100,000 to 12,000 years ago) and particularly the last glacial maximum (approximately 20,000 years ago) are thought to have exerted a significant influence over the current distribution of mesic forest taxa in southeast Australia. However, limited taxonomic resolution afforded by fossil pollen has meant that the nature of glacial biotic communities remains poorly understood.

Pollen-based palaeoclimate reconstructions of southeast Australia have invoked a mostly treeless, 'glacial steppe' environment characterised by cold, dry, windy conditions. But, in contrast with the Northern Hemisphere evidence of continental-scale migration to and from southern refugia during successive Pleistocene glaciations, contemporary patterns of species diversity and endemism suggest that forest taxa persisted widely in southeast Australia, in multiple, localised refugia. Resolving this conflict is the focus of this study.

Based on species-level identifications of plant macrofossils, we will provide precise new insights into the southeast Australian glacial climate and biotic communities. Improvements to the taxonomic resolution of palaeobotanical records will allow for the use of bioclimatic niche models to quantitatively reconstruct palaeoclimate. Porch (2010) demonstrated this concept elegantly, but at Spring Creek, too few beetle taxa available for analysis resulted in an inconclusive finding. By applying this method to the plant macrofossil assemblage from this site, we hope to reconstruct the environmental parameters likely to have predominated at the time. Preliminary results suggest that the climatic tolerances of the late-Pleistocene flora of Spring Creek did not differ substantially from those of the modern-day assemblage.

The results of this study will contribute to a globally significant debate about the role of the Pleistocene glacial-interglacial cycles in the generation and maintenance of terrestrial biodiversity, and also to the increasingly urgent discussion of the degree of sensitivity of iconic Australian plant taxa to changing climate in general.

A review of sea-level history over the last glacial cycle in Australia

Craig Sloss

Queensland University of Queensland , Brisbane , Australia

Abstract

In the Australian region, maximum sea-level was between +2 and +4 m above PMSL during MIS5e. Due to limited tectonic uplift in the Australia region, sedimentary facies of Late Pleistocene interstadials (MIS5c, 5a and MIS 3) rarely crop-out above PMSL. For this reason, there is a dearth of studies that accurately trace the characteristics of sea-level oscillations between the Last Interglacial (*sensu stricto*) and the Last Glacial Maximum (LGM). Previous research does indicate that from the close of the Last Interglacial to the LGM was characterised by oscillating sea levels concentrated in a depth range of 70 to 20 m below PMSL which are superimposed on a general decline in sea-level. The positive oscillation (interstadials) occurred at:

-ca93,000 yr BP (MIS5c) with similar sea-level height above PMSL that have been observed in MIS5e;

-ca83,000 yr BP (MIS5a) with sea-levels ca28 m below PMSL; and

-at three specific times (60,600±300, 50,800±300 and 36,800±2,000 yr BP) during MIS 3 where sea-levels ranged between 85 and 74 m below PMSL.

Early in MIS 2 sea-level fell rapidly to ca-110 m (ca24,000 years ago), before dropping further to the LGM sea-level lowstand of between 120 and 130 m below PMSL between ca20,000-22,000 years ago. In the Australian region, Yokoyama *et al.* (2001), reviewing data from the Joseph Bonaparte Gulf, the Gulf of Carpentaria, the Great Barrier Reef and off the Sydney coast, concluded that around Australia sea levels during the LGM were between -110 and -120 m below PMSL. Melting of the continental ice sheets following the LGM resulted in a rapid rise in sea-level. In response to the rising sea-level associated with the most recent PMT, sediment stored on the inner continental shelf migrated shoreward. The stabilisation of the sea surface and subsequent sea-level highstand promoted the shoreward prograding and the geomorphological evolution of coastal depositional environments.

Abstract

In order to explore past changes in the Mediterranean Outflow Water (MOW) we analyzed the fine sand content in the sediments together with some geochemical proxies and planktic and benthic stable isotopes at IODP site U1389. This site was recovered in the vicinity of the Strait of Gibraltar along the path of the main core of the MOW. The content of fine sand together with Zr/Al ratios were used to investigate the MOW speed variability along the past 500 ky. The MOW speed variability at this site was mainly driven by changes in the density contrast between the Inflow and Outflow, which was, in turn, governed by changes in the Mediterranean heat and freshwater budgets. Events of enhanced freshwater input to the Mediterranean associated to northward shifts of the Intertropical convergence Zone reduced the density contrast at Gibraltar and weakened the MOW at Gibraltar. Weak MOW events were recorded at times of sapropel deposition in the eastern Mediterranean.

At millennial scale, the MOW intensified at times of Greenland stadials and weakened during interstadials. However, during Heinrich stadials typical three-phase events were observed, with a sandy contourite layer at the bottom and top and a phase of weak MOW in the middle of the stadial, coinciding with the arrival of icebergs to the Gulf of Cadiz. For Heinrich stadial 1 this weak MOW event occurred at the time of the massive release of icebergs from the Laurentian ice sheets. However, the inflow of less saline water to the Mediterranean should have increased not decreased the density contrast between the Inflow and Outflow, especially because freshwater discharge to the Mediterranean from the African monsoons was extremely low. We propose different scenarios to explain these weak MOW events in the middle of Heinrich stadials that were certainly triggered by prominent changes in the Mediterranean heat and freshwater budget.

Post-glacial recolonisation of *Globorotalia truncatulinoides* in the western Mediterranean Sea

Angela Cloke-Hayes, Teresa Broggy
Mary Immaculate College, University of Limerick, Limerick, Ireland

Abstract

The planktonic foraminifera, *Globorotalia truncatulinoides* is known to have five cryptic species (Types 1-5). Of these, types 2 and 5 are the only genetic types that contain the dextral coiling variant and only type 2 is present in the Mediterranean Sea. Under present day conditions, populations of *G. truncatulinoides* in the western Mediterranean Sea are dominated by the sinistral coiling variant. In particular, the species is abundant during the winter season, where vertical mixing within the water column and subsequent high nutrient availability promote juvenile growth. This research focuses on the quantitative analysis of the coiling variation observed in three western Mediterranean Sea sediment cores taken from the Gulf of Lions and the Balearic and Tyrrhenian basins throughout the Holocene. Sea Surface Temperatures (SSTs) were reconstructed for each core using Artificial Neural Networks (ANN) which suggested that SST was not a controlling factor on coiling direction, as has been previously suggested, but rather ecological conditions relating to water column stability and the presence / depth of a thermocline. Specifically this study identifies a series of post-glacial bioevents associated with the recolonisation of *G. truncatulinoides*. The early to mid-Holocene is characterised by the near absence of *G. truncatulinoides* from the faunal record. It is concluded that the absence of the species is associated with a stratified water column likely the result of post glacial sea level rise and increased river runoff. The onset of a significant increase in the abundance of *G. truncatulinoides* is observed during the mid-Holocene, broadly corresponding with the end of the African Humid Period and a transition to a more semi-arid climate. At this time peak frequencies in the dextral variant was observed across all cores, possibly indicating a weakly stratified water column after a prolonged period of stratification. The onset of modern hydrological conditions coincides with the demise of the dextral variant and subsequent dominance by the sinistral variant at approximately 3 ka. Modern day hydrological conditions in the western Mediterranean Sea support the development of deep vertical mixing, in particular in the north-western basin associated with Western Mediterranean Deep Water formation, providing the means for *G. truncatulinoides* to complete its life cycle thereby contributing to the proliferation of the species.

Abstract

Gerard C. Bond established a Holocene series of North Atlantic ice rafted debris events based on quartz and hematite stained grains recovered from subpolar North Atlantic marine cores. These so-called 'Bond events' document nine large-scale and multi-centennial North-Atlantic cooling phases that might be linked to a reduced thermohaline circulation. Regardless of the high prominence of the Holocene North Atlantic ice rafted debris record, there are critical scientific comments on the study: the Holocene Bond curve has not yet been replicated in other marine archives of the North Atlantic and there exist only very few palaeo-climatic studies that indicate all individual Bond events in their own record. Therefore, evidence for consistent hydro-climatic teleconnections between the subpolar North Atlantic and distant regions is not clear. In this context, the Western Mediterranean region reveals key hydro-climatic sites for the reconstruction of a teleconnection with the subpolar North Atlantic. In particular, variability of Western Mediterranean winter precipitation might be the result of atmosphere-ocean coupled processes in the outer-tropical North Atlantic realm.

Based on an improved Holocene $\delta^{18}\text{O}$ record from Lake Sidi Ali (Middle Atlas, Morocco) we correlate Western Mediterranean precipitation anomalies with North Atlantic Bond events to identify a probable teleconnection between Western Mediterranean winter rains and subpolar North Atlantic cooling phases. Our data show a noticeable positive correlation between Western Mediterranean winter rain minima and Bond events during the Early Holocene and an opposite pattern during the Late Holocene. There is evidence for an enduring hydro-climatic change in the overall Atlantic atmosphere-ocean system and the response to external forcing during the Mid-Holocene.

Abstract

The Western Mediterranean has known recurrent drought periods after the 1970s, and climate models anticipate a decrease of annual precipitation by the last 21st century. Essential information on climate variability and the involved forcing mechanisms in this region remains however scarce due to the lack of long instrumental datasets. Thus, additional paleoclimate records are highly required. Here, we present three well-dated and high-resolution speleothem $\delta^{18}\text{O}$ records from different caves in Morocco. The speleothem records are interpreted as proxies of rainfall variability during the last millennium, mainly dominated by the North Atlantic Oscillation (NAO). They reveal substantial decadal to centennial alternations of dry and humid periods, with prevailing dry conditions during the Medieval Climate Anomaly (MCA), wetter conditions during the second half of the Little Ice Age (LIA), and a trend towards dry conditions during the modern period. Interestingly, Low $\delta^{18}\text{O}$ values, and hence negative phases of NAO that bring precipitation to the Western Mediterranean, are observed during periods of solar minima. This is confirmed by high power and persistent centennial-scale periodicities, similar to the Vries-Suess 200-year solar cycle, that are observed in the speleothem records as well. Hence, we provide proxy-evidence of the linkage between the hydro-climate variability in the Western Mediterranean and insolation through the NAO, consistent with previous model results describing low irradiance as a trigger for southward shifts of precipitation-bearing westerlies during winter.

Abstract

The Adriatic Sea, as the northernmost and practically landlocked part of the Mediterranean Sea, is influenced by both Atlantic and Mediterranean air masses, so the isotopic records from coastal cave speleothems are expected to reveal local and regional responses to global climate changes on that bordering region.

In this study we present a 365-kyr long composite isotopic record of three speleothems from Modrič Cave located 120 m from the shoreline on the central part of the eastern Adriatic coast. Results of a 4-year monitoring program of the surface and cave microclimate, rain and drip water stable isotope composition and rain and drip intensities, show cave air temperature variations within 1 °C, a relative humidity of 100%, dripwater O and H stable isotopic composition (range 0.4‰) very well buffered against the seasonal rainfall range (6.8‰). Such conditions enable calcite deposition without strong kinetic isotopic disequilibrium effects, as validated by Hendy tests, and give us confidence that the isotopic signal is faithfully recording climate changes.

All three speleothems (MOD-31, MOD-32, MOD-33) were active, collected from their growth position, so Holocene signals can be traced in all of them. Within their older parts, U-Th dating reveals the following growth periods: MOD-31 from MIS 10 to MIS 7, MOD-32 from MIS 4 to MIS 2, and MOD-33 from MIS 6 to MIS 5. Relatively large $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ ranges (-8.16‰ – -2.97‰ and -13.11‰ – -1.00‰, respectively) indicate significant environmental changes whose comparison with stable isotope time series of adjacent speleothem records and other regional proxies provides the longest eastern Adriatic speleothem-based record.

Millennial-scale coccolithophore paleoproductivity record and water column dynamics in the Alborán Sea (Western Mediterranean-ODP 977) during Marine Isotope Stage 11

Alba González-Lanchas¹, José - Abel Flores¹, Francisco J. Sierra¹, María Ángeles Bárcena¹, Lucía A. Azibeiro¹, Joan O. Grimalt²

¹Departament of Geology, University of Salamanca, Salamanca, Spain. ²Department of Environmental Chemistry, Spanish Council for Scientific Research (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Barcelona, Spain

Abstract

Proxy-based reconstructions of past interglacials is a key to improve the understanding of paleoenvironment and paleoclimate evolution, and in particular for the comparison with the Holocene. A high-resolution coccolithophore analysis along with oxygen and carbonate isotopes and alkenone-derived sea surface temperature (SST) was carried out in the western Mediterranean Site ODP 977 (Alborán Sea) with the aim to reconstruct changes in paleoproductivity and surface dynamics at millennial-scale during the Marine Isotope Stage 11.

Gephyrocapsa is the most abundant taxa of the interval with the dominance of small *Gephyrocapsa* (<3mm), revealing high-frequency variations in productivity through the upper photic zone, related to weakening and strengthening of upwelling conditions, as well as changes in the Mediterranean – Atlantic water exchange. During Termination V, the high amplitude warm-up pattern of deglaciation is well expressed by high percentages of “warm water” taxa and temperature proxies. Two contrasted paleoproductivity scenarios highlights during the full interglacial of homogeneous high temperatures MIS 11c, showing independence in the behavior of large part of the coccolithophore assemblage with temperatures after comparison with the alkenone record. The MIS 11 – MIS 10 transition is characterized by the millennial-scale variability. Cold abrupt events identified with the high representation of subpolar subspecies *C. pelagicus* spp. *pelagicus* and high percentages of reworked calcareous nanofossils are correlated with drops in temperature defining two abrupt events. These events are consistent with a decrease in coccolithophore productivity and related to general processes linked to variations in the North Atlantic dynamics.

Short-term oscillations in wind and precipitation controlled by the North Atlantic Oscillations during MIS 11 are here proposed as responsible for this variability in surface water features.

Alternatively, in this study, we paid attention to the identification of several morphotypes/species of *Gephyrocapsa* (“*G. Caribbean*”, *G. oceanica* and *G. muelleriae*) with variable calcification using image analysis techniques. We hypothesized about the relationship between these changes and oceanic processes at the regional and global level.

O-3077

New insights on Holocene climate dynamics in the southern Mediterranean as deduced from the Sebkhia Kelbia multi-proxy record (Central Tunisia)

Sahbi Jaouadi¹, Jean-François Berger², Vincent Lebreton¹, Karim Boujelben³, Mélanie Montalti², Margot Bruneau¹, Mostapha Karbouch¹

¹Département Homme et Environnement, Muséum National d'Histoire Naturelle, UMR 7194 CNRS, Paris, France.

²Université de Lyon, CNRS, Université Lyon 2-Lumière, UMR 5600 EVS, F-69007, Lyon, France. ³Laboratoire de Cartographie Géomorphologique des Milieux, des Environnements et des Dynamiques (CGMED, LAB-ST-04), Tunis, Tunisia

Abstract

Continuous palaeoecological records are still needed in the southern Mediterranean arid lands in order to fill in the map of Holocene climate change and to improve our understanding of climate dynamics and their geographical discrepancies during the Holocene. In arid regions where suitable sediments are lacking, the Sebkhia Kelbia sequence constitute a unique archive spanning the last 8kyr that allows a detailed, multi-proxy and high-resolution study of landscape and climate dynamics in the semi-arid region of Central Tunisia. Multi-proxy analyses are carried out on a 15 m long core in order to characterize sedimentary environments, paleohydrological changes and associated vegetation landscapes. It includes geochronological, palynological (pollen, non-pollen palynomorph, micro-charcoal) and sedimentological (magnetic susceptibility, loss on ignition, granulometry) analyses.

The sedimentological and palynological results highlight recurrent changes on the sebkhia function and vegetation landscapes associated to the Middle Holocene long-term aridification trend that initiated during the 6th millennium BP. Climate aridity trend is documented through sedimentation phases indicating the succession of three paleohydrological systems with first a lake, then a temporary lake and finally a sebkhia. Pollen data, mainly related to the mountainous hinterland, document also this aridification trend with the gradual establishment of the xerophytes Mediterranean taxa (mainly *Olea*, *Pinus*, *Pistacia* and *Juniperus*).

The data provide evidence of Rapid Climate Changes (RCCs) during the Middle and Late Holocene. Comparison with available palaeoecological records both in the Mediterranean and in the Sahara are used to discuss climate dynamics and connection with climate events previously documented further south in the Sahara, such as the end of the African Humid Period (AHP), and other events recorded in the Mediterranean, such as North Atlantic Cooling events. Especially the inedit data from Sebkhia Kelbia emphasize a contrasting climate pattern across the Mediterranean Basin triggered by the differential impact of the North Atlantic Oscillations (NAO) and the Mediterranean Oscillations (MO).

The Diluvium aquarum: geologic evidence and geoarchaeological constrains of extreme floods in Northern Italy during early Middle Ages

Alessandro Fontana¹, Paolo Mozzi¹, Rossato Sandro¹, Michele Bassetti², Livio Ronchi¹, Matteo Frassine³

¹University of Padova – Department of Geosciences, Padova, Italy. ²CORA Società Archeologica s.r.l., Trento, Italy.

³Soprintendenza Archeologia, Belle Arti e Paesaggio, Padova, Italy

Abstract

In the Mediterranean region the period following the collapse of the Roman Empire is described by many authors as an interval characterized by important alluvial processes (e.g. floods, river avulsions, alluvial aggradation in the valleys), strongly contrasting with the general geomorphological stability of Roman Age and Late Antiquity. Some important chronicles of early Middle Ages report the occurrence of very high-magnitude floods, often described by ancient historians as *diluvium* (deluge), contributing to create a sort of myth around an out-of-scale event or a longer meteo-climatic phase.

In the framework of the INQUA project “EX-AQUA: Palaeohydrological Extreme Events, evidence and archives” (1623P), a review of the traces of early Medieval floods occurred in Northern Italy was carried out. The study considered new information and previous available data supplied by geomorphological, stratigraphic and geoarchaeological evidence, ancient documents and written sources.

In the investigated area a fast and strong sedimentary phase occurred between 5th and 9th century AD, leading many large Alpine rivers to avulse. In the system of Tagliamento, thanks to recent geoarchaeological excavations and geochronological analyses, a major extreme event is clearly constrained between the second half of the 6th and the first part of the 7th century, when the river avulsed and destroyed the ancient city of Concordia Sagittaria. This episode overlaps with the one reported by the Lombard historian Paolo Diacono, dated to 589 AD, which strongly damaged Verona and, downstream of this city, possibly triggered the avulsion phase of Adige River near the so-called “Rotta della Cucca”. Important fluvial changes affected also the Piave and Livenza rivers, while an avulsion channel of Brenta River started to form in the 6th century AD.

Notwithstanding, for some minor alluvial systems the detailed chronology supported by archaeological and radiocarbon chronology allows to detect the existence of earlier flooding units, formed since the 2nd and 3rd century AD. Recent data in the Alpine valley of Adige River, around the city of Trento, point towards the occurrence of some important flood events in the alluvial cones of the major tributary creeks already during the 3rd century AD. However, in the same area the floor of Adige valley experienced a vertical aggradation only since the 4th and 5th century AD, with an enhanced rate of deposition between 6th and 10th century AD. A rather comparable chronology characterizes part of the alluvial cones of the main Apennine streams flowing towards the Po Plain (e.g. near Modena), which aggraded during early Medieval, but this trend started already in the 3rd century AD.

This research supports new data for comparing the palaeoflood record of early Middle Ages with palaeoclimatic proxies, with the aim of distinguishing global forcing factors from regional constrains and anthropogenic disturbances.

O-3079

Palaeoflood hydrology of the Duero River (Spain and Portugal) during the Late Pleistocene and Holocene

Gerardo Benito¹, Noam Greenbaum², Olegario Castillo³, Alicia Medialdea⁴, Mikel Calle¹, Yolanda Sánchez-Moya⁵, Maria Machado¹, Mariano Barriandos⁶

¹National Museum of Natural Sciences, CSIC, Madrid, Spain. ²Department of Geography and Environmental Studies, University of Haifa, Haifa, Israel. ³Dpt. de Ingeniería Industrial e Ingeniería Civil, Escuela Politécnica Superior de Algeciras, Algeciras, Spain. ⁴Institute of Geography, Fac. Mathematics & Natural Sciences, University of Cologne, Cologne, Germany. ⁵Instituto de Geología Económica, CSIC-UCM, Madrid, Spain. ⁶Dpt. D`Història Moderna, Universitat de Barcelona, Barcelona, Spain

Abstract

The Duero River is one of the three major rivers in the Iberian Peninsula, draining an area of 98,073 km² (20% in Portugal and 80% in Spain) into the Atlantic Ocean, producing some of the highest peak discharges to be found in European rivers with similar drainage area. The estimation of peak discharges during historic and prehistoric periods and its temporal correlation with climate variability is thus fundamental in flood hazard and dam safety analysis. A palaeoflood study was carried out along a 3 km reach between Vilariño (Spain) and Bemposta (Portugal) at the Natural Park of Los Arribes, a ~200-m deep bedrock gorge cut into Hercynian granite and granodiorite rocks. Slackwater deposits (SWDs) are preserved in thick, high-standing benches in canyon expansions and tributary mouths. Twelve high-resolution stratigraphic profiles were studied, and the deposits dated using optically stimulated luminescence, covering the last 14.4 ka. The most complete record is found at the Duero-Tormes river junction, which comprises five inset SWD benches at elevations between 15 and 25 m above river thalweg (ART). The highest bench (Muga profile) comprises six flood units within four sequences, dated to 13.8ka, 8.4ka, 2.4ka and post-2.4ka. At 23.5 m ART, the Tormes profile recorded 23 flood units organized into four sequences separated by well-developed paleosols, and dated to 11.6ka, 9.5ka, 4.4ka and <1ka. The third inset bench (Cicutina profile; 20 m ART) comprises 19 flood units, whereas in the fourth inset (Tabanera profile; 17.5 m ART), 17 flood units were identified; here the OSL dating is in process. The fifth inset bench (Borbon profile; 14 m ART) was likely deposited during historical and recent flooding, since recent events are known to cover this bench. Sedimentary archive from SWDs was compared to historical flood record from documentary archives in the region. A record of 70 historic floods was compiled over the period 1256-1911, and classified into three categories, catastrophic, extraordinary and ordinary floods. A total of 11 catastrophic floods were identified during the pre-gauged period including the outstanding floods of 1860 and 1909, with estimated discharges at the study area of 7600-7700 m³s⁻¹. The hydroclimatic analysis of the flood record shows a good temporal correlation between the occurrence of catastrophic floods and the existence of anomalous negative NAO index phase. The Duero's palaeoflood and historical flood records are in good agreement with flood episodes recorded in other Iberian rivers (e.g. Tagus, Guadiana), which highlights the impact of atmosphere-ocean hemispheric coupling conditions on extreme floods in the region. These findings suggest a response, at centennial scale, between climatic factors and the outcome variability in the magnitude and frequency of floods.

O-3080

A four-dimensional integration of multi-archive datasets to understand historical flood pattern in alpine catchments

Lothar Schulte¹, Juan Carlos Peña², Oliver Wetter³, Filipe Carvalho¹, Stefanie B. Wirth⁴, Bruno Wilhelm⁵, Benjamin Amann⁶, Antonio Gómez-Bolea⁷, Laura Barbería²

¹Department of Geography, University of Barcelona, Barcelona, Spain. ²Meteorological Service of Catalonia, Barcelona, Spain. ³University of Bern, Bern, Switzerland. ⁴CHYN, University of Neuchâtel, Neuchâtel, Switzerland. ⁵University Grenoble Alpes, CNRS, IRD, Grenoble, France. ⁶Renard Centre of Marine Geology, Ghent University, Ghent, Belgium. ⁷University of Barcelona, Barcelona, Spain

Abstract

Natural and historical evidence of severe and catastrophic floods that have really occurred, and which are not extrapolated, can be inferred from different types of past flood archives, whether of natural or anthropogenic origin.

In the framework of an innovative research initiative located in the Bernese Alps (Schulte et al., 2019), multi-archive flood series, that include floodplain sediments (4 records), lake sediments (4), documentary data (4), instrumental measurements (4), and lichenometric-dated flood heights (4 profiles), were analyzed to reconstruct accurately flood periods during the past six centuries. Based on this assembled multiple flood data sets of the rivers Hasli-Aare, Lütschine, Kander, Simme, Lombach, and Eistlenbach, Lake Thun, and the pre-alpine Aare river Thun-Bern, i) common flood pulses were determined, ii) records which are out-of-phase were identified, and iii) the sensitivity of the different natural archives were investigated.

The most continuous and accurate series were integrated over the period from AD 1400 to 2005 into a synthetic flood master curve that defines ten dominant flood pulses around AD 1410, 1480, 1570, 1650, 1710, 1760, 1830, 1850, 1870 and 2005. Six flood periods correspond to cooler climate pulses, three to intermediate temperatures, whereas the youngest flood period occurs during the pulse of current Global Warming.

For the ten flood periods, the location and magnitude of all the compiled flood records were plotted in maps that illustrate accurately the spatial pattern of flooding during the last 600 years in an alpine region of 2,117 km². The spatial pattern of the historical flood pulses was analyzed and compared with the most recent floods (e.g. 1999, 2005, 2011) that occurred during the warmest pulse of the recent Global Warming. Furthermore, maps of atmospheric conditions were generated to compare flood behavior in the catchment with the variability of the modeled atmospheric pattern during the flood pulses. Six of ten periods coincide with the positive mode of the Summer North Atlantic Oscillation (SNAO), which is defined by a strong anticyclone blocking between the Scandinavia Peninsula and Great Britain.

Finally, the comprehensive four-dimensional model of paleofloods allows us to understand in depth the extreme riverine flooding phenomena in mountain catchments with regard to their triggering, mechanisms, and forcings at multi-centennial timescales. We suggest that this new methodology can be transferred to other mountain regions.

Figure 1. Location of the study area in the Alps. Shaded relief, location and type of flood archives (dots) mentioned in text.

A millennial-scale multi-proxy Palaeoclimate database for a better understanding and prediction of extreme hydroclimatic events in South East Queensland, Australia

Jacky Croke¹, Sahar Amirnezhad-Mozhdehi¹, Ramona Dalla Pozza²

¹UCD School of Geography, Dublin, Ireland. ²The Department of Environment, Land, Water and Planning (DELWP), East Melbourne, Australia

Abstract

Eastern Australia's hydroclimatic variability is extreme compared to the rest of the world on seasonal to multi-decadal scales. Although this variability is reflected to some extent in the existing instrumental records (e.g. mean annual rainfalls between 650-2850 mm), the relatively short instrumental records (~60-120 years) do not cover the full range of hydroclimatic variability and limit the calculation of robust statistics around the baseline risk of extreme events. However, this hydroclimatic variability is well documented in the paleoclimate proxy records, as potential surrogates for rainfall, streamflow and temperature, which in turn can be correlated with large-scale ocean-atmospheric processes such as El Niño/Southern Oscillation (ENSO) and local hydroclimatology.

Queensland contains the highest proportion of palaeoclimate proxies in Australia, and the contribution of each dataset is considerable, both in resolution and geographic coverage. Furthermore, when combined, their potential is enormous. Each dataset provides an independent control of the key periods of overlap, similarities and drivers of past changes in rainfall and streamflow, helping assess existing and potential future changes in the frequency, duration, magnitude and timing of floods and droughts. Collective analysis of these datasets will also provide a structured and targeted approach to identifying and filling key knowledge gaps.

This study is the first to collate, synthesise and statistically analyse all available proxy climate data for the region and the resulting database will be the most comprehensive dataset of the frequency, duration, magnitude and timing of both flood and drought events during the last 2-3000 years for this region in Australia. This presentation showcases the nature of the existing proxy records and preliminary results of statistical analyses on their spatial correlation across Queensland.

Reconstruction of early historic topography of a large lowland area for palaeo-hydraulic analyses

Bas van der Meulen¹, Harm Jan Pierik¹, Hans Middelkoop¹, Kim Cohen^{1,2}

¹Utrecht University, Utrecht, Netherlands. ²Deltares, Utrecht, Netherlands

Abstract

Reconstruction of past topography in a palaeo-DEM is useful for a range of geological, geomorphological and archaeological applications. One novel application is palaeoflood analysis using numerical hydraulic modelling, aiming to quantify past flooding patterns and magnitudes. This requires a representation of the past topography as input, with an effective resolution below the model grid size. Here, we present a palaeo-DEM of the Lower Rhine valley (North Rhine-Westphalia, Germany) and delta apex (the Netherlands) for circa 1000 CE. The study area of $4.5 \cdot 10^3 \text{ km}^3$ is spread over two countries and includes densely populated and industrialized areas. In this presentation, we will focus on the critical steps in construction of the palaeo-DEM, on the completed end product, and on its applications as part of extreme-event palaeo-hydrological investigations.

Two contrasting approaches exist for constructing a palaeo-DEM, namely starting from subsurface data (bottom-up approach; interpolating between scarce data points) and starting from the present-day topography (top-down approach; stripping young morphological features from a modern DEM). Data required for the second approach, most importantly LiDAR DEMs, are relatively easy to collect over large areas. However, correcting a modern DEM to a palaeo-DEM becomes difficult for increasing spatial resolution and periods further back in time.

For our study area, we have developed a protocol for top-down palaeo-DEM construction that can remove considerable anthropogenic overprints and replace young, human-managed river morphology with a representative natural river geomorphology (proximal floodplain topography and channel bathymetry). A key step in our approach was deploying different reconstruction strategies to the area occupied by the post 1000 CE channel belt in the centre of the valley (active zone) and to the rest of the valley floor (inactive zone). The infilling methods for the active zone are a hybrid between top-down and bottom-up approaches, as we used existing geological, geomorphological, and historical geographical data as guidelines (Fig. 1). The workflow we developed can be applied to other lowland fluvial areas at different spatial and temporal scales. The resulting palaeo-DEM is an essential starting point for advanced palaeo-hydraulic analyses.

Fig. 1. Reconstruction of floodplain topography upstream of Düsseldorf. A) Present-day LiDAR DEM. Red line indicates active zone boundary based on geological maps. B) Intermediate Palaeo-DEM. Points are placed along and inside the active zone for reconstruction of proximal floodplain. C) Example of an earlier reconstruction of local Rhine river position in medieval times (Scheller, 1965). The influence of land-use changes and river management on extreme-floods in the Southeastern Spain. The case of the River Antas

Carlos Sánchez-García, Lothar Schulte, Filipe Carvalho

FluvAlps-PaleoRisk Research Group, Department of Geography, University of Barcelona, Barcelona, Spain

Abstract

During the last centuries, the southeastern Iberian Peninsula has undergone significant morphological and land-cover changes. Run-off might have increased and the floods damaged historical infrastructures near the river because of the higher discharges. This study aims to determine the influences of these land-use changes in the dynamics of the fluvial system. The study area is located in the lower catchment of the Antas River (SE Spain), a 5-kilometer stretch that have several historical aqueducts and a weir from the 18th Century, which have not been damaged until the last extreme flood (2012). Since the 16th Century, land-use was defined by a symbiosis of water resources, irrigation systems, farming and grazing, adapted to the arid environmental conditions of the Southeastern Spain, the driest region of Europe.

Historical flood-series, historical maps and aerial photographs from different periods have been analyzed, in order to recognize extreme flood-events damages, morphological changes, climatic dynamic (temperature) and land use changes in the study area. The historical map (1887 and 1924) shows the difference between the traditional land uses and the current land use. In order to compare those periods, several sets of aerial photos, from 1956 and 1973-1986 (before changes), 1998-2000 (during changes) and 2010-2015 (after changes). In 1956 and 1973-1986 different land uses related with irrigation ditches and old dams in the riverbed were mapped, In addition, the Antas riverbed were used as a pathway of livestock. In the next generation of aerial photographs (1998-2000), not only the land use near the riverbed changed, but also its morphology. As a consequence of the abandonment of this pathways vegetation colonized the river channel and floodplain obstructing the water flow. The old hydraulic structures as two aqueducts and a weir (1867, 1880 and 1544, respectively) survived all historical extreme events (e.g. 1924, 1973, 1989), but not the 2012 flood.

Furthermore, the weirs and irrigation channels detoured in an uncontrolled manner large amount of discharges from the river channel to the irrigation plots, causing massive aggradation and erosion. Since 1973, Magnitude 3 flood-event had not affected the region until 2012-flood event. We suggest, that these severe damage results from synergetic processes: large peak discharge, exceptional land-use changes (destruction of agriculture terrace) and the abandonment of traditional irrigation techniques. Most of these changes have increased the vulnerability and the exposition of population and infrastructures. To sum up, increased flood damage might be related to the poor integrated and environmental management of the ephemeral fluvial system.

The sedimentary record of Alpine lake tsunamis: Assessing an underexplored natural hazard

Flavio Anselmetti¹, Valentin Nigg¹, Stéphanie Girardclos², Katrina Kremer³, Robert Boes⁴, Donat Faeh³, Stefan Wiemer³, Achim Kopf⁵

¹Univ. of Bern, Institute of Geological Sciences, Bern, Switzerland. ²Dept of Earth Sciences / Institut des Sciences de l'Environnement (ISE) University of Geneva, Geneva, Switzerland. ³Swiss Seismological Service (SED) ETH Zurich, Zurich, Switzerland. ⁴Laboratory of Hydraulics, Hydrology and Glaciology (VAW), ETHZ, Zurich, Switzerland. ⁵MARUM and Dept. of Geosciences University of Bremen, Bremen, Germany

Abstract

Historic chronicles and previous studies document that tsunami waves occur not only in the oceans but also in lakes potentially causing widespread coastal damage and even casualties. With a detailed historic database and its extensive previous limnogeological and paleoseismic research, Central Switzerland offers an outstanding field laboratory to assess the relevant lake-tsunami processes. A multidisciplinary project aims at unraveling the trigger mechanisms, preconditions, processes and impacts of seismic and aseismic subaquatic slope instabilities and related lake tsunamis- a so far underexplored natural hazard. Results are anticipated to be applicable to other lake districts and gained knowledge of underlying processes will contribute to a better general understanding of mass-movement induced tsunami waves in the marine realm. The goals of this research program are thus to understand governing mechanisms of genesis and propagation of tsunamis in lakes by using these continental basins as analogues for their marine counterparts. Through a multidisciplinary approach involving limnogeologists, seismologists, geotechnical specialists, hydraulic engineers and hazard specialists, key concepts and factors relevant for causes and controls of these tsunamis will be developed.

Sublacustrine mass-movements causing these lake tsunamis can be identified in the basal sediments by large volumes of displaced sediments, which provide critical data to model the tsunami propagation including their inundations. Geotechnical properties and geometries of charged slope sediment control threshold conditions at which slope instabilities are triggered. To complete the event catalogue of these events and to verify inundation processes, a series of sediment cores around the lakeshores target the identification of tsunami deposits that witness historic and prehistoric events. For this purpose, various marsh lands and coastal depressions have been cored mostly in shore-perpendicular transects. New lake-sediment-tailored methodologies are currently developed to identify these lacustrine tsunami deposits; key challenges for successful identification of tsunami layers in the lacustrine realm are the impact of lake-level fluctuations on available accommodation space, sediment-availability in the near-shore / on-shore environment, preservation of the associated deposits, the disentangling from flood- and storm-induced detrital layers, anthropogenic impact on coastal morphology and (core-recovery) quality/recovery of cores in these petrophysically highly contrasting lithologies. These challenges can be overcome by a sensitive choice of coring locations and a sophisticated sediment-core analysis, eventually leading to a tsunami-event stratigraphy of the postglacial epoch.

All knowledge gained from studying slope instabilities and from identifying tsunami deposits will be used as input parameters into numerical models of tsunami-wave propagation and inundation yielding a holistic framework for probabilistic tsunami hazard assessment. The results from process understanding, different modeling methods and data developed in the project will provide the baseline for assessing the risks for people, lifelines and structures along lakeshores and coasts.

A 1000-year history of the great tsunamis recorded in emerged sea cave, southern Kanto, Japan

Osamu Fujiwara¹, Cohe Sugiyama², Shinji Uemoto³, Minoru Yoneda⁴

¹Geological Survey of Japan, AIST, Tsukuba, Japan. ²Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan. ³Kanagawa disaster archaeology research institute, Kanagawa, Japan. ⁴The University Museum, The University of Tokyo, Tokyo, Japan

Abstract

Locating near the Tokyo metropolitan area, Sagami Trough great earthquake (Great Kanto earthquake) has been a source of care in Japan for the last several decades. The last two events, 1923CE (M7.9) and 1703CE (M8.2), caused severe seismic and tsunami disasters around the Kanto region. However, the older history of the Kanto earthquakes is still unclear. Because the Kanto area had been uncivilized place located far from the capital region in these days, few reliable documents about the Kanto earthquakes are still in existence. Additionally, number of reliable geological evidences are still insufficient to discuss the recurrence history of Kanto earthquakes. Here we report a series of possible tsunami deposits from an emerged sea cave located on the Miura peninsula facing the Sagami Trough. This is the first report of tsunami deposits from Japanese sea caves and improve our knowledge of the frequency and magnitude of large tsunamis around the Kanto region.

The Shiraishi cave is located on the sea cliff of Late Pleistocene marine terrace. Its open width, depth and top board height are about 5 m, 21 m and 10 m, respectively. Excavation researches in the cave revealed the remains of fireplace and tombs at the level of 6.0-6.4 m. Their ages range from the first century BC to 9th century. Covering the ruins, about 1.7 m-thick alternation of mud, sand and gravel layers is distributed in the cave. Main components of these deposits are scoria and mud balls (mainly fragments of loam soil covering the marine terrace) and different from the cave wall geology (Late Miocene tuffaceous sandstone). They are classified into at least five layers with 10 to 60 cm-thick based on the basal erosion surfaces and sedimentary facies. Each layer shows normal or reverse grading, sometimes multiple layered structure. Current ripples and dunes show that these deposits were derived from the outside of the cave. Fossil marine diatoms also characterize these deposits.

Wave heights during the typhoons are not high to inundate the Shiraishi cave. Tsunami height during the 1923 nor 1703 Kanto earthquakes did not reach the cave. It can be still disputable to consider the coseismic uplift (wave cut benches emerged by the 1703CE earthquake is now located around 2.3 m in elevation), plausible sources of the five sediment layers in the Shiraishi cave are large tsunamis.

A total of 10 radiocarbon ages and archaeological evidences roughly placed the five layers 9th to 10th century (lowest layer), 1300-1400CE (second one), 1450-1530CE (third and fourth one) and 1550-1640CE (upper most layer), respectively. Comparing with the historical documents, candidate source of four events are 878 Gangyo, 1293 Einin and 1495 Meio Kanto earthquakes and 1605 Keicho earthquakes, possible Izu-Ogasawara trench earthquake (Ishibashi and Harada., 2013).

Abstract

Tsunami evidence from coastal lakes and lagoons has not yet been exploited to the same extent as the more conventionally studied terrestrial records from e.g. coastal lowlands. Lakes, however, are often considered superior event archives, as they have more accommodation space for sediments to accumulate in, and preservation potential is better compared to terrestrial records, which are often strongly affected by erosion due to interseismic coastal elevation changes or due to inundation by subsequent tsunamis. Even though these qualities apply to most lake basins, a spectrum of different settings should be regarded, depending on geography, climate, geomorphology and geology of the surroundings, basin morphology, lake origin etc. These factors determine the characteristics and quality of the lake record and the possible presence of tsunami deposits within. A well-considered selection of lakes with different characteristics and in diverse settings along subduction zones in Thailand, Chile and Japan allows to achieve a conceptual understanding of how external factors influence the potential and limitations of lakes as tsunami archives. Characteristics of each site were studied by executing geophysical surveying techniques (reflection-seismics and side-scan sonar), coring (gravity and piston) and core analyses (e.g. CT scans, XRF scans, grain size, ¹⁴C dating, tephrochronology...). This toolbox of methods helps to identify and characterise tsunami deposits and to define which (combination of) proxies are most successful in highlighting marine inundation. The case studies include three small, former tin mining ponds from the last century in Khao Lak, Thailand, two isolated river valleys (Gemelas West and Vichuquén) in Chile that formed due to eustatic regression and dune formation during the Pleistocene, and one big, tidal lake (Hamana) in Japan that is the result of an interaction between Pleistocene incision and complex coastal processes. The Chilean coastline is free of tropical storms and Khao Lak has no history of significant storms, whereas the Lake Hamana area is prone to both tsunamis and typhoons (i.e. extreme wave events). Given the difficulty to distinguish between both types of extreme wave event deposits, this has major implications for Hamana as a tsunami archive. In addition to that, Lake Hamana is directly connected to the ocean and hence experiences a strong influence of relative sea-level changes on deposition and preservation. The Khao Lak ponds, in contrast, are geomorphologically perfectly positioned to serve as tsunami archives. However, their man-made origin strongly limits the record length, only capturing high-resolution deposits of the 2004 Indian Ocean Tsunami. Both lagoons in Chile are capable of successfully recording long (pre)histories of tsunami inundation, but might be infiltrated by other event deposits with a comparable imprint apart from tropical storms (e.g. floods, earthquakes and strong aeolian activity). Identifying appropriate proxies to disentangle the different event signatures is key.

Coupling tsunami field data and numerical modeling to better understand the AD 1755 tsunami

Pedro José Miranda Costa¹, Francisco Dourado², Seanpaul La Selle³, César Andrade¹, Guy Gelfenbaum³, Ana Nobre Silva¹, Ivana Bosnic¹

¹Instituto Dom Luiz, Departamento de Geologia, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal.

²CEPEDES, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil. ³Pacific Coastal and Marine Science Center, Santa Cruz, USA

Abstract

The application of numerical models of tsunami inundation and related sediment transport have been used recently to better understand the processes involved in tsunami deposition. With reliable and extensive field data these models can provide insights into physical aspects of specific tsunami events and contribute, for instance, to better define its mechanisms.

We applied a coupled field data and numerical modelling approach for the AD 1755's tsunami along the southern Portuguese coast, using Delft3D Flow Mode. Two onshore study sites (Boca do Rio and Salgados) were selected to model tsunami inundation and sedimentary dynamics. In both areas the AD 1755's tsunami deposit, typically, consists of massive or normally-graded, landward thinning layers of shell-rich medium sand with an erosive base within the mud-dominated lowlands. Applying provenance techniques (textural, microtextural and heavy minerals) it was possible to establish the likely sediment sources of this deposit (dune and beach).

This work used geological signatures (both depositional and erosional) of the AD 1755's tsunami to validate tsunami hydrodynamic and sediment transport models from 7 different proposed fault ruptures. These epicentral areas have been previously proposed in literature and include Marquês de Pombal Fault, Gorringe Bank, Cadiz Accretionary Wedge, Horseshoe Fault and 3 different scenarios combining some of these structures with deeper (30-60 km) ones. Results allowed to establish the more likely generation-mechanism and epicentral location based on the best correlation between field and modelled results (tsunami travel time, run-up, erosion depth, volume of sediment and post-event coastal profile). Furthermore, we also tested variations on composition and grain-size and the way it affects the sedimentary imprint laid down by the tsunami event.

Results are promising and suggest that recent advances in numerical modelling can provide useful insights to tsunami geoscience namely by allowing to reconstruct physical parameters and morphodynamic changes caused by tsunami events.

A multiproxy analysis of extreme wave deposits in a tropical coastal lagoon in Jamaica, West Indies

Suzanne Palmer¹, Michael Burn¹, Jonathan Holmes²

¹The University of the West Indies, Kingston, Jamaica. ²University College London, London, United Kingdom

Abstract

The Caribbean Region is vulnerable to natural disasters including earthquakes, tsunamis and tropical cyclones; however, there are few studies of coastal lagoons that attempt to document and distinguish between marine washover layers deposited by storms and those emplaced during a tsunami, which in turn hampers the interpretation and reconstruction of past extreme wave events. Here, we present a 1000-year multiproxy record of extreme washover events deposited within a coastal mangrove lagoon on the south coast of Jamaica. Manatee Bay lagoon is a permanent fresh-brackish water mangrove lagoon separated from the Caribbean Sea by a carbonate beach. Fifteen sediment cores were recovered through ~0.4m of water along five shore-normal transects encompassing ca. 1200 years of sedimentation. The organic and carbonate contents of all cores were determined using LOI and geochemical analyses were performed on the ITRAX μ -XRF scanner at Aberystwyth University. The lagoon depositional environment comprises micro-fossil-rich authigenic carbonate lake muds dominated by the brackish-water ostracod *Cyprideis mexicana*. The carbonate muds are separated by organic mangrove deposits which are similarly dominated by *Cyprideis mexicana* but contain an increased abundance of *Heterocypris punctata*, which generally prefers fresh-brackish water conditions. Stratigraphically distinct carbonate beach sand lenses occur within the sediment record. Near-surface sediments from cores across the modern washover fan drape the underlying lagoon muds with a sharp, non-erosional contact and are readily distinguished by abrupt positive excursions in Ca, Sr and Fe and concomitant declines in organic matter, Br and Cl. Washover sediments are dominated by bioclasts of *Halimeda* sp., echinoid spines, sponge spicules, reef benthic foraminifera and molluscan fragments. Evidence of multiple palaeo-washover deposits is contained within 13 of the 15 sediment cores. Fresh-brackish water fossil ostracods and charophytes, typical of the contemporary lagoonal sediments, are notably absent in surface and palaeo-washover deposits. The primary washover deposit that occurs in multiple cores can be cross-correlated across the lagoon by an abrupt positive excursion in Fe. This deposit ¹⁴C-dated at 1810-1925 cal CE encompasses a period of both extreme tectonic and meteorological events most notably the 1907 earthquake, the second most devastating in Jamaica, which generated a tsunami in Kingston Harbour, just 10km east of the study site. However, during this timeframe there were also a series of major hurricanes that passed within 20-35 miles of the lagoon thereby complicating the attribution of this event to any specific cause. The sedimentology, geochemistry and ostracod fauna provide an indication of the extent of marine incursion for different washover events over the ca. 1200 years and their impact on lagoon development, however, it remains unclear as to whether the primary washover deposit has been emplaced by a tsunami or other extreme wave event.

The sedimentary record and numerical simulation of a tsunami associated with the 7.3 ka eruption of the Kikai volcano, Japan

Masaki Yamada¹, Yuchen Wang¹, Fukashi Maeno¹, Shigehiro Fujino², Kenji Satake¹

¹The University of Tokyo, Tokyo, Japan. ²University of Tsukuba, Ibaraki, Japan

Abstract

The 7.3 ka eruption of the Kikai volcano, occurred in a shallow sea area of southern Kyushu, Japan, is one of the largest caldera-forming eruptions in Holocene. A huge tsunami has been generated by a sea-level change caused by caldera collapse and/or an entrance of pyroclastic flow into a shallow sea. Tsunami deposits associated with this eruption have been observed at three distant coastal lowlands (~560 km from the volcano). They are overlain by volcanic ash from the eruption (Kikai Akahoya tephra: K-Ah) and exhibit sharp contacts with the upper tephra and lower muddy sediment in onshore sediment cores. A tsunami deposit overlain by the Koya pyroclastic flow deposit (K-Ky) is also observed at Yakushima and Kuchino-erabujima Islands near the volcano (Geshi et al, 2017; Nanayama and Maeno, 2018). These stratigraphic relationships indicate that the tsunami hit the distant coastal lowlands and the nearby islands immediately before the arrival of the K-Ah fall tephra and the K-Ky pyroclastic flow, respectively. Based on these widely-distributed geological evidences, this study aims to unravel the tsunami size and triggering volcanic phenomena by numerical simulations of both caldera collapse and pyroclastic flow tsunamis.

A tsunami generated by caldera collapse was numerically simulated based on the method proposed by Maeno et al. (2006) and using the non-linear long wave model (JAGURS; Baba et al., 2015). Assuming that a hypothetical volcano (15 km × 10 km) collapsed from 800 m high to 500 m deep in 1 hour, a first wave of the resultant tsunami arrived at the lowlands between 2.5 and 3.5 hours since the caldera collapse started. The amplitude of the simulated tsunami were less than 1 m at all lowlands. A tsunami generated by an entrance of pyroclastic flow was also numerically simulated by a non-linear two-layer model and pyroclastic flow parameters by Maeno and Imamura (2007). A first tsunami arrived at the lowlands approximately 2 hours since the eruption. The tsunami amplitudes are smaller than those generated by caldera collapse. The stratigraphy at the nearby islands suggests that the tsunami was most likely generated by an entrance of pyroclastic flow because caldera collapse probably occurred at the end of the eruptive process, and that its associated tsunami cannot reach the island before the arrival of pyroclastic flow (Geshi et al, 2017; Nanayama and Maeno, 2018). However, the results of this study indicate that the tsunami generated by pyroclastic flow is probably not powerful enough to form a tsunami deposit at the distant locations. Thus, we will give consideration to the possibility that the tsunami was generated by both caldera collapse and an entrance of pyroclastic flow almost at the same time.

Alluvial Fans And Their Relationship To African Humid Period Climate Dynamics

Martin Stokes¹, Alberto Gomes², Ana Carracedo-Plumed³, Fin Stuart³

¹University of Plymouth, Plymouth, United Kingdom. ²University of Porto, Porto, Portugal. ³SUERC, East Kilbride, United Kingdom

Abstract

We investigate the size, timing and impact of African Humid Period (AHPs) flood events along the margins of upland landscapes within the Sahara Desert. AHPs relate to the wobbling of the Earth's axial spin, which alters atmospheric circulation patterns every ~20ka, repeatedly bringing elevated hydrological conditions (~5ka duration) to low-mid latitudes of continental Africa ('Greening' of the Sahara). Insights are provided using alluvial fans, cone-shaped sediment bodies that develop along mountain fronts or at river tributary junctions, hydrologically and sedimentologically linking hillslopes to channels. These landforms possess significant but unrealised large spatial and long temporal potential to inform on climate change sensitive drylands; areas with evidence for early humans and pressures from modern population growth. In this presentation alluvial fan-AHP dynamics are illustrated using examples from the Cape Verde volcanic archipelago (low latitude, offshore west Africa), a terrestrial offshore climatic extension of the Sahara Desert.

Coalescent coastal alluvial fans have developed along the SE volcanic edifice flank margin on Santo Antão island. Fans display an expansive relict surface incised by up to 120m, revealing an up to 100m thick sequence of coarse-grained cobble-boulder dominated fluvial sediments interbedded with a with basaltic lava flows (undated) and tephra (Argon dated = 193 +/-23ka). Fan surface morphology is characterised using 10m TanDEM-X data and targeted field survey with UAV drone mapping. The surface morphology comprises low relief (<3.5m) distributive fluvial bars and channels. Fan surface age-relationships were determined using ³He cosmogenic exposure dating. Results suggest the fan surface is a composite Late Pleistocene feature formed by spatially and temporally distinct lobes between 1) 80-90ka; 2) 50-60ka and 3) 10-20ka; a chronology coincident with the onset of AHP events. We present a climate-avulsion model in which the elevated hydrological conditions during the onset of AHP events has triggered avulsions of the alluvial fan channel network, switching floodwaters and sediments to different fan surface regions. Furthermore, we quantify the flood magnitude of these AHP-related avulsion events using competence based palaeohydrological methods.

We are expanding research into mainland Africa (e.g. Southern Morocco), using alluvial fans to 1) investigate how and when landscapes responded to AHP events outside of the lowland lake-dune dominated continental interiors of the Sahara; 2) to explore the sensitivity of alluvial fans to AHP events in different latitude and longitude contexts along the NW African continental margin; and 3) to investigate the impact of alluvial fan-AHP flood avulsions in an early human archaeological context.

Large rivers and a green coast: summer and winter precipitation control on North African landscapes over the past 220 kyr

Cecile Blanchet¹, Anne Osborne², Rik Tjallingii¹, Werner Ehrmann³, Warner Brückmann², Martin Frank²

¹GFZ-Potsdam, Potsdam, Germany. ²GEOMAR, Kiel, Germany. ³University Leipzig, Leipzig, Germany

Abstract

Changes in past hydrological regimes led to drastic alterations of North African landscapes and shifted ecological boundaries over thousands of kilometres. Understanding how prehistoric human populations reacted to these environmental changes remains a burning issue. However, the lack of continuous archives of North African hydrological variations has hindered our understanding of past climate and human population dynamics.

We present the first continuous and high-resolution climatic record from the Gulf of Sirte (offshore Libya) covering the last 220 kyr that documents fluvial pulses linked to the reactivation of Saharan paleo-rivers as well as coastal runoff. Monsoon-related summer precipitation reached as far north as 25°N during insolation peaks and led to massively increased fluvial runoff from the central Sahara and coincided with the deposition of sapropel layers in the Gulf of Sirte. Intermittent humid periods are detected during MIS6, MIS4 and MIS3, and are inferred to result from enhanced winter precipitation due to an orbitally-forced southward shift of the Mediterranean storm tracks. In addition, our record suggests the occurrence of humid conditions in both southern and northern Libya during MIS5e and MIS7, which may either indicate mega-monsoon events with convective cells reaching as far north as 30°N and/or winter precipitation, both related to periods of high obliquity of the Earth's axis. We argue that the opening of either N-S or E-W green corridors during MIS5 and MIS3-4, respectively, as well as large-amplitude climatic swings during MIS5 and MIS7 played a central role for trans-continental human migration waves and the development of highly developed populations in North Africa.

Sedimentary fillings of mountainous valleys as evidences of climatic and anthropogenic changes around Wakarida's archaeological site (Tigray, northern Ethiopia)

Ninon BLOND^{1,2}, Nicolas JACOB-ROUSSEAU^{1,2}, Yann CALLOT¹

¹Laboratoire Archéorient, UMR 5133, Lyon, France. ²Université Lumière Lyon2, Lyon, France

Abstract

Well known in West Africa, the *African Humid Period* (AHP) can also be spotted in sedimentary accumulations in East Africa. The earlier deposits (7th millennium BCE), found in valleys around the axumite (1st-6th Century CE) site of Wakarida (northern Tigray, Ethiopia), seem to correspond to wet conditions of the end of the AHP. Ages range from the 7th millennium BCE to the 17th Century CE and analyses show variations in depositional environments. Gaps in the dating in Wakarida could correspond to drier spells, identified by Dramis et al. (2003) in other Ethiopian places. At the turn of the 3rd/2nd millennium BCE, the aridification of the climate, pointed by Pietsch and Machado (2014) in Yeha, is sensible through the accumulation of silts, interbedded with gravels. This evolution towards a drier climate has consequences for the vegetation cover and the erodibility of the hillsides. At the end of the AHP, the sediment accumulations are mainly fine-grained, testifying of low competence processes. Nevertheless, coarse beds (with pebbles and gravels) show the occurrence of higher energy events and/or higher sensitivity of the drainage basins to erosive processes. Those can be attributed to climatic changes but they can also be the results of a progressive opening of the vegetation by a growing population. It is not easy to determine whether those changes are the result of climatic, anthropogenic or mixed processes. Sedimentary records dating from the pre-axumite period (800-0 BCE) could indicate the beginning of the clearing of the vegetation by population living in or around the archaeological site, even though no archaeological evidence of cultivation has been found in the excavations. Climatic and anthropogenic processes continue to combine in more recent periods, with two wetter spells leading to sedimentary accumulations in the 8th Century BCE and around the 12th-14th and 15th-17th Centuries CE. After the 17th Century, we lose track of accumulations processes and ablation seems to take place, leading to the erosional forms that we can see nowadays. At present time, the area around Wakarida seems to meet an unprecedented phase of incision and sedimentary crisis, which results in important headward erosion in the valleys' sedimentary fillings and endangers food security in this dry and highly populated area. This chronostratigraphic work has been conducted within a five-kilometre radius study area around the archaeological site and relied on the interpretation and sampling of sixteen sections, laser granulometry and C14 dating of charcoal samples. Working at the scale of small watersheds and multiplying the number of studied sites allows to understand the functioning of the catchment on long time and to identify and integrate some controlling factors like the organisation of the basin or the connectivity between upstream and downstream parts of the valley.

Excavations at the Stone Age site of Nyabusora, Tanzania in the context of hominin adaptations to equatorial African landscapes.

Laura Basell¹, Merrick Posnansky²

¹Queen's University, Belfast, United Kingdom. ²Emeritus Professor at University of California, Los Angeles, USA

Abstract

This paper presents the results of excavations at the Sangoan site of Nyabusora in northern Tanzania. Excavations in 1959 were conducted by M. Posnansky and the late W. W. Bishop, and in 1961 by M. Posnansky. Hitherto only preliminary reports have been published on this site but new work on the unpublished archive has confirmed the value and future potential of the site both archaeologically and palaeoenvironmentally. The finds, which include lithics and more unusually, bone, take on new significance in light of recent developments in Early and Middle Stone Age (MSA) Archaeology in East Africa. In addition the site provides valuable sedimentological information which has implications for Quaternary landscape change in the Kagera River and Lake Victoria region. Nyabusora is one of several Stone Age sites currently under renewed investigation in the Kagera Catchment by Basell, and is one of only a handful of stratified sites to have yielded Sangoan assemblages. Following a summary of excavations and interpretations of the key finds, future directions for work at Nyabusora will be considered in the broader context of hominin adaptations to equatorial African landscapes.

Fromontane-Afroalpine ecosystems as long-term sensors of environmental change

Graciela Gil-Romera^{1,2}, Lucas Bittner³, David A. Grady¹, Henry F. Lamb¹, Michael Zech^{4,3}

¹Dept. Geography and Earth Sciences, Aberystwyth University, Aberystwyth, United Kingdom. ²IPE-CSIC, Zaragoza, Spain. ³Institute of Agronomy and Nutritional Sciences, Soil Biogeochemistry, Martin Luther University, Halle-Wittenberg, Halle (Saale), Germany. ⁴Institute of Geography, Chair of Landscape Ecology, TU Dresden, Dresden, Germany

Abstract

The two most important African mountain ecosystems are the Afroalpine and Afromontane ecosystems. Ranging in altitude from 2000 to more than 4500 m asl, they hold distinctive endemic faunas and floras. The best preserved examples are in the Ethiopian highlands but these still face the challenges of current global change, including increasing human action. Their high-altitude ecological communities are very sensitive to environmental fluctuations, being limited to relatively small areas. They are thus often the focus of ecological research, since conservation managers need informed evidence as the basis for management decisions. However little is known of their response to long-term environmental change, which is critical for understanding their likely response to future global change.

Palaeoenvironmental records from the Ethiopian highlands show patterns of increasing temperature and changing regional rainfall since the last glacial that may be linked to vegetation dynamics and human agency. We hypothesize that African mountain ecosystems are sensitive to climate variation and anthropogenic disturbance while being resilient to long-term change. We thus aim to answer the following questions: 1) How have varying moisture patterns affected the Ericaceous belt from the Lateglacial to the present? 2) What are the relationships between climate, vegetation and fire in these ecosystems?

To address these questions, we revisit lake Garba Guracha (GGU, 3950 m asl, Fig 1), presenting a new palaeoecological record of the last 16 kyrs. Our new record includes high-resolution time series of pollen, charcoal, diatoms and stable isotopes ($\delta^2\text{H}$ and $\delta^{18}\text{O}$), where the latter constitute independent evidence of climate variation. The Lateglacial landscape at GGU was an open, dry, steppe-like environment. The record shows increasing moisture and temperature from 16 ka BP to the mid-Holocene (11-6 ka BP), concurring with the African Humid Period. Vegetation cover responded rapidly to the increasing moisture, with denser Ericaceous vegetation and thicker forest in the lowlands from the Holocene onset. This clear response of the Ericaceous belt to climate change is partially modulated by fire activity, which is dependent on biomass as a limiting factor, establishing a climate-vegetation-fire loop. The coupled climate, heathland, and fire dynamic is punctuated by drought events until 5 ka BP, when a longer, drier period established, lasting to the present and defining a new landscape where human impact became clearly distinctive. We discuss our results in the light of conservation measures for Afromontane and Afroalpine environments.

Abstract

Articulating anthropogenic impacts on tropical rain forests within the broader schema of Pleistocene-Holocene climate change remains one of the most challenging research objectives facing Quaternary scientists. Plagued by problems of equifinality and polemic 'climate vs. culture' theoretical frameworks, this body of research can only be advanced through interdisciplinary collaborations focused on building empirically grounded case studies of coupled climatic and cultural change within tropical ecosystems. Records of past vegetation and human activities in the Congo Basin are extraordinarily rare compared with other tropical regions, despite the significance of Congolian Rain Forests within the Earth System and as one of the crucial zones of human adaptation and cultural-ecological coevolution.

Understanding rain forest response to anthropogenic impacts and climatic changes within the Late Holocene offers benefits to our understanding of the rain forest system at large as well as the core dynamics governing anthropogenic impacts. Of particular significance is contextualizing more detailed synchronic observations within diachronic changes over the last two millennia. Radiocarbon dating from excavated sites in the Democratic Republic of Congo indicates that forest settlement spans the last 2,500 years B.P. Excavation of archaeological sites and sampling of associated paleoecological records provides a basis for considering critical questions about anthropogenic impacts and the historical dimensions of modern forests. To what extent do modern anthropogenic impacts reflect past anthropogenic impacts? What can paleoecological archives tell us about the state of modern rain forests and their conservation status? In pursuit of these questions, this project brings together observations from archaeological, archaeobotanical, and paleoecological datasets; permitting consideration of technological and subsistence adaptations within a broader envelope of past vegetation change spanning on-site and off-site records.

Archaeological, archaeobotanical, and paleoecological study at the sites of Iyonda and Bolondo in the Democratic Republic of the Congo records a uniquely detailed Late Holocene record of past cultural and vegetation change on the Congo and Tshuapa rivers. Capturing some of the earliest and latest phases of colonization of the forest zone by prehistoric agriculturalists, these sites provide rare insights into the ecological contexts and outcomes of forest settlement. The presence of *Pennisetum glaucum*, a cultivar of the Sahelian zone, as well as evidence for iron metallurgy at these sites signals regional economic exchange and technological complexity. The evidence from these sites provides direct insights into vegetation change and forest diversity through critical phases of regional climate change and prehistoric settlement. Furthermore, this study makes concrete steps towards identifying and evaluating anthropogenic impacts by bridging archaeological records of human activity and local records of vegetation change.

Abstract

Ethiopia/northeast Africa has been considered as one of the key sites for the origin of Anatomically Modern Humans (AMH) and possibly the region out of which AMH dispersed. There is a significant debate about the role of climate variability in human evolution and dispersal “Out of Africa”. High-resolution paleoclimate records from this region are therefore required to shed light on this debate. Climate records from speleothem archives using multi-proxy approach (oxygen and carbon isotopes, growth rate and trace element data) from southeastern Ethiopia spanning important time windows between the last interglacial and the late Holocene provide significant input to this effect. The record from the GM1 speleothem which intermittently grew during the last interglacial for instance shows that the earliest human migration during MIS 5e occurred during a major wet event in northeast Africa. Other speleothems from the same region which have been dated to the critical period of 120 - 50 ka are under investigation and pilot proxy records show rather drier conditions during the major episode of human dispersal at ~50 - 75 ka, suggesting a more complex relationship between climate change and human dispersal episodes. Comparison of high resolution but intermittent speleothem records from southeastern Ethiopia with continuous but lower resolution records from the northwestern Ethiopian highlands (the Tana Lake record), southern Ethiopian rift (the Chew Bahir Lake record), archaeological and sedimentological records of the Goda Buticha cave on the southeastern Ethiopian plateau, and marine records from the Gulf of Aden shows the relative significance of regional versus local climate variabilities.

Abstract

A molecular approach to lake sediments used for artificial islands (crannogs) is here used to reconstruct the environmental record from a natural island in Lough Catherine Northern Ireland. The island, named 'Island McHugh', was excavated in the 1940s-1950s and again in the 1970s. It has yielded artefacts from most periods including; Neolithic worked flint, a Bronze Age sword, worked wood, and charcoal, an early medieval crannog, and lastly a post-Medieval castle. The excavations by in the 1940s revealed a complex stratigraphy which has been re-evaluated as part of the *Celtic Crannogs Project*. A core from just off the island has revealed a complex stratigraphy extending back to the early Neolithic. Extracellular *sedaDNA* from the site shows three principal phases of human activity including both domesticates and synanthropes. In the first phase provisionally dated to the Iron Age open ground and grazing taxa increase with a small increase in arable indicators. There is also the appearance of cattle, pigs and sheep. In the second phase more securely dated to the early Medieval period there is a larger increase in both grazing and arable indicator taxa and a very strong increase in domesticated animals. In the Post-Medieval period horse is present and there is a comprehensive reflection of 18th century landscaping. The later two periods (Early Medieval and Post-medieval) are well represented in the excavations but the earlier phase (Iron Age) is not, so we are undertaking a further review of the existing excavation data as well as proposing re-excavation of some, somewhat enigmatic, features. The lipid biomarker evidence is also strong with high faecal stanols from the Iron Age to the Medieval levels. A clear peak at c. 600 BC enables the identification of the source as almost certainly of human origin. The faecal stanols record is shown to mirror the animal *sedaDNA* results. This study illustrates the ability of *sedaDNA* to identify both the impact of human activity on local ecology, but also the causes - from the presence of cultivars to domesticates such as cattle, pig and sheep. The presence of horse only in the Post-Medieval levels suggests stabling of horses at the castle on the island. Taken with the direct evidence of human habitation from the faecal stanols we can see how these techniques could be used to provide an archaeological record of sites that had never been excavated.

Abstract

Both wetland settlements and crannogs (artificial islands) were constructed in Scotland and Ireland from the Iron Age to the Medieval period. Excavations of partially or fully submerged wetland or crannog structures can be logistically and financially challenging, therefore the timing of site occupation and function remains poorly constrained. Analysis of sedimentary archives adjacent to wetland sites and crannog structures can be used as a complementary, and possibly an alternative, approach to excavation. However, currently applied palaeoenvironmental analyses can only provide indirect evidence of human occupancy. Our new research provides direct anthropogenic evidence using steroid biomarkers (stanols and bile acids) contained within wetland sediments. These compounds provide evidence of human and animal faecal matter in a range of depositional contexts, but their application to wetland archaeology has so far been limited.

Steroid analysis was undertaken on sediment archives proximal to two neighbouring Iron Age wetland settlements in southwest Scotland: Black Loch of Myrton and White Loch of Myrton. Evidence of human faecal matter was identified at both sites, demonstrating preservation of faecal steroids within wetland sedimentary environments. The ability of stanols and bile acids to provide direct evidence of human occupation is supported by occupation dates independently obtained from archaeological excavations (Figure 1). Steroid ratios also indicate the presence of ruminants within the settlements, which is confirmed by sedimentary DNA (*sedaDNA*) analyses and supported by palaeoecological reconstructions of faecal matter (from *Coleoptera*) and nutrient-driven changes in aquatic ecology (diatoms and chironomids). The similarities between faecal steroid records and independent lines of chronological and palaeoenvironmental evidence highlights the ability of lipid biomarkers to provide direct evidence of human occupation from wetland sediments, but also demonstrates the ways in which these analyses can be used to characterise occupation phases and advance interpretations of wetland archaeological sites.

Figure 1: Sedimentary evidence of Iron Age anthropogenic activity at Black Loch of Myrton, Scotland. Faecal steroid compounds (stanols and bile acids) provide direct evidence of multiple human occupation phases (A-C). The timing of these phases identified within the sedimentary archive corresponds with the archaeological site chronology. Carbon-nitrogen ratios and $\delta^{13}\text{C}$ values indicate that the site was terrestrialising during the occupation phases.

Abstract

Humans have always been attracted to lakes as resource hotspots. In the Iron Age to Medieval Period in Ireland and Scotland, this is reflected in the construction of lakeside settlements and artificial islands called crannogs, in thousands of small and largely lowland lakes. Due to the complex nature of these archaeological sites, excavations of wetland structures can be logistically and financially challenging, meaning our ideas concerning prehistoric wetland societies are based on a limited number of sites.

Sedimentary records from very close to archaeological sites offer the opportunity of retrieving information from a range of proxies regarding lakeside settlement usage and environmental impact that would otherwise be difficult to obtain without excavation. It is possible to detect human activities with both high-temporal and high analytical resolution, and these human impacts appear to have had profound effects on and within small lake environments that were typically sensitive to environmental change.

Our research on crannogs and lakeside settlements characterises these prehistoric human-environment interactions using proxies of geochemical and biological signals preserved within both the crannog and wetland/lake sediments. This presentation specifically focuses on palaeoecological proxies e.g., chironomids, diatoms, pollen, beetles and ectoparasites.

Results of the palaeoecological analyses reveal short-lived construction and occupation phases of crannogs from the Iron Age to the Medieval Period. The main effects of human activities on the lake ecosystems are nutrient-driven increases in productivity and shifts in aquatic species to indicate more eutrophic conditions. Site abandonment reduces nutrient inputs and therefore levels of aquatic productivity, as evidenced by decreases in the abundance of siliceous algae. Despite returns to pre-settlement nutrient and productivity levels, indicator species suggest lake ecosystems do not return to their previous ecological state. Results from beetles and ectoparasites highlight a number of taxa typically associated with occupation layers including fly pupal remains, giving an indication of on-site conditions. Detailed investigations using these proxies allow us to understand possible activities undertaken within these prehistoric wetland structures.

Tracking land-use legacies in boreal and alpine landscapes of Sweden using multiproxy analyses of lake sediment records

Richard Bindler¹, Sofia Nannes¹, Loïc Harrault², Johan Rydberg¹, Doreen Huang¹, Johan Olofsson¹, Jonatan Klaminder¹
¹Umeå University, Umeå, Sweden. ²Université Pierre et Marie Curie, Paris, Gabon

Abstract

Large areas of the boreal and alpine landscapes of Scandinavia are protected today for their (perceived) untrammled beauty, natural biodiversity and wilderness character. However, although spatially patchy and temporally discontinuous, there is increasing evidence suggesting these landscapes have been culturally imprinted since the retreat of the last ice sheet, but especially over the past millennium. Documenting archaeological sites, such as Sámi stáallo settlements in mountain areas or summer forest farms (*fäboddar/säter*) in boreal regions, is a core component in reconstructing the human history of these landscapes, but many of the associated activities such as animal husbandry were widely dispersed in the landscape and would have left little direct physical evidence. From archaeological sites alone it can be difficult to discern not only the full timeline of human occupation but also the extent to which humans may have shaped terrestrial and aquatic ecosystems.

As a complement to traditional field archaeological surveys, analyses of natural archives such as sediments from lakes in close proximity to specific sites offer the potential for a continuous, undisturbed record of past change. Deciphering the imprint of human activities in these records separate from natural climate and environmental changes can be challenging. Here we present data from two pilot studies that combined established techniques in paleolimnology (geochemistry, pollen) with emerging techniques (infrared spectroscopy, pyrolysis-GC/MS, fecal biomarkers, sedDNA) to identify and track the early history of remote summer farming with domestic livestock in the boreal landscape and reindeer husbandry in the alpine landscape. In the boreal lake, pollen analyses suggest a diffuse, discontinuous human presence from 2000 BP with continuous evidence from about 500 BP (the established historical phase), including also PAHs. However, coprostanol increases from 1300 BP, along with changes in organic biomarkers indicating ecosystem changes in the lake and catchment, which accelerated from 800 and again from 500 BP, indicating a much longer human history in this region.

In the northern mountains, although animal DNA was not successfully extracted, fecal biomarkers indicative of reindeer were extracted for the entire Holocene record. An increase in dwarf birch from c. 1200 BP, with a slight increase in fecal biomarkers, occurs together with changes in geochemistry – the timing of which is consistent with the age of dated stáallo settlements in the region. A brief excursion in lead also records short-lived silver mining in the area in the late 17th century. In the past 150 yr a sharp increase in fecal biomarkers occurs along with other geochemical indicators indicating more significant human-driven changes in the surrounding landscape.

Middle-Holocene Sea-Level Fluctuations Interrupted the Developing Hemudu Culture in the Lower Yangtze River, China

Keyang He¹, Houyuan Lu¹, Yunfei Zheng², Jianping Zhang¹, Shao Lei³, Deke Xu¹, Xiujia Huan¹, Jiehua Wang³

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China. ²Zhejiang Provincial Institute of Cultural Relics and Archaeology, Hangzhou, China. ³Ningbo Municipal Institute of Cultural Relics and Archaeology, Ningbo, China

Abstract

The eastern coastal zone of China is densely populated and widely recognized as a center of rice domestication, which has undergone dramatic sea-level fluctuation during the Holocene epoch. Hemudu culture is distributed mainly in the eastern coastal area and was once presumed as a mature agricultural economy based on rice, making it an ideal case for examining the remarkable human-environment interaction in the Lower Yangtze River. Though numerous studies have been conducted on the cultural evolution, ecological environment, and rice domestication of Hemudu culture, the impact of sea-level fluctuation on human settlement and food production remains controversial. In this study, we report high-resolution pollen, phytolith, and diatom records, and accurately measured elevation from the Yushan site, which is the closest site of Hemudu culture to the modern coastline. Based on the data gathered, we suggest that the Hemudu culture and subsequent Liangzhu culture developed in the context of regression and were interrupted by two transgressions that occurred during 6300-5600 BP and 5000-4500 BP. The regional ecological environment of the Yushan site alternated between intertidal mudflat and freshwater wetlands induced by sea-level fluctuations in the mid-late Holocene. Though rice was cultivated in the wetland as early as 6700 BP, this cultivation was subsequently discontinued due to the transgression; thus, full domestication of rice did not occur until 5600 BP in this region. Comprehensive analysis of multiple proxies in this study promote the understanding of the relationship between environmental evolution, cultural interruption, and rice domestication.

Phytolith Research on Modern Paddy Soil

Xiujia Huan¹, Houyuan Lu^{1,2,3}, Jianping Zhang^{1,3}, Can Wang⁴

¹Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment, Beijing, China. ²University of Chinese Academy of Sciences, Beijing, China. ³CAS Center for Excellence in Tibetan Plateau Earth Sciences, Beijing, China. ⁴Hebei Normal University, School of history and culture, Shijiazhuang, China

Abstract

Rice, as staple crop, is crucial to the formation of civilization of China and makes great contribution to the development of worldwide civilization. However, there is still controversy regarding when, where and how the domestication of rice began since current methods cannot effectively identify early rice remains recovered from archaeological sites. In particular, the lack of quantitative indicators differentiating wild rice and domesticated rice makes it difficult to establish early rice domestication process, thereby limiting the study of early rice origin.

Here, based on systematical study on differences in bulliform phytolith fish-scale decoration numbers between domesticated rice paddy soil and wild rice field soil in South China, results showed that, in domesticated rice soil, the proportion of bulliform phytoliths with ≥ 9 fish-scale decorations was higher than $57.7\% \pm 8.7\%$, whereas the proportion was less than $17.5\% \pm 8.3\%$ in wild rice soil. The results therefore indicate that the proportion of bulliform phytoliths with ≥ 9 fish-scale decorations can be used to discriminate between wild and domesticated rice. This method is potentially significant in the study of domesticated rice origin.

Furthermore, by analyses phytoliths in 168 soil samples from wild and domesticated rice fields and non-rice fields, we established the discriminant functions which can correctly classified 89.3% of the above samples. The results provide us a robust method for identifying rice paddies and distinguishing between wild and domesticated rice fields.

Early urban impact on vegetation dynamics: palaeoecological evidence from the Dongzhao site, Henan Province, China

Xiaolin Ren

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

The evolution of early urbanism and its environmental consequences have gained great interests, however, the urban impact on vegetation dynamics remains unclear, especially during the early Bronze Age in China. Here, we report vegetation dynamics and early urban impacts based on pollen analysis for an age-controlled profile from late Neolithic to Bronze Age at the early urban settlement Dongzhao, Henan province, China. Our results show that steppe forests developed well around the study site from late Neolithic to Bronze Age. Anthropogenic signature associated with cereal cultivation has been detected by pollen data during the late Neolithic period. The intense human impact from early urban management and arable farming expansion was recorded after 3850 BP, equivalent the period of the Xinzhai and Erlitou cultures. Forest recovery occurred following the abandonment of Dongzhao urban settlement during 3600 ~ 3400 BP. Vegetation degradation between 3400 and 2910 BP happened probably due to increasing human land use coupled with a drying climate.

¹University of Cologne, Institute of Geography, Cologne, Germany. ²University of Jena, Institute of Earth Sciences, Jena, Germany. ³Royal Belgian Institute of Natural Sciences, Geological Survey of Belgium, Brussels, Germany. ⁴GFZ German Research Centre for Geosciences, Potsdam, Germany. ⁵Free University Berlin, Institute of Geographical Sciences, Berlin, Germany. ⁶Technical University of Braunschweig, Institute of Geosystems and Bioindication, Braunschweig, Germany. ⁷Max Planck Institute for Biogeochemistry, Research Group Molecular Biogeochemistry, Jena, Germany

Abstract

Drill cores in the sabkha of the oasis of Tayma (NW Saudi Arabia), revealed the existence of an Early to Mid-Holocene palaeo-lake 250 km away from the Red Sea and about 800 m above sea level. It yielded a fauna almost completely composed of the barnacle *Amphibalanus amphitrite*, two gastropods (*Melanoides tuberculatus*, *Hydrobia* sp.), four foraminifer species (*Ammonia tepida*, *Quinqueloculina seminula*, *Flintinoides labiosa*, *Trichohyalus aguayoi*), and the brackish water ostracod *Cyprideis torosa*, beside very rare freshwater ostracods. The association indicates a brackish water lake with temporary inflows of freshwater. All of the documented species originate from the intertidal zone of the Red Sea or the Mediterranean, and are adapted to highly variable environmental conditions. Morphological and taphonomical analyses of *Cyprideis torosa* (i.e., sieve pores, population structure, preservation status) and test malformations of foraminifers reveal salinity changes and habitat types typical for the center and the margins of the lake basin.

Micro- and macrofossils occur almost exclusively in the laminated and varved sediment unit of the cores. Macrofossils, the two gastropod species, and the barnacle *Amphibalanus amphitrite* occur mainly in its upper part, seeds of *Ruppia maritima* both in its lower and uppermost parts. Based on the faunal and floral distribution the section can be subdivided into four ecological zones:

In the lowermost Zone I, plant remains and rare freshwater ostracods indicate slightly brackish, very shallow conditions, probably a swampy wetland which had established around 9000 cal BP due to humid climate conditions. In the following Zone II, the high abundance of the brackish ostracod *Cyprideis torosa* indicates a lake-level rise and the first development of a permanent water body, starting about 8600 cal BP. In this phase, the sieve-pore analysis of *Cyprideis torosa* points to a variable salinity and therefore to unstable conditions of the early phase of the lake. After a short break, where all fossil abundances decrease, *Cyprideis torosa* increases again in number, and foraminifers reach their first maximum, roughly around 8300 cal BP (Zone III). All parameters indicate an increase in salinity, followed by a relatively stable salinity level, which characterizes a fully established, relatively large water body. The high number of juvenile foraminifers indicates stable environmental conditions of a permanent saline lake. The decrease of all microfossil taxa and the increase of coastal brackish macrofossils, like gastropods and barnacles, point to a lake-level drop, starting ca. 8100 cal BP (Zone IV). About 7800 cal BP started the definite trend to aridification; as a consequence, the lake of Tayma vanished.

This study is a contribution to the research project "CLEAR – Holocene Climatic Events of Northern Arabia" (DFG ref. nos. PL 535/2-1, FR 1489/5-1, EN 977/2-1; <https://clear2018.wordpress.com/>).

O-3107

Hydroclimate of the western Nefud Desert during humid phases of Marine Isotope Stage 5

Richard Clark-Wilson¹, Simon Armitage^{1,2}, Ian Candy¹

¹Royal Holloway University of London, Egham, United Kingdom. ²University of Bergen, Bergen, Norway

Abstract

Fossil, genetic and archaeological evidence increasingly support the idea that *Homo sapiens* populations dispersed from Africa and into Eurasia during Marine Isotope Stage (MIS) 5. However, the dispersal pathways used remain contentious, despite considerable efforts to understand them. This is primarily due to a sparse fossil record coupled with a limited understanding of resource distribution across southwest Asia. The western Nefud Desert lies at a critical crossroads between Africa and Eurasia as it is just ~550 km southeast of the Sinai Peninsula, the only terrestrial route from Africa. Today the region is hyper-arid and a formidable barrier to overland movement, yet in the past has experienced episodic humid phases characterised by increased resource availability in the form of a savannah grassland containing freshwater interdunal lakes. However, detailed empirical palaeoenvironmental records in direct association with archaeology and/or fossil remains are rare. Here, we reconstruct freshwater availability within the western Nefud Desert during MIS 5. We apply a multi-proxy palaeoenvironmental analysis to four interdunal palaeolake sediment deposits with direct evidence for human occupation. A combination of macro-sedimentology, micromorphology, diatom palaeoecology, and oxygen and carbon isotope analysis, in combination with a luminescence-based chronology, demonstrate that the western Nefud Desert contained interconnected, freshwater and perennial interdunal lakes during two separate humid phases in MIS 5. These lakes lay within a resource rich landscape inhabited by *Homo sapiens*, suggesting that the Nefud Desert was an important dispersal pathway out of Africa.

Last interglacial lacustrine/wetland records from the Umm ar-Rimmam depression Kuwait

Adrian Parker¹, Gareth Preston¹, Teresa Mikolajak¹, Adam Blakeley¹, Andrew Rendell¹, Derek Kennet², Gerwin Wulf³, Frank Preusser³

¹Oxford Brookes University, Oxford, United Kingdom. ²Durham University, Durham, United Kingdom. ³University of Freiburg, Freiburg, Germany

Abstract

Compared with other regions of the Arabian Peninsula the Quaternary palaeoenvironmental history of Kuwait is poorly understood. Geological and geomorphological mapping of the Kuwaiti landscape has been well documented but depositional ages and palaeoenvironmental details are lacking from Quaternary sediments. The Dibdabba Formation represents distal alluvial outwash fan gravels, which cover ~60,000 km², fed by the Wadi Al Batin. The fan forms one of several large outwash complexes derived from drainage originating on the Arabian Shield. The fan covers the southern part of western Iraq, the northeastern corner of Saudi Arabia, and the northern desert of Kuwait. The Wadi al-Batin extends 700 km from its headwater source region on the Arabian Shield. The Umm ar-Rimman, located towards to distal end of the outwash fan, forms a large depression formed in the Miocene sediments located on the backslope of the Jaz az-Zor escarpment. The sink area of the depression covers approximately 12 km² and comprises two playa basins (khabra). Remnant shorelines, which form low ridges above the playa floor, show the former extent of wetland/lake level highstands. These comprise lacustrine/wetland, carbonate rich silts, underlain by coarse sands. Physical, chemical and biological analyses provide detailed records of palaeoenvironmental change as well as the first terrestrial-based chronology from this region from the last interglacial. Lacustrine/wetland facies are dated to MIS5c (~110 ka) and MIS5a (~80 ka). During MIS5a both playa basins were connected indicating a waterbody over 5m in depth with the waterbody extending over 10 km². Phytolith analysis indicates the development of savanna grassland cover with changes in C₃ and C₄ composition across the surrounding landscape. Microscopic charcoal analysis indicates episodes of burning associated with drier conditions and a shift to predominantly C₄ grassland. Geochemical analyses trace changes in lake/playa development /composition. The importance of Wadi Batin as a potential corridor for human dispersals across Arabia during MIS5c and MIS5a is considered under wetter conditions and grassland vegetation cover.

Precipitation in the semi-arid region of the Northeastern Brazil dependent on the contraction/expansion of the tropical rainbelt

Abstract

Recent paleoclimatic studies suggest that changes in the tropical rainbelt across the Atlantic Ocean during the past two millennia are linked to a latitudinal shift of the Intertropical Convergence Zone (ITCZ) driven by the Northern Hemisphere (NH) climate. However, little is known regarding other potential drivers that can affect tropical Atlantic rainfall, mainly due to the scarcity of adequate and high-resolution records. This study fills this gap by reconstructing precipitation changes in Northeastern Brazil (NEB), a semi-arid area, during the last 2,300 years from a high-resolution Boqueirão lake record of hydrogen isotope compositions of plant waxes (dD_{wax}). Changes in dD_{wax} reflect changes in dD precipitation used by terrestrial plants for biosynthesis of wax lipids. The lake record documents a predominantly humid period between 500 yrs BCE and 420 yrs CE associated with lower dD_{wax} values. These climate conditions are followed by an abrupt aridification and a long dry phase from 500 to 1,300 yrs CE as revealed by higher dD_{wax} . Between 1580 and 1900 yrs CE, the dD_{wax} values rapidly declined, reaching values similar to those prior to 420 yrs CE, thus characterizing a long humid period during the Little Ice Age (LIA) in NEB. The latitudinal ITCZ displacement was investigated by comparing the dD_{wax} from Boqueirão Lake and the Ti record from Cariaco Basin. Both periods, from 500 to 1,300 yrs CE and from 1580 and 1900 yrs CE present a northern and southern ITCZ displacement, respectively. This is consistent with the traditional pattern of meridional ITCZ displacement regulating precipitation at both sites. Before ~500 yrs CE, relatively humid conditions prevail in both NEB and Cariaco, which is not consistent with the pattern of meridional ITCZ. The lake record combined with the Cariaco, instead suggest an expansion of the tropical rainbelt that would correspond to a longer rainy season in both hemispheres. The results indicated that regional precipitation along the coastal area of South America was not solely governed by north-south displacements of the ITCZ due to changes in NH climate, but also by the contraction and expansion of the tropical rainbelt due to variations in sea surface temperature and southeast trade winds in the tropical South Atlantic Basin. Searles Lake evaporite sequences: indicators of paleotemperatures and $p\text{CO}_2$

Kristian Olson¹, Tim Lowenstein¹, David McGee², Justin Stroup³, Mark Peuple⁴, Sarah Feakins⁴, Christine Chen², Joe Janick⁵, Steve Lund⁴, Jade Brush⁶, Joe Smoot⁷

¹Binghamton University, Binghamton, NY, USA. ²Massachusetts Institute of Technology, Cambridge, MA, USA. ³SUNY Oswego, Oswego, NY, USA. ⁴University of Southern California, Los Angeles, CA, USA. ⁵Keystone College, Factoryville, PA, USA. ⁶Searles Valley Minerals, Trona, CA, USA. ⁷USGS, Reston, VA, USA

Abstract

Searles dry lake is located in the Mojave Desert of southeastern California, USA. A new drill core, SLAPP-SRLS17, collected from Searles Lake in January 2017, extends from the surface to 76 m and records continuous lake deposition through the past ~150 kyr. During pluvial conditions, Searles Lake was integrated into the Owens Valley watershed as one in a chain of five lakes which spilled into each other (Smith, 1979; Smith et al., 1983). During drier climates, increased evaporation concentrated Searles Lake waters into Na-CO₃-SO₄-K-B-Ca-Mg-Cl brines which deposited chemical sediments. The Searles Lake deposit contains at least 25 different evaporite minerals, where the mineral phase, abundance, and precipitation sequence is controlled by climate-related conditions, such as temperature, salinity, and $p\text{CO}_2$.

The computer program EQL/EVP simulates stepwise evaporation of natural waters, and subsequent mineral precipitation, using Pitzer equations to determine activity coefficients of high ionic-strength brines (Risacher and Clement, 2001). Here, EQL/EVP is used to simulate the evaporation of the presumed source waters to Searle Lake, the Owens River (Hollett et al., 1991; Smith, 2000), under various input conditions, including: temperatures from 0-30°C; $p\text{CO}_2$ of 200 and 1200 ppm; and equilibrium vs. fractional crystallization system behavior.

EQL/EVP model runs indicate that the solubility of each mineral phase responds uniquely to changes in temperature and $p\text{CO}_2$. Therefore, for each evaporite layer within the SLAPP-SRLS17 core, we can constrain the temperature range, $p\text{CO}_2$, and degree of evaporation based on which minerals are present, their relative abundances, and their stratigraphic position within the evaporation sequence.

For example, evaporating Owens River water at 25°C and 200ppm $p\text{CO}_2$ produces the following sequence of major minerals: NORTHUPITE [Na₃Mg(CO₃)₂Cl] → TRONA [Na₂CO₃ · NaHCO₃ · 2H₂O] → BURKEITE [Na₆(CO₃)(SO₄)₂] → HALITE [NaCl]. However, the solubility of BURKEITE is significantly more sensitive to changes in temperature and $p\text{CO}_2$ than TRONA, resulting in BURKEITE precipitating before TRONA at 200 ppm $p\text{CO}_2$ and temperatures ≥ 30°C. Both sequences are found in the SLAPP-SRLS17 core which enables us to constrain temperature and $p\text{CO}_2$ conditions at each stratigraphic interval.

More broadly, the saline mineral sequences found in the SLAPP-SRLS17 core can be used to define crystallization and hydroclimate conditions at Searles Lake. For example, the Lower Salt unit of the Searles Lake deposit is ~13 m thick and composed of 7 salt layers and 6 saline mud intervals which were deposited from 24-32 ka (Smith et al., 1983). Here, the high-frequency mineralogical variability indicates temperatures between 10 and 30°C and $p\text{CO}_2$ values of ~200 ppm, in equilibrium with the atmosphere.

Tropical and high-latitude influence on annual to centennial precipitation variability in Southern California's Mediterranean climate during the Holocene.

Ingrid Hendy¹, Xiaojing Du¹, Arndt Schimmelmann², Dorothy Pak³, Linda Hinnov⁴, Erik Brown⁵

¹University of Michigan, Ann Arbor, USA. ²Indiana University, Bloomington, USA. ³University of California, Santa Barbara, USA. ⁴George Mason University, Fairfax, USA. ⁵University of Minnesota, Duluth, USA

Abstract

Southern California (SC) experiences an extreme Mediterranean-type hydroclimate with dry summers and wet winters. Droughts occur when winter rains fail, yet winter can also produce extreme rainfall *via* atmospheric rivers (ARs) generating flooding. The Santa Barbara Basin (SBB), SC preserves an annually laminated marine sedimentary archive of hydroclimate variability. A continuous 9 ka record that includes the 20th century was generated from spliced cores SPR0901-04BC (34°16.8950' N, 120°02.4890' W, 588 m water depth), SPR0901-03KC (34°16.914' N, 120°02.419'W; 591 m water depth), and MV0811-14JC (34°16.906'N, 120°02.162'W; 580 m water depth) collected from SBB. Here we present sub-annually (4-7 samples per year) resolved scanning XRF titanium data to reconstruct an annual precipitation record for the past 9000 years. Titanium (associated with siliceous detrital sediment) is delivered to SBB sediments by river runoff after winter rains. Droughts indicated by low Ti counts, accompanied by fewer floods (identified as gray clay layers) coincide with low regional lake levels at 800-1500, 2300-2700, 3300-3800, 4800-5300, 5700-6600 and 8000-8400 yr BP. Ti variability in the El Niño-Southern Oscillation (ENSO) band (2-7 years) increases after ~4500 yr BP.

SC rainfall is influenced by changes in the strength and location of the North Pacific Jet (NPJ), which is atmospherically teleconnected to the equator and high latitudes through atmospheric pressure systems. Changing climate patterns on centennial to interannual time scales shift the NPJ equator- or poleward across the Pacific, influencing the trajectories of storm tracks and ARs. The probability of drought in SC increases during Northern Hemisphere (NH) warming when the ITCZ is shifted poleward, enhancing high pressure ridging over the NE Pacific and pushing the NPJ away from the region. This weakens the ENSO teleconnection and interannual hydroclimate variability is reduced. During NH cooling, multi-decadal hydroclimate variability in SC follows high latitude climate change via the Aleutian Low. As the ITCZ moves equatorward and the Aleutian Low strengthens, the NPJ steers storms and AR events toward SC and increases the precipitation response to ENSO and the possibility of flooding.

Holocene paleolimnology of Walker Lake, Nevada, USA

Christopher Scholz¹, Mattie Friday¹, Matthew Kirby²

¹Syracuse University, Syracuse, USA. ²Cal-State Fullerton, Fullerton, USA

Abstract

Drought conditions have come to dominate the climate of the western USA in recent decades, even as dryland communities continue to expand. We use paleolimnological records from Walker Lake, Nevada, to assess the timing and amplitude of hydroclimate variability in the westernmost Basin and Range province, USA, to generate a Holocene record of drought in this extensive catchment. Walker Lake is a terminal basin that contains a long sediment record, and formed part of the Lahontan Lake system in the late Pleistocene. Abundant Pleistocene-age lacustrine tufas are observed around the margins of the basin, and recent tufas are observed near the modern shorelines. Ten kullenberg sediment cores, and ~300 km of high-resolution seismic reflection data were acquired from the lake in 2013 and are used to evaluate the basin's environmental history. We develop a robust seismic-stratigraphic framework based upon observed stratal relationships, which suggest several lake lowstand or desiccation events in the basin. Fossil pollen, concentrated using flow cytometry, was used to date the sediment and to develop the core chronologies, rather than dating of bulk sediment. Core climate proxy analyses include bulk organic (abundance and isotope analyses) and physical properties analyses. Using integrated seismic stratigraphic and sediment core analysis, we interpret three periods of lake-level drop during the Holocene at ~8600 cal. year B.P., ~7630 cal. year B.P., and ~3540 cal. year B.P., interpreted to correspond to regional drought conditions at those times in the western Basin and Range and eastern Sierras.

Cryptotephra and sulphur in polar ice: a powerful tandem for climate research

Michael Sigl^{1,2}, Gill Plunkett³, Joseph R. McConnell⁴, Nels Iverson⁵, Matthew Toohey⁶

¹Climate and Environmental Physics, University of Bern, Bern, Switzerland. ²Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland. ³School of Natural and Built Environment, Queen's University Belfast, Belfast, United Kingdom. ⁴Desert Research Institute, Reno, USA. ⁵New Mexico Tech, Socorro, USA. ⁶GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany

Abstract

Volcanic eruptions have been identified as a primary driver of climate variability, impacting surface air temperature, atmospheric circulation and hydroclimate. The observational record of the timing of volcanic eruptions, their location, magnitude of sulphate aerosol injection and its atmospheric life-cycle, however, is incomplete, with gaps in our record of past volcanic activity increasing dramatically before the Modern (pre-1800) era. A 2,500 year-long ice-core record of volcanic activity (Sigl *et al.*, 2015) and resulting stratospheric sulphur injections and radiative properties (Toohey & Sigl, 2017) sheds new light on past volcanism and its relation to climate. Sulphuric acid layers in ice cores prove that several centuries were volcanically much more active than the 20th century.

The polar ice sheets also contain an abundance of cryptotephra from past eruptions, sometimes transported over several thousands of kilometers (Jensen *et al.*, 2014). However, finding these precious deposits in ice cores has proven challenging. Here, we demonstrate novel approaches to detect the presence of cryptotephra in ice cores that take advantage of new-generation aerosol records obtained from ice cores in Greenland and Antarctica. These records allowed, for the first time, the discovery and precise dating of tephra from East Asia (Changbaishan 946 AD; Sun *et al.*, 2014) in an ice core from Greenland, and tephra from New Zealand (Taupo's Oruanui supereruption, 25.3 kyr BP; Dunbar *et al.*, 2017) in an ice core from Antarctica.

Using specific ancient eruptions (e.g., those causing the "worst year to be alive" in 536 AD; Gibbons 2018) we discuss the potential and limitations of combining state-of-the-art aerosol and geochemical records from ice-cores and other archives to advance our understanding of the timing and location of past eruptions and their consequences to climate and human societies.

Abstract

Volcanic ash (tephra) markers represent a powerful geochronological tool: rapid widespread deposition allows for correlation of geological records across vast areas. This enables us to study the behavior of Earth's climate system through time and across space. Analytical advances over the past decades now allow identification of invisible (crypto) tephra deposited thousands of kilometers from their volcanic source. This greatly expands the reach and potential of tephrostratigraphy by, for example, connecting existing tephra frameworks or expanding them into new geographical areas. However, the laborious and specialized nature of lab routines involved in extracting ash shards and establish tephra concentration profiles from geological archives hamper progress. Computed Tomography (CT) scanning may help us overcome some of these limitations by allowing non-destructive and rapid visualization of both visible and invisible ash horizons in 3D. We explore the potential of this tool using a controlled experiment: adding known (visible to invisible) amounts of rhyolitic or basaltic tephra to different sediment matrices (organic to minerogenic) in 50 ml test tubes. To calibrate floating CT greyscale values, we add standards of a known density to each of our artificial sediment cores. Our results show that we can identify invisible ash horizons down to 600 shards.

O-3115

Examining experimental methods in tephra extraction and preparation

Claire Cooper, Graeme Swindles, Ivan Savov
University of Leeds, Leeds, United Kingdom

Abstract

The reliable and non-destructive extraction of tephra is essential for modern applications of tephrochronology and volcanology. While many methods have been proposed and practiced for the separation of tephra from peat and lake sediments, including the acid digestion method of Persson (1971) and the density separation method of Blockley (2005), doubts have been raised concerning the geochemical alteration of volcanic glass through these processes. In particular, the use of acid and base digestion methods have been indicated in the formation of alteration zones around small glass shards, resulting in complications when performing scanning electron microscope (SEM) analysis or electron probe microanalysis (EPMA). Several attempts have been made to introduce less damaging techniques. However, the efficacy of these techniques in removing unwanted biogenic and organic material, such as plant material, peat, and biogenic silica, is questionable in comparison to traditional chemical digestion-based methods. This trade-off between sample cleanliness and geochemical purity is the cause of some dispute, all the more so as the differing methods have not been thoroughly and comprehensively tested against each other. In this project, we present the results of an experiment designed to compare and quantify the degree of geochemical alteration and the efficiency in removing excess organic material produced by three common chemical-based methods of tephra preparation, and outline our recommendations for future procedures.

We compare the effects of diluted hydrochloric acid, concentrated nitric and sulphuric acids, and concentrated potassium hydroxide on eleven samples of tephra ranging in composition from basaltic (Katla 1357) to ultra silicic (Lipari obsidian). We observe that, while the concentrated acid digestion method is highly effective and time-efficient in the removal of unwanted material, it also causes a significant degree of destruction to volcanic glass. This alteration is present in all glass compositions tested in this experiment, but is most notable in those of a basaltic composition (<52% silica). The alteration creates a hydration rim which may be up to 70 μm in width, creating significant difficulties in the analysis of smaller shards, such as those utilised in most cryptotephra studies. We observe similar hydration rims in the samples treated with dilute hydrochloric acid, though to a much less significant degree, typically creating rims 10-15 μm across. The samples treated with potassium hydroxide present a lower degree of alteration than those treated with acid digestion, but we found this method to be the least efficient in removing organic material.

This presentation challenges the procedures accepted as standard in the preparation of cryptotephra for EMPA and SEM analysis, a crucial step in all applications of tephrochronology. We recommend against the use of concentrated acids or bases in the preparation of basaltic tephra, and in the preparation of shards <150 μm in width.

O-3116

New distal cryptotephra findings in annually laminated lacustrine sediments of northern Poland

Małgorzata Kinder¹, Sabine Wulf²

¹University of Gdansk, Gdańsk, Poland. ²University of Portsmouth, Portsmouth, United Kingdom

Abstract

Cryptotephra findings, especially ultra-distal discoveries of Icelandic ash on the European continent, have fascinated multidisciplinary researchers. Tephra from explosive volcanic eruptions can be transported for long distances from the source and therefore is ideal for dating and synchronising sedimentary records. Numerous tephra studies during the last three decades showed that continental northern and central Europe was regularly impacted by large-scale eruptions from Iceland and the Eifel Volcanic Field since the Late Glacial. Tephra studies in Poland were so far limited to only a few sites due to the distal to ultra-distal position to European volcanoes restricting a deposition of macroscopic visible ash layers. Moreover, time consuming extraction techniques and uncertain success, discouraged conducting tephra research and forced to develop effective techniques.

We took advantage of annually laminated sediments from selected lakes along a W-E transect in northern Poland in order to extend the knowledge about the occurrence and dispersal of cryptotephra. We investigated short gravity cores from nine lakes and focused on the detection of tephra from Askja AD 1875 (VEI=5), Eyjafjallajökull AD 2010 and Grímsvötn AD 2011 (VEI=4) eruptions. Additionally, three lakes were selected for the Late Glacial and Early Holocene tephra investigations. Volcanic glass shards were found in all sites, however, extreme low concentrations and small grain sizes of single shards are a challenge for geochemical fingerprinting. As a first result, however, the rhyolitic cryptotephra originating from Askja AD 1875 eruption was confirmed by WDS-EPMA in the far east located site in Poland, in Lake Szurpiły. This finding allows us to extend the previously known tephra dispersal fan further to the SE.

Further new findings will improve usage of this particular and other cryptotephra as isochrones and enable precise correlation of palaeo-records. Our study indicates the potential of distal, annual laminated lacustrine sites in Poland as valuable tephra archives, but also the need for more effective methods dedicated to extremely low glass shard concentrations.

This work was supported by the Polish National Science Centre grant no. 2015/19/D/ST10/02854.

O-3117

The potential of tephrochronology for linking climate, environmental change and human colonisation of the South Pacific

Anna Bourne¹, David Sear², Peter Langdon², Shane Cronin³

¹Queen Mary University of London, London, United Kingdom. ²University of Southampton, Southampton, United Kingdom. ³University of Auckland, Auckland, New Zealand

Abstract

The archipelagos of Polynesia (some 7,500 islands) in the South Pacific were the last habitable places on earth colonised by prehistoric humans. However, the timing of this colonisation has been poorly resolved across many islands, with dates varying by up to 1000 years, precluding understanding of the interplay between human, ecological and climate impacts on these pristine ecosystems. The late colonisation of many Pacific islands makes them, theoretically, the ideal location to study natural environments prior to, and subsequent to the arrival of humans, but conversely there is a paucity of palaeoenvironmental research. Very little high quality well dated palaeoenvironmental data spanning this period exists for the South Pacific. In order to begin to answer questions about the interplay between prehistoric human migration, the climate and environment, archaeological and palaeoenvironmental records need to be well dated and independently synchronised, something which is not currently possible. Existing chronologies are based on radiocarbon dating which is challenging in some of these sites especially where plant macrofossils are not available. Here we examine how volcanic ash can provide a chronological framework for dealing with these questions against a suite of new palaeoenvironmental and palaeoclimate data from Holocene lake sediment archives across the South Pacific. Results are presented from Lake Lanoto'o in Samoa and Lake Teroto in the Cook Islands, where discrete cryptotephra layers are identified throughout the Holocene sequences. Geochemical results indicate non-local sources for the layers, highlighting the potential of tephrochronology in this part of the world.

O-3118

Evidence for multiple large Holocene eruptions of Mt. Churchill, Alaska

Lauren Davies, Britta Jensen, Duane Froese
University of Alberta, Edmonton, Canada

Abstract

Mt. Churchill, located in the Wrangell Volcanic Field close to the Alaska/Yukon border, is the suggested source of the late Holocene White River Ashes (WRAn and WR Ae). Studied extensively since the late 19th century, the thick, widespread visible deposits in the Yukon and eastern Alaska were initially believed to be from one bilobate eruption but were later reinterpreted as two separate eruptions with distinct plume directions.

More recent discoveries - a cryptotephra record from Alaska (Payne et al., 2008) and one visible bed in the Yukon (Preece et al., 2014) - suggest at least one, potentially two, additional Holocene eruptions from this volcano. Here we present evidence from a new cryptotephra record from the central Yukon, and visible samples collected from Alaska and the Yukon in 2018, with evidence for a total of at least seven Mt. Churchill eruptions since ~9000 yr cal BP.

A cryptotephra record from DHP174, located along the Dempster Highway in central Yukon 460km NNE of Mt. Churchill, is produced from a soligenic peatland that records 10,400 cal yr BP of peat accumulation. Using major element glass EPMA data, seven glass peaks are identified as 'primary eruptions' where evidence for a unique airfall event is clear (including WRAn and WR Ae correlatives). One additional period of activity is defined, where Mt. Churchill-like glass is present but there is some ambiguity in peak identification (related to possible reworking in the permafrost active layer).

New visible samples present further opportunities to support the distal cryptotephra records as they allow analysis of associated volcanic minerals (e.g. magnetite, ilmenite). This is important as previous analyses of the White River Ashes and the one additional visible bed (Preece et al., 2014) show Fe-Ti oxide data are more diagnostic for differentiating between eruptions than the more commonly used major element glass geochemistry.

These new data are compared to previous sites with beds that have geochemical data similar to Mt. Churchill in order to produce the best estimate to date of its' Holocene eruption frequency. Our results represent a significant revision for the eruptive history of Mt. Churchill and have implications for regional tephrostratigraphies, natural hazards and our understanding of palaeoenvironmental responses to volcanic activity in the area.

Tephabase and the lessons learned over the past 25 years

Anthony Newton, Andrew Dugmore, Oana Huminyik
School of GeoSciences, University of Edinburgh, Edinburgh, United Kingdom

Abstract

Tephabase is a tephrochronological database launched in June 1995. It was initially aimed at providing locational and geochemical tephra data to the fledging European tephrochronological community. Initially, the database developed as a repository for what were thought be Icelandic-origin distal cryptotephra layers, but over time it has expanded to include macroscopic tephra layers in Iceland, Germany and Mexico. Initially, all the European tephra layers included in Tephabase were thought to be erupted in Iceland, but it is now clear that is not the case with ultra-distal tephra layers identified as coming from North American volcanoes. In addition, in 2011, sites (recent updated to 570) containing the Laacher See tephra were added. The Laacher See records include both macroscopic and more distal tephra records. In total, Tephabase currently holds records of some 4,500 tephra deposits, from over 1100 sites and over 6500 geochemical analyses.

Maintaining Tephabase over nearly a quarter of a century has highlighted a number of issues and one highlighted in this talk is the naming of distal layers and tephra layers in general. In Iceland, proximal, historically dated tephra layers are dated using the volcano's name (which is usually known) and the year it was erupted (e.g. Hekla 1341). However, it becomes more problematic when correlating distal tephra layers across large distances, where layers identified as one tephra layer on further investigation turn out to be another. The tephra may also be first identified at a distal site and lack a source name. Also, the name of the identified layers may also change due to new data, dating or the adoption of a more "sensible name". Ice-core dates may change, resulting in a tephra layer with an inappropriate name. There are many reasons for names changing, but it is important that the tephra layers found at a particular site remains identifiable. Tephabase always had a naming hierarchy and recent updates have made sure that all new data include a local name included in the published work, along with any "correlated name". If a local name is not available, a local name is given based on the site and depth the tephra layer occurs at. Older data in the database is being updated to include this information and other useful metadata. Tephabase also provides alternative names for tephra layers, which is not definitive, but growing. This also highlights a wider naming issue the community should discuss.

Databases work best when data is easily compartmentalised, is "correct" when inputted and is consistent across all researchers. Tephra data, and especially distal tephra, often does not always meet these criteria and as a community we need to establish standards for how data is recorded in our systems.

A review of Lake-Dust-Snow dynamics “from sources to sinks” in the semi-arid Bonneville Basin, Utah, USA

Kathleen Nicoll

University of Utah, Salt Lake City, USA

Abstract

The Great Basin physiographic province is the largest desert region in the USA, and a known source area for windblown dusts, including aerosols, black carbon, nutrients, and mineral particles. This paper reviews what is known about dust composition, atmospheric loading and fluxes “from sources to sinks.” Within this semi-arid region, intermountain cyclonic storms and aeolian dynamics are important drivers of dust entrainment and transport. In the 1930s, Utah newspapers reported spring cold front passages and dust storms that caused it to “rain mud.” Various studies on the prevailing winds and synoptic meteorological conditions relate the development of strong intermountain cyclones with elevated wind speeds and dust storm events. Dust event days (DEDs) peak in frequency during spring months (March-April) when southerly ‘Hatu winds’ blow.

Key source areas providing dust for transport downwind to the populated regions of Utah were identified by assessing 51 DEDs that affected air quality in Salt Lake City during the 2004-2010 period. Among the recurrently active “hotspot” areas prone to dust emission are: barren and sparsely vegetated land; fallow fields; playa (ephemeral lake) surfaces relict from Pleistocene Lake Bonneville (per G.K. Gilbert); and areas disturbed by wildfire, agriculture, vehicular traffic, and military activities. Intensified winds enhance dust outputs downstream of mountain gaps, or along fetches with higher wind speeds from terrain contouring. Enhanced dust production occurs after severe drought and/or disturbance by wildfire, agriculture, and military activity. The 2007 Milford Flat Burned Area (Utah’s largest wildfire) actually generated more dusts after revegetation techniques disturbed soil via drilling, chaining, and herbicide use.

Dust storms may deposit materials on montane snowpack; Dust-On-Snow (DOS) affects surface albedo and radiative properties and may increase melt rates, causing an earlier “snow-free” date by up to a month, causing higher peak streamflows. Dust-forced changes in hydroclimatology can adversely impact Salt Lake City, which relies on seasonal snowpack in the Wasatch Mountains as their main water supply.

An intense intermountain cyclone affected the Salt Lake City, UT region on 14-15 April 2015, providing a case study of a DED from inception to dust deposition on montane snowpack. Analyzing the “Black Tuesday” storm from “cradle to grave” or “source to sink” enabled real-time documentation of storm development, dust-source emission and associated DOS in the Wasatch Mountains. We resolved particle size, elemental composition, albedo and radiative properties of samples of a single specific dust storm event layer. Plumes observed on MODIS imagery indicate dust mobilization from known point sources in the Escalante Desert, Sevier Lake region and modern playas within Paleolake Bonneville Basin. Snowpack dust includes metals sourced to urban and industrial activities, including heavy metals (Cu, Pb, As, Cd, Mo, Zn) common in regional mine operations.

Abstract

Wind action in mountain environments is a topic seldom investigated from geomorphological and geopedological standpoints. Mountainous environments are known as a loess source during glacial phases and as a potential sink for long-range (hundreds to thousands of km) contribution of dust and volcanic ashes (e.g., Saharan dust to the Alps and Pleistocene tephra over European mountains). However, the short-range (tens to hundreds of km) transport of aeolian materials within mountain environments during cool and dry phases is poorly understood and in general downplayed in the larger system of wind deposition dynamics. When climatic conditions shift towards increasing aridity, the potential for aeolian activity in these environments greatly increases. Moreover, the complexity of topography in these regions offers ideal conditions for development of intense localised air fluxes. As a result, systems of micro-sources and micro-sinks take form, changing in intensity and shifting in space with the variation of local air circulation patterns, often climate induced. Processes of denudation and loss of vegetation cover as a consequence of cool and dry periods strongly contribute to the mobilization of aeolian material and its redeposition over short distances.

We investigated the geomorphological setting of a mountain ridge in the high Northern Apennines (Cusna Ridge, Italy) characterised by strong constant winds perpendicular to the direction of the ridge itself. A detailed field geomorphological and soil survey allowed to find evidence for aeolian sources and deposits. On the summit of the ridge, we found multiple deflation areas tens of meters wide, which signal the action of intense wind erosion. Evidences of dust deposition were found in the adjacent soils: a discontinuous and distinct layer of recently deposited fine sand and silt covers the ridge top itself. We relate this layer to a combination of low-energy colluvial activity and short-range wind transport from lower elevations. In one soil sequence, analytical data from sedimentological and micromorphological analyses allowed to observe four different phases of deposition with possible aeolian contributions. These phases potentially correspond to short-timed Holocene periods of denudation and deflation triggered by enhanced wind strength.

Abstract

Sediment provenance can be a powerful tool in understanding sediment system dynamics, and through them, climate. Loess sequences preserve evidence of source regions, and therefore can be used to investigate and quantify the production, transport and deposition of dust during the past. These investigations can also provide insights into sedimentary dynamics on a range of scales, from local to continental. By complimenting these understandings of sediment processes and provenance with chronologies, we can quantify rates of process over the longer term, which is crucial when using loess as palaeoclimatic and palaeoenvironmental proxies.

Here we present the results of a provenance analysis from three loess-palaeosol sequences along the Danube. Erdut (Croatia), Surduk (Serbia), and Slivata (Bulgaria) were selected to investigate source variability along the Danube River. This research is predominately focused on single grain detrital zircon techniques, which have greatly advanced our understanding of the Chinese Loess Plateau's provenance (c.f. Nie et al., 2015). We provide the results of U-Pb dating combined with Hf isotopes from single grain zircons obtained from multiple loess-palaeosol units. By supplementing this work with chronologies based on Optically Stimulated Luminescence (OSL) dating we are able to investigate provenance changes over time at each site. Finally, single grain zircon analysis is combined with the results of bulk sample trace elements, and Nd-Sr isotopes to achieve a better understanding of source regions. We also compare our new single-grain zircon datasets with existing published potential source geochemical records to explore the primary sediment sources and sediment transport pathways on a source to sink scale.

Comparative study of silt production under Natural and Simulated conditions

Raj Kumar

Geology and Mining Department , Jammu, India

Abstract

A comparative study of silt from NW Himalaya produced under the influence of natural environment by glacial grinding was conducted with the silt production from Cretaceous Leighton Buzzard Quartz Sand from Bedfordshire, England under laboratory simulation giving different conditions like load, speed, wet/dry, duration of grinding and quantity of sample were taken into consideration. The silt studies of the Himalayan region was accomplished by filtration of suspension, wet/dry sieving and particle size analysis conducted on particle size analyser (Malvern U.K. Make). The studies were conducted on Naradu Glacier Himachal Pradesh (H.P.), Kol Glacier Jammu and Kashmir (J&K) and Chourabari Glacier Uttra Khand (U.K.) all located in western Himalaya (India). The grinding of Cretaceous Leighton Buzzard Quartz Sand was accomplished on Bromhead Ring Shear Machine in Nottingham Trent University. On the completion of each test conducted in laboratory the obtained production was analysed on a Coulter Counter to determine particle size range besides its proportion by wet/dry sieving. The study was carried out with the objective to compare the level of production of silt under natural environment and simulated conditions from two different regions. The results indicates that the dominant silt size produced was medium to fine i.e. 20 - 63 μm whereas under nature environmental conditions the dominant size of silt production was also ranges from medium to fine with dominance of fine silt. The variation in dominance of the silt size is attributed to the diversity in the composition , type, structure of the respective bedrocks of the areas as well as the glaciated valleys taken into consideration.

Abstract

The Sahara is the world's largest hot desert and therefore it is and was one of the biggest global dust emitter today and during the past. Several environmental archives indicate fluctuations of aridity during the Quaternary. The interpretation of Loess-Paleosol-Sequences (LPS) may help to enlarge our understanding of this fluctuations.

Thick and widespread distributed Desert Margin Loess-deposits are quite rare. In surrounding areas of the village of Matmata in southern Tunisia, Quaternary Loess deposits are still preserved. Especially valley and depression floors are covered by up to 30 m of clayey and silty Loess with intercalated sandy Paleosols.

Our first results from the Matmata loess area in Southern Tunisia will be presented aiming to reconstruct the Quaternary environmental changes between Loess deposition and soil formation.

More than 11 LPS have been investigated so far in order to build up a solid loess stratigraphy for this region. The deposits show a clear internal stratigraphy of loess units interrupted by intercalated reddish sandy paleosols. These soils have clear features of CaCO₃-leaching in the main soil horizon, whereas lower parts show a strong enrichment of carbonate (Cc-Horizon).

These features should be a result of more humid conditions under which soil formation could happen in contrast to arid loess forming environments. However, soils and loess within the same sequence show distinct analytical results. A look into the sediment sources may contribute to understand this phenomenon.

Our chronostratigraphy frame will be based on several OSL age estimations.

Abstract

The thick loess and Red Clay deposits in northern China preserve unique records of past climate changes and atmospheric circulation during the Quaternary and Late Neogene. Provenance analysis of these sediments is essential for understanding the wind patterns, climate conditions and tectonic activities of northern China during the Cenozoic Era. A variety of tools have been applied to investigate the sources of these aeolian deposits, including grain-size analysis, whole bulk geochemistry, heavy mineral assemblage, isotopic composition and single grain zircon U-Pb chronology. Among these methods, detrital zircon U-Pb dating has been increasingly used because of its advantage in distinguishing multiple sources for the sediments. However, as a heavy mineral, zircon grain cannot be transported with bulk sediments over long distance. Such hydraulic/ density property of zircon may bias the results interpretation towards proximal source regions.
