Abstract. To investigate the chemical characteristics of precipitation in the polluted urban atmosphere in Beijing and possible mechanisms influencing their variations, a total of 131 event-based precipitation samples were collected from March 2001 to August 2005. The concentrations of major ions in the samples were analyzed by using ion chromatography. Intermediate pH (6.1–7.3) was recorded in approximately two-thirds of the precipitation samples and acidic pH (4.2–5.6) in only 16 % of the samples. However, the precipitation acidity was on the growth track and the process was likely being accelerated. SO_4^{2-}, NO_3^-, NH_4^+, and Ca^{2+} were the most abundant ions in the precipitations, with their single volume-weighted mean (VWM) concentration all above $100\,\mu eq\,l^{-1}$. The two major anions and two major cations accounted for more than 80 % of total anionic and cationic mass, respectively. The VWM SO_4^{2-} concentration decreased by 13 % compared to that during 1995–1998, much less than the 58 % reduction in the annual average SO_2 concentration from 1998 to 2005 in Beijing. What seems more counterintuitive is that the VWM NO_3^- concentration nearly doubled over the period although the annual average NO_2 concentration decreased by 5 % from 1998 to 2005. These results imply that the conversion of gaseous precursors to acid compounds and/or the regional transport were reinforced over the decade. The average ratio of neutralizing potential to acidifying potential (i.e. NP/AP) was as high as 1.2 but experienced an evident decline trend. This was mainly ascribed to reduced input of NH_4^+ and Ca^{2+} and

increased input of NO_3^-. Furthermore, the equivalent mass ratio of NO_3^- to non-sea-salt SO_4^{2-} presented an increasing trend over the study period, suggesting that the contribution of NO_3^- to the precipitation acidity increased in recent years. However, the mean ratio was only 0.37 ± 0.11 in the study period, which is significantly lower than those reported in some metropolitan areas in developed countries. This shows that the precipitation acidity in Beijing was still dominantly from SO_2 while the SO_2 contribution was progressively substituted by NO_x.

1 Introduction

Long-term variation in the chemical characteristics of dry and wet depositions provides important information on the temporal evolution of atmospheric pollution, and can be used as a pertinent indicator to evaluate natural process versus anthropogenic influences (Grodzińska-Jurczak and Godzik, 1999; Tang et al., 2005). Because wet deposition often plays a more important role in flux compared to dry deposition, chemical analyses of precipitation enables a partial assessment of local air quality (Özsoy et al., 2008). In China, acid deposition has been one of the most significant environmental issues since the late 1970s. Widespread acid rain was observed in southern and southwestern China before the 1990s (Zhao et al., 1988; Wang and Wang, 1995; Ding et al., 1997), and more recently it has extended to eastern and

Fig. 1. Sampling site (THU) in Beijing. The locations of some major cities with more than one million population related in this study (such as Tianjin, Shijiazhuang, Jinan, Handan, and Zibo) are marked with square symbol in the right-hand figure. The locations of remote Mt. Waliguan ($36°17'$ N, $100°54'$ E; elevation 3816 m) with rare anthropogenic impact, Mt. Tai, and two typical mega cities suffering severe acid rain – Chongqing and Guangzhou – are also marked in the left-hand figure. The topographical map was derived from the Microsoft[®] Encarta[®] 2009 © 1993–2008.

central China (Larssen et al., 2006; Huang et al., 2008; Wang and Xu, 2009; Xie et al., 2009; Tang et al., 2010; Ge et al., 2011). Beijing is located out of the traditional regions impacted by acid rain in China. However, high concentrations of air pollutants in and around Beijing most likely lead to high loadings of various chemical species to the ecosystem through atmospheric depositions. For example, the average concentrations of sulfate and nitrate in fine particles – two dominant acidic species – were much higher than those in some cities suffering severe acid deposition in southern China, such as Chongqing and Guangzhou (Yang et al., 2011b). Thus the trend in precipitation chemistry and its influence on the ecosystem are of great concern, particularly when considering the fast economic and population growth in Beijing.

As the capital and one of the most populated mega cities in China, Beijing has experienced rapid urbanization and motorization in the past three decades, which leads to soaring demand for energy. During the process, the motor vehicle pollution emerges and becomes increasingly prominent while the traditional pollution caused by coal burning has not yet been effectively controlled, a common phenomenon in Chinese megacities (He et al., 2011). In addition, a great deal of construction activities inevitably cause fugitive dust and exacerbate particulate pollution. To improve the capital's air quality, the municipal government has initiated a series of clean air programs starting in 1998 (www.bjepb.gov.cn), and Beijing has been leading the country in progressive introduction of increasingly stringent emission standards for motor vehicles and coal-fired boilers compared to state criteria. As

a result, the air quality compliance days have kept increasing thereafter (www.bjepb.gov.cn), but less than what is expected in terms of particulate pollution as compared to SO_2 and NO_2 (Yang et al., 2011a).

Meanwhile, the precipitation acidification in Beijing is undergoing an evident increasing trend, especially under the background of complex air pollution mentioned above (Ding et al., 1997; Wang and Zhang, 1997; Feng et al., 2001; Hu et al., 2005). Some recent studies showed that pH and precipitation chemistry in Beijing were noticeably different before and after the year of 2000, which was likely related to the variations in atmospheric pollution type (Tang et al., 2005; Hu et al., 2005; Xu and Han, 2009). To our knowledge, there are no studies that are based on long-term surface measurements to track the changing precipitation chemistry along with the changing emissions of acidic precursors and neutralizing substances in Beijing after 2000. In 2001, we initiated a precipitation monitoring program in urban Beijing to evaluate the magnitude as well as temporal trends and sources of acids and toxics substances in atmospheric depositions. This paper will summarize the major findings with a focus on the temporal variations in the precipitation chemistry. Possible mechanisms influencing these variations will also be discussed.

2 Experimental

2.1 Sampling location and sample collection

Beijing is located at the northern tip of the Great North China Plain with a landmass of $16\,410\,km^2$ (Fig. 1). As one of the most populated cities in China, its 20 million inhabitants are concentrated in the urbanized area, which is only 6 % of the city's landmass (Beijing Municipal Bureau of Statistics, 2011). The main terrain of Beijing is plain, with surrounding mountains on three sides, i.e. the Mongolia to the north, the Yanshan Mountain to the northeast. The Bohai Sea is about 160 km to the southeast. This topography does not favor the dispersion of the air pollutants. Lying in the north warm temperate zone, Beijing has typical continental monsoon climate with four distinct seasons. From November–April (dry months), the prevailing airflow from the northwest is dry and cold, while at other times the local winds are moderate and mostly from the south and southeast (Yang et al., 2011a).

Sampling of atmospheric precipitations was conducted in the semi-residential area inside the campus of TsingHua University (here referred to as THU, $40°19'$ N, $116°19'$ E) from 15 March 2001 to 18 August 2005 (Fig. 1). About 12 km northwest of the city centre, the THU site lies within the western part between the northern fourth and fifth ring roads, which are two of the artery roads with busy traffic encircling urban area at about 9 and 14 km radii from the city centre, respectively. Precipitations were collected with a dry-wet deposition auto-sampler (DRS-154W, Koshin Denki Kogyo, Japan), which was deployed on the rooftop of a 5 m tall building. The sampler has a removable lid activated by a wetness sensor, which opens the funnel above a 5 l polyethylene bucket under a funnel of 155 mm in diameter when precipitation happens. The wet deposition sample was collected for every continuous rainfall. In total, 137 precipitation samples were collected over the study period.

2.2 Sample analysis and quality control

The precipitation samples were weighed in the laboratory and calculated for the volume. The precipitations were then filtered through a Millipore filter with a pore size of $0.45\,\mu m$. The pH of the filtrate was measured with a pH meter (pH/Ion meter F-24, Horiba) under controlled room temperature ($25\,°C$), and the electrical conductivity (EC) was measured with an electrical conductivity meter (AOL-40, Denki Kagaku Keiki). H^+ concentration was calculated from the pH of the filtrate. The concentrations of ten major ions (Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, F^-, Cl^-, NO_3^-, SO_4^{2-}, and HCO_3^-) were determined with Ion Chromatography (IC7000-1, Yokogawa Analytical Systems) (Okuda et al., 2005). The separator column was ICS-C25 (YAN) and the eluent was 5 mM Tartaric acid/1mM 2,6-Pyridinedicarboxylic acid/24 mM Boric acid 1.0 [ml min^{-1}] for cations. For anions except HCO_3^- the separator column was AS12A (Dionex) and the eluent

was $2\,mM$ Na_2CO_3/4 mM $NaHCO_3$ 1.0 [ml min^{-1}], while for HCO_3^- they were ICE-AS1 (Dionex) and Milli-Q (Millipore), respectively. Note that we excluded 6 out of the 137 precipitation samples, whose volume is too small to reliably determine the concentrations of all the above mentioned ions except HCO_3^-.

Precision of ionic analysis was determined from at least 4 replicate measurements. The result showed that the variation for Na^+, NH_4^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^-, SO_4^{2-}, and HCO_3^- was $\leq 2\%$, while for K^+ it was 7 %. The quality of analytical data was also checked by a cation-anion balance and by comparison of the measured conductivity with the conductivity calculated from the concentration of all measured ions and their specific conductivity. As shown in Fig. 2a, the conductivity ratio of that calculated to measured was >1, indicative of an ionic deficiency in these cases. The ion balance check proved to be reliable according to the acceptable range (15–30 %) set for samples having ion sum $>100\,\mu eq\,l^{-1}$ by USEPA (Ayers, 1995). The ratio of total anions to cations was systematically <1 (Fig. 2b), suggesting an anion deficit. This predominance is frequently reported in the literature, and usually ascribed to some unmeasured anions such as bicarbonate (if not included) and short-chain organic acids (Zhang et al., 1996; Hontoria et al., 2003).

3 Results and discussion

3.1 Precipitation amount and pH distribution

The annual total precipitation amount was 345, 461, 411, and 546 mm from 2001 to 2004 with an average of 441 mm for the four years. These volumes were similar to the reported range of 339–483 mm for the whole city through the years (www.bjstats.gov.cn) but largely lower than long-term average of 630 mm in Beijing Metropolis (www.bjclimate.com). As shown in Fig. 3, monthly mean precipitation amount varied markedly with a peak in the summer. About 78 % of the rain was deposited from June to September (rainy months). The volume-weighted mean (VWM) EC in the precipitation was $66.5\,\mu S\,cm^{-1}$, which was larger by a factor of 4.6 than that ($14.6\,\mu S\,cm^{-1}$) measured at a remote site in Mt. Waliguan (Fig. 1), which is the Global Atmosphere Watch Baseline Observatory of World Meteorological Organization (WMO) located at the eastern tip of Qinghai-Tibetan plateau in Northwest China (Tang et al., 2000). This indicates a substantial impact of anthropogenic pollution on the urban atmospheric environment in Beijing.

As illustrated in Fig. 4a, the frequency distribution of precipitation pH is similar to a unimodal distribution. This is very different from the bimodal pH distribution found in the Mediterranean precipitation (Aiuppa et al., 2003). The pH value of single precipitation varied from 4.2 to 7.5 with an arithmetic mean of 6.3 and the VWM of 6.0 for the total 131 precipitation samples. Intermediate pH (6.1–7.5) was

Fig. 3. Monthly average amount and VWM pH values of the precipitations.

recorded in approximately two-thirds of precipitation samples, while acidic pH (pH <5.6) was observed in only 16 % of the samples. This distribution reflected the alkaline nature of rainwater in Beijing. It should be noted, however, that there existed a decreasing trend in the rainfall pH based on linear regression (Fig. 4b), which is consistent with the trend during 1980–2000 as noted earlier (Ding et al., 1997; Wang and Zhang, 1997). Furthermore, nine of thirteen low pH (<5.0) rain samples and the three lowest pH (<4.5) rain samples were collected in the latter two years (Fig. 4b). Therefore, the buffering capacity of Beijing precipitation was decreasing and the process was likely being accelerated, pointing to increased input of acid compounds and/or reduced input of neutralization of base agents. This will be further discussed in Sect. 3.4. The monthly VWM pH values varied from 5.3 to 6.8 with an average of 6.2. Only August had a VWM pH less than 5.6. There were eleven low pH rains collected during July–September and the majority of them were in August. Since summertime rainfall volume shared about two-thirds of annual volumes and usually presented low pH values (Fig. 3), the yearly wet deposition acidity was mainly determined by the rains falling in this season.

3.2 Chemical composition and sources of major ions

Figure 5 illustrates the statistics of concentrations of ions in the precipitations, including the 10th, 25th, 75th, and 90th percentiles and VWM of each ion. SO_4^{2-}, NO_3^-, NH_4^+, and Ca^{2+} were the most abundant ions as their single VWM concentration was all above $100 \, \mu eq \, l^{-1}$. NH_4^+ plus Ca^{2+} summed to $502 \, \mu eq \, l^{-1}$ and comprised 83 % of total cationic mass while SO_4^{2-} plus NO_3^- accounted for 84 % of total anionic mass. SO_4^{2-} was the most abundant single ionic component in the precipitations, accounting for 30 % of total ionic mass. NO_3^- was the second most abundant anion, followed in decreasing order by HCO_3^-, Cl^- and F^-. For the cations, NH_4^+ and Ca^{2+} were followed in decreasing concentration by Mg^+, Na^+, and K^+.

The major anthropogenic ions – SO_4^{2-}, NO_3^- and NH_4^+ – accounted for 63 % of the total ionic mass, indicating that anthropogenic sources predominated in rainfall ions. Despite high contribution of anthropogenic anions such as SO_4^{2-} and NO_3^-, H^+ accounted for only 0.2 % of total inorganic ionic mass due to the extensive neutralization by alkaline substances. Two major crustal-related ions – Ca^{2+} and Mg^{2+} – contributed 28 % to the total ionic mass, indicating crustal material was an important contributor to precipitation neutralization. The non-sea-salt calcium (nss-Ca^{2+}, calculated from the ion ratio Ca^{2+}/Na^+ in seawater equal to 0.0379) accounted for 99.6 % of the total calcium (i.e. non-sea-salt plus sea-salt calcium) for all the precipitation samples, indicating that sea salt did not have strong impact on wet deposition in Beijing. The non-sea-salt sulfate (nss-SO_4^{2-}, calculated from the ion ratio SO_4^{2-}/Na^+ in seawater equal to 0.252) accounted for 97.8 % of the total sulfate.

Table 1 lists the VWM pH and VWM concentrations of each ion, in addition to those from other earlier studies conducted in Beijing and other selected locations in East Asia. Compared to the long-term observation from 1990 to 2002

[a] The selected locations in China are marked in Fig. 1. [b] Not determined. [c] Nss-SO_4^{2-}.

in the Tokyo Metropolitan area suffering severe acid rain, the VWM concentrations of SO_4^{2-} and NO_3^- in Beijing were higher by a factor of 3.8 and 7.6, and those of NH_4^+ and Ca^{2+} by a factor of 6.5 and 9.6, respectively. The SO_4^{2-} level was also considerably higher than those measured in some typical acid rain regions in China, such as Guangzhou (Fig. 1, Table 1) (Huang et al., 2009). In comparison with those monitored at the remote Mt. Waliguan site, the VWM concentrations of SO_4^{2-} and Ca^{2+} in Beijing precipitations were 7.7 and 7.0 times higher, respectively. These comparisons reveal that both crustal-related and anthropogenic sources (such as fossil fuel combustion) had significant impact on the ambient environment in urban Beijing.

Factor analysis was performed to further investigate the major sources of chemical species in the precipitations.

Three factors were identified with the cumulative variance more than 90 % (Table 2). The communalities of all the ions are no less than 0.80, indicating that these extracted factors are reasonable. The first factor, which explains 40 % of variance, is strongly correlated with Cl^-, Na^+, and Mg^{2+}, and moderately correlated with K^+, F^-, and NO_3^-. This factor was likely associated with certain anthropogenic sources, such as industrial emissions, municipal waste incineration, biomass burning, coal combustion, and fugitive dust as well. It is noted that the concentration of F^- was one to two orders of magnitude higher than those observed in Tokyo (1.7–1.9 $\mu eq\,l^{-1}$) in Japan (Feng et al., 2003), Virginia (0.6 $\mu eq\,l^{-1}$) and Delaware (0.3 $\mu eq\,l^{-1}$) in USA (Barnard and Nordstrom, 1982), Mid-Wales (0.3 $\mu eq\,l^{-1}$) in the UK (Neal, 1989), and much higher than the World average
Fig. 5. Statistics of concentrations of ions in the precipitations. The box plots indicate the 10th, 25th, 75th, and 90th percentiles and VWM (cross symbol) of each ion.

Table 2. Factor analysis of ions in precipitation.

Variable	Factor 1	Factor 2	Factor 3	Communality
Cl^-	0.89	0.17	0.31	0.92
Na^+	0.88	0.31	0.28	0.94

F^-	0.56	0.40	0.58	0.80
Variance (%)	39.9	27.3	23.4	

3.3 Temporal variations in the concentrations of major ions

Monthly average concentrations of each ion in the precipitations were subject to large variations (Fig. 6). Both higher loadings of crustal-related and anthropogenic ions usually appeared during the dry months from November to April while lower loadings in rainy months. This seasonal pattern was most likely due to the combined effect of seasonal variations in emission and rain intensity. During the dry months, the northwesterly Asian monsoon was dominant, leading to frequent uplift of wind-blown mineral particles from both local areas and remote deserts or arid regions. In addition, the coal combustion activities were highly enhanced (about 5 million tons additional coal consumed) for heating in Beijing during the official four-month heating period lasting from mid-November to mid-March, resulting in extra anthropogenic emissions of gaseous pollutants and particles (He et al., 2001). Meanwhile, usually there are sparse rains (about 19 % of the annual rainwater volume in this study) during this period. For the effect of rain intensity on ionic mass, many previous studies demonstrated in different areas that ionic concentrations decreased with increasing precipitation amount due to processes such as diffusion aerosol, initial rain evaporation and dilution (Tuncer et al., 2001; Feng et al., 2001; Xie et al., 2009). The monthly variations in the VWM concentrations of precipitation ions in the present study were largely controlled by rainwater amount as well since all the ions were more or less negatively correlated with precipitation volume (correlation coefficient $r = -0.18$ to -0.34).

All ionic species reached their maximum monthly average concentrations in March 2003, followed by the preceding month. It is noted that there were only two precipitation samples collected in March over the study period and both in 2003. Of the two samples the one with much higher volume (17.4 mm vs. 5.1 mm for the other event) was collected on 20 March when daily PM_{10} concentration was as high as 179 μg m^{-3}. In addition, the average ionic concentrations in July and August of 2003 were higher than those in other years by a factor of 2.6–3.4. It is worth noting that the
(5.3 μeq l^{-1}) (Zheng, 1996), implying that a large fraction of the F^- in Beijing precipitation was likely from anthropogenic sources. Based on a field study during 1995–1998, Feng et al. (2003) ascribed the soil dust and coal combustion as the two major sources of F^- in Beijing precipitation. Although a strong correlation exists between Na^+ and Cl^- ($r = 0.89$), the association of Na and Cl with the influence of sea breeze could be only a minor source, consistent with the findings by Tang et al. (2005) and Xu and Han (2009). This is supported by the fact that the average Na^+ and Cl^- ratio of 2.1 (ranging from 0.7 to 13) was much higher than the reported ratio of 1.16 from seawater (Moller, 1990). This is understandable since Beijing is about 160 km away from the Bohai Sea in the southeast and the wind from that direction in summer is usually mild (Yang et al., 2011a).

Factor 2 has high loading for SO_4^{2-}, NO_3^-, and NH_4^+, suggestive of the secondary pollution formed in the atmosphere from their precursors – SO_2, NO_x, and NH_3. While SO_2 and NO_x are believed to be mainly emitted from fossil fuel combustion such as coal combustion and vehicle tailpipe emission, the major anthropogenic emissions of ammonia in East Asia were estimated to be mainly from chemical fertilizer used in agriculture, livestock breeding, and energy consumption (Zhao and Wang, 1994; Fujita et al., 2000). Vehicle emission, chemical engineering, biologic process and biomass burning could play a role as well in the high levels of NH_4^+ in Beijing precipitation (Tang et al., 2000; Hu et al., 2005).

Factor 3 is dominated by Ca^{2+}, F^-, NO_3^-, and K^+, likely indicative of soil dust as a major source. It is noted that there are plenty of calcareous soil and high aerosol loadings in Beijing and surrounding region, of which a large portion was expected from soil dust (Yang et al., 2004; Guinot et al., 2007). Also noted is that a significant part of NO_3^- is usually associated with soil particles in coarse mode (Seinfeld and Pandis, 2006).

Fig. 6. Monthly variations in the VWM concentrations of ions in precipitation from April 2001 to August 2005.

seasonal distribution of precipitation volume in 2003 differed enormously from those in the other years. The precipitation volumes in the winter, spring, and fall in 2003 increased by 50–160 % whereas the summer rain volume substantially declined. The low annual volume and abnormal seasonal distribution of the precipitations likely played a role in the unusual monthly variations in precipitation chemistry in 2003. High concentrations of precipitation ions in Beijing in the year 2003 were also reported by Hu et al. (2005).

Based on linear regression throughout the study period, SO_4^{2-} maintained a steady concentration level, whereas NO_3^- exhibited an increasing trend and NH_4^+ and Ca^{2+} a decreasing trend in their concentrations. In comparison with the study conducted in Beijing during 1995–1998 (Table 1), the VWM concentrations of most ions in this study decreased by 13 % (SO_4^{2-}) to 64 % (Cl^-), whereas those of NO_3^- and NH_4^+ increased by 94 % and 75 %. This is in agreement with the finding by Okuda et al. (2011) that opposite to the decreasing trend in other water-soluble ions of particulate matter in Beijing was an evident increasing trend in nitrogen-containing species in recent years. However, the decrease in SO_4^{2-} level did not scale to the 58 % decrease in the annual mean SO_2 concentration from 1998 to 2005 (50 µg m^{-3} in 2005). What seems more surprising is that the NO_3^- growth was opposite to the 5 % reduction in the annual mean NO_2 concentration from 1998 to 2005 (66 µg m^{-3} in 2005).

These counterintuitive long-term changes in SO_4^{2-} and NO_3^- concentrations in the precipitations as compared to their precursors were likely due to the increased regional transport and reinforced conversion of precursors to acid compounds and/or secondary particles. While huge progress has been made in eliminating small coal-fired boilers in urban Beijing (Okuda et al., 2008), it is still popular to burn coal at the household level in sprawling brick-home suburbs and surrounding areas, and to burn agricultural field residue after harvest (Yang et al., 2010). Opposite to the more or less decline of ambient SO_2 and NO_2 levels in Beijing from 1998

to 2005, the national SO_2 emissions (2549.3 Mt in 2005) increased by 22 % in the span (EQA, 1998, 2005). The national NO_x emission had undergone even much larger growth during the period (18.6 Mt in 2004 vs. 11.7 Mt in 1998) according to Zhang et al. (2007). Therefore, it was anticipated that there were growing transport of the acid compounds (i.e. SO_4^{2-} and NO_3^-) formed from gaseous precursors to Beijing, especially from the vast eastern region upwind to the south in rainy months. This region is densely populated, with several large urban centers such as Tianjin Municipality (13 million), Shijiazhuang (10 million), Jinan (6.8 million), and Qingdao (8.7 million), which are typical industrial, coal-burning cities within several hundred kilometers of Beijing (Fig. 1). In these areas, emission controls on stationary sources and vehicles are not as stringent as in Beijing, and emissions are high (Streets et al., 2007). The SO_2 and NO_2 emission per land area in the eastern region of China was 3.3 and 4.4 times of their corresponding national averages (Yang et al., 2011b). In addition, the sulfate reduction frees up ammonia to react with nitric acid to form more nitrate (Seinfeld and Pandis, 2006), which was at least partly responsible for the nearly doubled NO_3^- concentrations in the precipitations. More careful study is needed to quantitatively determine all the contributions.

3.4 Trends in the acidifying and neutralizing potential, and the form of acidity

Tsurata (1989) defined $[NO_3^- + \text{nss-}SO_4^{2-}]$ as acidifying potential (AP) and $[NH_4^+ + \text{nss-}Ca^{2+}]$ as neutralizing potential (NP). Time series of the ratios of NP to AP (NP/AP) were plotted in Fig. 7a. The high NP/AP (1.2 on average) indicates that wet deposition in Beijing had strong neutralization potential to offset the acidity caused by high loadings of sulfuric and nitric acids. However, the NP/NA ratio exhibited a significant decreasing trend with the regression intercept down from 1.5 to less than 1.0 over the study period. The average ratio was significantly lower than that (1.45) determined
Fig. 7. Time series of **(a)** the equivalent mass ratios of NP (neutralizing potential) to AP (acidifying potential), **(b)** the NF (neutralization factor) of NH_4^+, **(c)** the NF of Ca^{2+} and **(d)** the NF of Mg^{2+}.

in Beijing during 1995–1998 (Feng et al., 2001), suggesting again the decreasing neutralization trend was likely a long-term trend for Beijing precipitations.

Time series of the neutralization factors (NFs) of NH_4^+, Ca^{2+}, and Mg^{2+} based on the following empirical relation are plotted in Fig. 7b–d:

$$(NF)_X = [X]/[NO_3^- + nss\text{-}SO_4^{2-}]$$

where $X = NH_4^+$, nss-Ca^{2+}, and nss-Mg^{2+}.

The NFs of NH_4^+, Ca^{2+} and Mg^{2+} varied largely from 0.19–1.5, 0.15–2.4 and 0.02–0.40 with their average values of 0.60 ± 0.25, 0.60 ± 0.31 and 0.13 ± 0.17, respectively, reflecting the dominant neutralization of NH_4^+ and Ca^{2+} over Mg^{2+}. There were evident decline trends in the NFs of NH_4^+ and Ca^{2+}, whereas that of Mg^{2+} underwent a clear growth over the study period. Although of small neutralization fac-

tor, the trend in NF of Mg^{2+} likely pointed to a growing contribution from construction activities since magnesium has been identified as an indicator element of cement dust (Yang et al., 2005). Along with other measures to control stationary and mobile source emissions in Beijing, construction and demolition areas have been required to control fugitive dust. However, ambient PM_{10} were still at high levels with the annual mean concentrations ranging $141\text{–}165\,\mu g\,m^{-3}$ over the study period (www.bjepb.gov.cn). This was attributed partially to the unprecedented high levels of construction activities due to rapid urbanization. For example, Yang et al. (2004) reported that there were more than 1200 construction and demolition sites in urban Beijing in June 2001, covering a total area of about $32\,km^2$.

Nitrate-to-sulfate equivalent ratio (i.e. $[NO_3^-]/[SO_4^{2-}]$) can be used to infer the form of acidity in the precipitation
Fig. 8. Time series of the equivalent mass ratios of NO_3^- to SO_4^{2-}.

(Tuncer et al., 2001). As illustrated in Fig. 8, a clear increasing trend in $[NO_3^-]/[nss-SO_4^{2-}]$ with a ~0.05 increment to 0.4 for its regression intercept was found over the study period. The ratios varied from 0.16 to 0.74 with an average of at 0.37 ± 0.11. This average ratio was more than twice that (0.15) calculated from the data measured in Beijing during 1995–1998 (Feng et al., 2001), indicating that the relatively reinforced contribution of nitric acid to precipitation acidity was also a long-term trend. This is in agreement with the trend in $[NO_3^-]/[SO_4^{2-}]$ of fine particles in Beijing (Yang et al., 2011b). This $[NO_3^-]/[nss-SO_4^{2-}]$ value was twice as much as that during the same period in Chongqing (0.18 ± 0.35) – a typical acid rain area with abundant high-sulfur coal consumption in Southwest China (marked in Fig. 1) – but was significantly lower than that in Tokyo Metropolis (Okuda et al., 2005) and a metropolis (Newark) in the US East Coast (Song and Gao, 2009). These comparisons showed that the precipitation acidity in Beijing was still dominantly from excessive emissions of sulfur (i.e. sulfur type).

4 Conclusions

Event-based precipitation samples were collected from March 2001 to August 2005 at an urban location in Beijing to investigate the temporal variations in the precipitation chemistry and to explore the possible mechanisms influencing the variations. The pH of single rain sample varied from 4.2 to 7.5 with an arithmetic mean of 6.3 and VWM of 6.0 for the total 131 rain events. About 16 % of rain events were acidic and the yearly wet deposition acidity was dominated by the summertime precipitations, as they shared about two-thirds of the annual volume and usually had low pH values. The precipitation acidity was on the growth track and the process was likely being accelerated. SO_4^{2-} was the most abundant ion with the VWM concentration of as high as $314\,\mu eq\,l^{-1}$. 84 % of anionic mass was from SO_4^{2-} and NO_3^-, followed in decreasing order by HCO_3^-, Cl^- and F^-. The precipitation acidity was predominantly neutralized by NH_4^+ and Ca^{2+}

with their percentage contribution of 83 % to total cationic mass.

The concentrations of both crustal-related and anthropogenic ions in the precipitation were much higher during the dry months than during the rainy months. The high NP/AP ratio (1.2 on average) indicated that the precipitations in Beijing had strong neutralizing potential to offset the acidity caused by high loadings of sulfuric and nitric acids. However, the NP/AP ratio exhibited a significant decreasing trend over the study period and particularly compared to that (1.45) determined pre-1998. This was mainly resulted from reduced input of NH_4^+ and Ca^{2+} and increased input of NO_3^-. In comparison to more or less decline of SO_2 and NO_2 in the ambient air of Beijing, the mean concentrations of SO_4^{2-} and NO_3^- in the precipitations showed much less decline and unexpected growth over the past decade, respectively. The growing contribution of NO_3^- to the precipitation acidity was also a long-term trend, although the acidity was still dominantly from sulfur oxide emissions but not nitrogen oxide.
