Abstract. The topographic evolution of continents and especially the growth and dismembering of mountain ranges plays a major role in the tectonic evolution of orogenic systems, as well as in regional or global climate changes. A large number of studies have concentrated on the description, quantification and dating of relief building in active mountain ranges. However, deciphering the topographic evolution of a continental area submitted to recurrent tectonic deformation over several hundred millions of years remains a challenge. Here we present a synthesis of the tectonic, geochronological and sedimentological data available on the intracontinental Tian Shan Range to describe its general topographic evolution from Late Palaeozoic to Early Tertiary. We show that this evolution has occurred in two very distinct geodynamic settings, initiating during the Carboniferous in an ocean subduction – continent collision tectonic context before becoming, from Early Permian, purely intra-continental. We show that during most of the Mesozoic, the topography is mostly characterized by a progressive general decrease of the relief. Nonetheless localized, recurrent deformation induced the formation of small-scale reliefs during that period. These deformations were driven by far field effects of possibly several geodynamic processes in a way that still remains to be fully understood.

1 Introduction

It is now largely accepted that the tectonic evolution of mountain ranges, climatic variations and feedback between the two is intimately linked to the topographic evolution of orogenic belts (e.g. Molnar and England, 1990; Batt and Braun, 1999; Whipple and Mead, 2006). Indeed, the topographic growth of an orogenic relief can influence the regional and sometimes global climate (e.g. Raymo and Ruddiman, 1992; Ramstein et al., 1997; Bookhagen and Burbank, 2006; Molnar et al., 2010). In turn, topographic changes due to climatic variations, which can modify the erosion rate and pattern in a range, can affect a tectonic evolution by, for example, impeding or accelerating the propagation of the deformation (e.g. Willett, 1999; Wobus et al., 2003; Thiede et al., 2004; Whipple, 2009). For those reasons, a large number of studies recently concentrated on describing the topographic evolution of active mountain ranges over a period of time spanning from a few thousands of years (e.g. Vassallo et al., 2007a; Nissen et al., 2009) to a few tens of million years (e.g. Metivier and Gaudemer, 1997; Sobel and Strecker, 2003; Yin, 2006; Liu-Zhen et al., 2008). In contrast, deciphering the topographic evolution of a mountain range area over several hundred millions of years remains a challenge and only a few studies have addressed that issue (e.g. Hendrix et al., 1992; Hendrix, 2000; Juez-Larré et al., 2010). However, understanding the long-term evolution of the topography is of primary interest to understand the relief and sedimentary basin dynamics in orogenic areas, the structural

and topographic inheritance in present day mountain ranges, or regional and global climate evolutions. The Tian Shan is one of the main intra-continental mountain ranges in Central Asia (Fig. 1). It forms a strong orographic barrier blocking the fresh and humid air masses coming from Siberia to the north and northwest, preventing them to reach the Tarim Basin and the Tibetan Plateau (e.g. Li et al., 2011; Zhao et al., 2013). The late Oligocene to Present growth of the Tian Shan Range resulted from crustal shortening related to the ongoing India-Asia collision (e.g. Tapponnier et al., 1986; Yin, 2010). However, the large-scale structure of the Tian Shan lithosphere was set by complex accretions of island arcs and amalgamation of continental blocks during the whole Palaeozoic (e.g. Windley et al., 1990; Charvet et al., 2011). This initial structure that was completely established by Late Permian, and especially the major tectonic boundaries separating the various terranes played a first order role in the subsequent evolution of the range.

The Palaeozoic and Cenozoic tectonic evolutions of the Tian Shan have been and are still widely studied and discussed. However, while the Mesozoic tectonic evolution of the range seems to have a major impact on its Tertiary development and topography (e.g. Dumitru et al., 2001; De Grave et al., 2007; Glorie et al., 2010; Jolivet et al., 2010), many uncertainties remain on the topographic evolution of the range during that period separating the two main orogenic events.

Here we present a short synthesis of the available data in order to draw a general picture of the topographic evolution of the Tian Shan from Late Palaeozoic to Early Cenozoic. We aim to describe the main phases of that topographic evolution, but also to point out the remaining inconsistencies between the various observations and to provide ideas for further investigations of the Mesozoic topography of Central Asia.

2 Synthesis of the available tectonic, geochronology, sedimentology and geomorphology data

A summary of the main data discussed below is presented in Fig. 2.

2.1 The Carboniferous – Permian evolution

It is commonly admitted that the Palaeozoic construction of the Tian Shan lithosphere through accretion of various continents and arc terranes ended during the Carboniferous by the collision between two blocks: the Yili – Central Tian Shan block and the North Tian Shan volcano-sedimentary complex – Junggar block (Figs. 1 and 3a) (e.g. Han et al., 2009; Wang et al., 2009; Charvet et al., 2011; Xia et al., 2012). However, the modalities of that last accretion event are still discussed. Two contrasting types of models are proposed.

The first models imply that the Late Carboniferous – Early Permian lavas that are widely exposed in the Yili block

were emplaced in a continental rift setting (e.g. Xiao et al., 1992; Che et al., 1996; Xia et al., 2004, 2008). Based on geochemical analysis and zircon U/Pb dating of the various Early to Middle Carboniferous volcanics and ophiolite suites occurring in the North Tian Shan block and indicative of an oceanic domain, Xia et al. (2005) suggested that this North Tian Shan Ocean was a Early Carboniferous short-lived ocean which closed before Late Carboniferous generating the North Tian Shan Middle Carboniferous ophiolite suite. This closure was followed by post-orogenic extension and transtension associated to continental rift-type volcanism in the Yili, Turfan and associated basins during the Late Carboniferous – Permian.

These models have been challenged by a number of tectonic, stratigraphic and geochemical evidences. Wang et al. (2009) indicated that magmatism in the Tian Shan has been continuous from Early Carboniferous to Permian with a magma composition evolving from essentially calc-alkaline and seldom transitional during the Carboniferous to coexisting calc-alkaline, transitional and alkaline during the Permian. Hence, alternative models proposed that the Carboniferous magmas would have been generated during southward subduction of the North Tian Shan Ocean (in these models a branch of the wide Paleo-Asian Ocean) underneath the Yili block (e.g. Wang et al., 2006, 2009; Han et al., 2009; Charvet et al., 2011). The North Tian Shan ophiolite sequence would correspond to an accretionary wedge developed in front of a Carboniferous forearc. This subduction ended with the Late Carboniferous – Early Permian closure of the North Tian Shan Ocean and the collision between the Yili block and the North Tian Shan – Junggar blocks (e.g. Gao et al., 1998, Wang et al., 2006, Charvet et al., 2007, Shu et al., 2010; Charvet et al., 2011) (Figs. 2 and 3a). The Permian magmas were then emplaced in a post-collisional setting and several authors suggested that slab break-off and lithospheric delamination may explain their mantle signature (Han et al., 1999, 2009; Chen and Jahn, 2004; Zhao et al., 2008; Shu et al., 2010). By Late Carboniferous – Early Permian, the Junggar Basin, disconnected from the Palaeo-Tethys ocean (Sha et al., 2011), initiated as a half-graben structure in a post-collisional extensional setting (Qiu et al., 2005, 2008; Yang et al., 2012).

All the models agree that during the Permian, the Tian Shan area was affected by a major transtension episode (Fig. 3b). Palaeomagnetic data analyses indicate that between the Upper Carboniferous and the Middle Permian, the Yili – West Junggar collage rotated counter-clockwise by $46.2^\circ \pm 15.1^\circ$ with respect to the Tarim and $31.6^\circ \pm 15.1^\circ$ with respect to Siberia (Wang et al., 2007b). As those continental blocks were amalgamated during the Upper Carboniferous this rotation has been accommodated by strike-slip motion along large lithospheric faults such as the North Tian Shan Fault, the Main Tian Shan Shear Zone, the Narat Fault or the Nikolaev Line in Tian Shan or the Erqishi shear zone in the Altay (Fig. 1). The total amount of E-W lateral displacement between Siberia and the Tarim is estimated at

1160 ± 380 km (Wang et al., 2007b). Similar structures, like the Dalabute Fault to the west or the Kelameili Fault along the Altai, were also active around the Junggar Basin itself submitted to significant extension (e.g. Allen et al., 1991, 1995; Allen and Vincent, 1997; Qiu et al., 2005, 2008; Yang et al., 2012). Those large strike-slip faults have been active from Early Permian to Early Triassic (ca. 290–250 Ma; Laurent-Charvet et al., 2002; Shu et al., 2002; Wang et al., 2004, 2007a, de Jong et al., 2009) and partially controlled the emplacement of the Permian granitoids in Tian Shan (Wang et al., 2009). Zircon (U-Th)/He Permian ages indicate a strong cooling – exhumation phase within the Tian Shan Range at that time implying the build-up of a major positive topography affected by erosion (Jolivet et al., 2010) (Fig. 3b). Along the southern Junggar margin, detrital zircon U/Pb analysis indicate a major source area in the North Tian Shan block associated to a widening of the drainage pattern towards the Central Tian Shan block (Yang et al., 2012), again suggesting the presence of significant reliefs. Pull-apart basins formed along those strike-slip fault zones, sometimes associated to volcanism as along the Dalabute Fault (Allen and Vincent, 1997) (Fig. 1). De Jong et al. (2009) suggested that the continental breakup regime that allowed the emplacement of the Late Permian – Early Triassic volcanic traps in Siberia (Courtilot et al., 1999) could have generated a widespread extensive event within Central

Asia, reaching the Tian Shan area. South of the Bogda Shan and between the Tarim and South Tian Shan, extension allowed the formation of relatively small-scale but deep basins that connected with the close-by Palaeo-Tethys Ocean to the south (in the Tarim) and filled with Permian marine sediments (Li et al., 2005; Shu et al., 2010) (Fig. 3b). The occurrence of these sediments contrasts with the near absence of post-Carboniferous marine formations within the whole Altai – Junggar – Tian Shan area to the north that remained completely disconnected from any marine environment since the Early Permian. The Permian – Early Triassic closure of the Palaeo-Tethys and the subsequent Middle Triassic collision between the Qiangtang and Kunlun blocks to the south (Fig. 1) (e.g. Roger et al., 2008, 2010, 2011) might have ended that extension phase (e.g. Allen et al., 1991; Wartes et al., 2002; De Grave et al., 2007). In the Turfan area, sediments were then deposited in intra-mountain lacustrine and fluvial environments with a major sediment source from the Jueluotage Range to the south (Shao et al., 1999) (see Fig. 1 for location).

2.2 Triassic – Jurassic evolution

During the Early Triassic, the tectonic regime in the Tarim – Tian Shan – Junggar area changed to become clearly compressive (Fig. 2). Apatite fission track data from the Tian

Fig. 2. Summary of the main Mesozoic tectonic, geochronological and sedimentological constrains in the Tian Shan Range and the Junggar and Tarim-Turfan basins. The data indicated in red are apparently in contradiction with the interpretation derived from other available data at the same time. The data in blue is contradicting the others but can be explained by local mechanisms. Column Topo. indicates the relative increase (wide black line) or decrease (thin black line) of the Tian Shan general topography. Column Tecto. recalls the major geodynamic events that affected Central Asia.

Shan clearly indicate a continuous cooling phase during the Triassic and Jurassic, even if the cooling rate become extremely slow during Middle to Late Jurassic (e.g. Dumitru et al., 2001; De Grave et al., 2007; Jolivet et al., 2010). Basement highs (imaged by seismic lines) that already started to uplift during the Carboniferous compressive (He et al., 2005) and Permian transpressive event in the western Junggar Basin continued to grow during the Triassic (Liu et al., 2006). However, within the Turfan Basin, tectonic extension still prevailed during the Early Triassic, associated to a strong thermal subsidence (Shao et al., 1999). Sediments were still derived from the south. In the northern Tarim Basin, south to southeastward directed palaeocurrents, as well as detrital zircon U/Pb dating, indicate a sediment source in the Central Tian Shan block and along the southern margin of the South Tian Shan block (Li et al., 2004, Li and Peng, 2010). This, associated with the occurrence of Lower Triassic conglomerates in the Early Triassic Ehuobulake Formation of the Kuqa sub-basin (the names of the various sedimentary formations can be found for example in Hendrix et al., 1992, Shao et

al., 1999; Jin et al., 2008 and Qiu et al., 2008), is consistent with the compression-related exhumation phase recognized by the low temperature thermochronology data within the range (Dumitru et al., 2001; Li et al., 2004; Jolivet et al., 2010). Detrital zircon U/Pb dating in the Middle to Late Triassic along the southern edge of the Junggar Basin (Xiao-quangou Group) indicate a strong widening of the drainage system towards the Central Tian Shan block associated to the progressive erosion of the Permian – Early Triassic topography (Yang et al., 2012). From Middle Triassic, basement highs also started to develop in the Turfan Basin, probably in a compressional setting (Shao et al., 1999). During the same period, tectonic subsidence ceased in the Junggar Basin, which became a slowly subsiding depression (Yang et al., 2012).

Except in the northern and western edges of the Junggar Basin, where Late Triassic thrusting occurred (Allen et al., 1991; Liu et al., 2006), and in the south Junggar, where small reverse movements took place (Yang et al., 2012), there is no obvious discordancy between the Upper Triassic and the

Fig. 3. Reconstitution of the main topographic pattern of the Tian Shan area through time. Lower Jurassic series (e.g. Sha et al., 2011). Indeed, from the Middle Triassic to the Middle Jurassic, a widespread coal-bearing sediment sequence developed throughout the Tian Shan and surrounding basins, most probably in a warm humid climate (Hendrix et al., 1992; Pfretzschner et al., 2005; Li et al., 2004; Tükten et al., 2004; Ashraf et al., 2010; Pan et al., 2013).

During the same period, the relative topography between the range and the northern margin of the Tarim decreased while the Junggar Basin widened towards the south (Li et al., 2004; Fang et al., 2005; Li and Peng, 2010; Yang et al., 2012). In Early Jurassic (Sinemurian Badaowan Fm.), a brackish-water fauna and flora (*Waagenoperma* bivalve assemblages and *Tasmanites* sp. alga) developed in some restricted areas along the southern margin of the Junggar Basin (Sha et al., 2011). Pan et al. (2013) suggested that small short-lived transtensional basins formed through reactivation of the North Tian Shan Fault. A contemporaneous increase in the water level of the North Tethys Ocean allowed a transgression event from the west along the southern margin of the Junggar (Fig. 3c). Small-scale tectonic activity, driven by a Jurassic – Early Cretaceous clockwise rotation of the Junggar block (Hou et al., 2009) is also observed in the northern and western Junggar during the Early and Middle Jurassic, both on thrust faults (Allen and Vincent, 1997) and normal faults (Liu et al., 2006). Seismic data interpretation indicates that this tectonic activity induced the uplift of topographic highs in the basin that propagated from south to north. However, the main driving mechanism for the subsidence of the Junggar basin would remain the thermal relaxation (Hou et al., 2009).

During the Early Jurassic (Badaowan Fm.), the Turfan Basin was also affected by extension that controlled its sedimentation during most of the Jurassic (Fig. 2). The sediments were still deposited in an environment influenced by surrounding topographic highs. Their main source area remained in the south (Qoltag and Jueluotage Ranges, Fig. 1), but small alluvial fans also formed on the northern edge of the basin, along the Bogda Shan. However, the topography of that range remained low (Shao et al., 1999, 2003). Normal faulting also affected the northern Tarim margin during the Jurassic (Allen et al., 1991).

By Middle Jurassic, a widespread planation surface started to develop over most of Central Asia, extending probably from Northern Tibet to SE Siberia (e.g. Allen et al., 2001; Vassallo et al., 2007b; Jolivet et al., 2007, 2009, 2010, 2013a). Remnants of that surface are still preserved in the central and northern part of the Tian Shan Range (e.g. Jolivet et al., 2010) (Fig. 3d). Over the same period, the apatite fission track data obtained from the central Chinese Tian Shan show a slow erosion period (isothermal to very slow cooling pattern compatible with a tectonically quiet phase) throughout the whole range (Dumitru et al., 2001; Jolivet et al., 2010; Glorie et al., 2010). However, further west in Kyrgystan, De Grave et al. (2007) indicate continuous cooling from

180 to 110 Ma. In the Junggar Basin, the long-lasting general retrogradation phase that initiated in the Late Carboniferous ended with the lacustrine facies of the Middle Jurassic Xishanyao Formation. The late Middle Jurassic change to a progradation phase suggests a renewed topography building in the Tian Shan or a strong climate change (Yang et al., 2012). However, the warm humid climate conditions that prevailed since Middle Triassic did not change until the onset of a strong aridification during the Late Jurassic (Qigu Formation) (Allen et al., 1991; Hendrix et al., 1992; Parrish, 1993; Shao et al., 2003; Li et al., 2004; Pan et al., 2013). Detrital zircons U/Pb dating still suggest a wide drainage system encompassing the North Tian Shan and the Central Tian Shan blocks but local recycling of the Early Mesozoic cover may have also occurred (Yang et al., 2012). The Middle and Upper Jurassic series of the southern Junggar are also marked by the occurrence of widely distributed volcanic ashes of intra-continental basaltic composition interbedded within the sediments (Wang and Gao, 2012; Yang et al., 2012).

As previously said, the Late Jurassic period is marked by a strong aridification and the widespread occurrence of the conglomeratic Kalaza Formation in the Junggar, northern Tarim and Turfan basins (Fig. 2). In the south Junggar and north Tarim, conglomerates are derived from the Tian Shan Range while in the Turfan Basin, southward thinning of the Kalaza Formation from the northern edge of the basin indicates a source in the Bogda Shan then forming a topographic high (e.g. Hendrix et al., 1992, 2000; Shao et al., 1999; Sha et al., 2011). Detrital zircons U/Pb dating in the southern Junggar indicates, that recycling of the Mesozoic cover sequence associated to some topographic growth initiated during Middle Jurassic (Yang et al., 2012). In the Kuqa sub-basin, similar detrital zircons U/Pb dating indicates a sediment source in the South Tian Shan where the sediment cover was progressively eroded. This front of the range progressively migrated towards the south, increasing the difference in topography between the basin and the uplifting range (Li et al., 2004).

Finally, at least in the Junggar Basin, the Lower Cretaceous series are described as unconformably lying on the Kalaza Formation (Sha et al., 2011), this again indicating a Late Jurassic tectonic activity (e.g. Hendrix et al., 1992, 2000; Shao et al., 1999; Sha et al., 2011). However, these tectonic movements are not or only poorly recorded by the low temperature thermochronology data in the central part of the Chinese Tian Shan (Dumitru et al., 2001; Jolivet et al., 2010). Contemporaneous cooling is only observed in the Kyrgyz Tian Shan further west (e.g. De Grave et al., 2007). Consequently, this near absence of cooling evidences in the low temperature thermochronology record, like the formation and the extensive preservation of the Jurassic planation surface within the range, are difficult to reconcile with Middle to Late Jurassic topographic growth and erosion revealed by the sedimentological and detrital zircon U/Pb data.

2.3 Cretaceous – Early Palaeogene evolution

Sediment analysis and detrital zircon U/Pb dating indicate that tectonic uplift continued during the Early Cretaceous along the southern edge of the Junggar Basin (Fang et al., 2006; Yang et al., 2012). An increase in the amount of detrital zircons derived from the North Tian Shan block suggests a noticeable uplift and denudation of this block. This uplift potentially formed a barrier to the sediments coming from further south. The southern edge of the basin was slightly uplifted and migrated northward to approximately its present-day position (Fang et al., 2006). The clockwise rotation of the Junggar block continued and intra-basin highs, which initiated during the Jurassic, reached their climax in Early Cretaceous with relative topographies up to 600 m based on erosion surfaces imaged by seismic data (Hou et al., 2009). A similar basin margin uplift is observed in the north Tarim Basin margin. Indeed, detrital zircon U/Pb analysis indicate an increase in denudation of the Central Tian Shan and South Tian Shan blocks associated to an increase of the differential topography between the basin and the range (Li and Peng, 2010).

Several authors suggested that the Early Cretaceous deformation around the Tian Shan Range resulted from the collision of the Lhasa block to the south (Figs. 1 and 2) (e.g. Hendrix et al., 1992; Gu, 1996; Fang et al., 2006a; De Grave et al., 2007). However, the absence of Late Jurassic – Early Cretaceous cooling episode in the Songpan – Garze area (East Tibet), immediately north of the Bangong – Nujiang suture Zone between the Lhasa and Qiangtang blocks suggests that this accretion generated only a very limited deformation (Coward et al., 1988; Roger et al., 2008, 2010, 2011). Nonetheless, further to the north, between the Kunlun Ranges and the Tarim Basin, low temperature thermochronology and sediment analysis do indicate some small-scale Cretaceous vertical movements potentially linked to the Lhasa collision (e.g. Vincent and Allen, 1999; Jolivet et al., 1999, 2001; Marshallsea et al., 2000). Within the Chinese part of the Tian Shan Range, the low temperature thermochronology data indicate that the near isothermal stage that started during the Middle Jurassic still prevailed during the Cretaceous (e.g. Jolivet et al., 2010). In Kyrgyzstan, this phase is also recorded from late Early Cretaceous up to the Palaeogene (e.g. De Grave et al., 2007; Glorie et al., 2010). As for the Middle and Late Jurassic, this contradicts the sedimentological (occurrence of conglomerates in the Cretaceous series) as well as recycling observed in the detrital zircon U/Pb data. However, Zhang et al. (2009), using apatite fission track analysis, reported evidences of Late Cretaceous exhumation near Aksu, along the northern margin of the Tarim Basin.

Eventually, the late Late Cretaceous – Early Palaeogene marks the onset of a new deformation phase that will culminate with the ongoing orogeny (Figs. 2 and 3e). Within the range, the low temperature thermochronology data show that

localized and rapid deformation and uplift occurred as early as 65 to 60 Ma on large inherited structures such as the Nikolaev line (Jolivet et al., 2010). Apatite fission track analysis in the Bogda Shan Range also show an onset of cooling and uplift around 65 Ma (Wang et al., 2008). The geodynamic mechanism driving those localized, Early Cenozoic deformations is still poorly known and might correspond either to far-field effects of the closure of the Mongol-Okhotsk Ocean in SE Siberia (Wang et al., 2008; Jolivet et al., 2009, 2010) or to terranes accretions such as the Kohistan-Dras Arc or the Kabul Block to the west in Afghanistan and northwestern Pakistan (Searle, 1991; Hendrix et al., 1992; Jolivet et al., 2010).

3 Discussion

Many evidences – tectonic, geochemical, geochronological and sedimentological – are in favour of the Late Carboniferous subduction – collision model (e.g. Gao et al., 1998, Wang et al., 2006, Charvet et al., 2007, Shu et al., 2010; Charvet et al., 2011). While the alternative rift model (e.g. Xiao et al., 1992; Che et al., 1996; Xia et al., 2004, 2008) would have generated a relatively low-relief topography distributed over most of the present day Chinese Tian Shan area, the subduction – collision model probably gave birth to a dissected, high relief, Andean- to Alpine-type topography (Fig. 3a). This kind of topography is consistent with the Late Palaeozoic – Early Mesozoic erosion of metamorphic basement rocks (e.g. Yang et al., 2012).

The Permian transtension event and the formation of large pull-apart basins along major strike-slip faults was certainly one of the main tectonic events in the geodynamic history of the range. The Late Carboniferous – Early Permian collision-related topography was dissected as strike-slip motion created the Yili, Bayanbulak, and Turfan basins. This event set up the tectonic framework of the Mesozoic and Tertiary Tian Shan (Fig. 3b). Continuous tectonic and/or thermal subsidence prevailed in the Junggar Basin during all that period. It was possibly linked to the general extensional setting that affected the northern part of Central Asia (De Jong et al., 2009), and allowed the deposition and preservation of the sediments issued from the widespread denudation of the adjacent areas as recorded by the low temperature thermochronology data (e.g. Dumitru et al., 2001; Jolivet et al., 2010).

The onset of renewed compression marked by basin inversion and basement cooling during the Early Triassic marks the end of the strike-slip phase (e.g. Dumitru et al., 2001; Liu et al., 2006; Jolivet et al., 2010). This Early Triassic event, probably linked to the final closure of the Palaeo-Tethys Ocean to the south (e.g. Roger et al., 2008, 2010, 2011), was followed by a general decrease in relief and the progressive formation of the flat topography that will characterize Central Asia during the Mesozoic. Local extension such as in the

Turfan Basin and thermal subsidence in the Junggar Basin maintained active sedimentation areas filled with sediments derived from erosion of remaining topographic highs.

Except for the development of basement highs within the Junggar Basin, flattening of the topography further continued during the Early and Middle Jurassic. The development of a flat topography is consistent with the widespread occurrence of a coal system throughout the whole area (e.g. Sha et al., 2011) (Figs. 3c and 2d). The relief between the Tian Shan area and the surrounding basins probably decreased through erosion. This phase of slow erosion is clearly recorded by the low temperature data that show a protracted isothermal stage during the whole Jurassic period (e.g. Dumitru et al., 2001; Jolivet et al., 2010; Glorie et al., 2010). However, tectonic activity probably still occurred along some of the major Permian tectonic structures, creating reliefs. For example, the formation of small-scale extensional (probably pull-apart) basins along the southern edge of the Junggar Basin, associated with volcanism, suggest strike-slip faulting along the North Tian Shan Fault zone (Pan et al., 2013). Evidence for local relief building is further attested by the observed, progressive recycling of the Mesozoic sediments along the southern margin of the Junggar (Yang et al., 2012). However, topographic highs were certainly not important and the peneplanation phase probably reached its maximum during the Middle or Late Jurassic like in most of Central Asia (e.g. Vassallo et al., 2007b; Jolivet et al., 2001, 2007).

The occurrence of the major alluvial fan system of the Late Jurassic Kalaza Formation seems to mark the onset of a new tectonic and topographic phase. While the low temperature thermochronology data obtained on basement rocks in the Chinese Tian Shan still indicate slow, erosion-driven cooling (Dumitru et al., 2001; Jolivet et al., 2010), sedimentological and tectonic evidences imply tectonic changes of topography. The Late Jurassic period is also marked by aridification (Allen et al., 1991; Hendrix et al., 1992; Parrish, 1993; Shao et al., 2003; Pan et al., 2013). The formation of the Kalaza alluvial fan could be linked to this climate change but relief building is also attested by the unconformity between the Late Jurassic and Lower Cretaceous sediments in the Tarim and Junggar basins (e.g. Hendrix et al., 1992, 2000; Shao et al., 1999; Sha et al., 2011). Similarly, Late Jurassic – Early Cretaceous basement cooling observed in the Kyrgyz Tian Shan suggest tectonic activity (De Grave et al., 2007). Altogether this tectonic phase remains poorly understood. Once again, relief building during that period must have been limited both in magnitude and extend. Widespread formation of relief is not compatible with the preservation – up to now – of the Mesozoic planation surface within the range. It has been suggested that the deformation observed in the Tian Shan was linked to the Early Cretaceous collision between the Lhasa block and the southern margin of Eurasia (e.g. Hendrix et al., 1992; Gu, 1996; Fang et al., 2006; De Grave et al., 2007). However, if the Late Jurassic Kalaza Formation marks the onset of the tectonic phase, it initiated prior to the colli-

sion. Furthermore this collision generated only a very limited amount of deformation and exhumation along the southern margin of the Qiangtang block (e.g. Coward et al., 1991; Roger et al., 2008, 2010, 2011). Why then did this collision affect the Central Asian crust several thousands of kilometers to the north? Another major geodynamic event, the closure of the Mongol-Okhotsk Ocean, affected Central Asia during the Mesozoic (e.g. Zonenshain et al., 1990a, b; Nie et al., 1990; Zorin et al., 1990; Metelkin et al., 2007, 2010). While the age of the final closure is still largely discussed (see Jolivet et al., 2009, 2013b and references therein), it probably occurred during the Cretaceous in southern Siberia. The far-field effects of that oceanic closure (combined or not with the effects of the Lhasa collision) could also be the driving mechanism for the Late Mesozoic deformations in the Tian Shan area.

Finally, the Late Cretaceous – Early Palaeogene reactivation of the Palaeozoic (mainly Permian) major strike-slip structures initiated the building of the present day Tian Shan topography (Fig. 3e). The relief first formed in highly localized zones along strike-slip faults like the Narat Fault (Jolivet et al., 2010). The preservation of large remnants of the Mesozoic planation surface implies that exhumation and erosion within the present day Tian Shan is still low and remains localized along discrete inherited tectonic structures.

4 Conclusions

The Late Palaeozoic and Mesozoic topographic evolution of the Tian Shan Range has been controlled by two, very different mechanisms:

- During the Late Carboniferous – Early Permian, oceans are still present around the Palaeo-Tian Shan and the topography is controlled by subduction and collision events. This probably first generated an Andean-type topography followed by an Alpine-type topography after the final closure of the Palaeo-Asian Ocean.
- After this final oceanic closure and up to now, the Tian Shan became an intra-continental area, only affected by the far field effects of continental collisions and oceanic closures that happened several thousands of kilometers away. During this second phase, the Middle-Permian – Early Palaeogene topographic evolution has been marked by the Middle to Late Permian dislocation of the Late Carboniferous relief and its progressive planation.

Indeed, several small-scale tectonic deformations affected the Tian Shan area during the Mesozoic. However the associated topographic changes remained limited and probably localized. While the Cimmerian collisions certainly induced the Triassic compressive event that ended the major

Permian strike-slip movements, the Late Jurassic and Cretaceous phase is still poorly understood. If the Cretaceous collision of the Lhasa block might have generated some of the stress that induced Late Mesozoic deformation in the Tian Shan, the effects of the Mesozoic closure of the Mongol-Okhotsk ocean should also be considered.

Finally, the synthesis of all the available data, and especially the discrepancy between the low temperature thermochronology data and the sedimentology data during the Late Mesozoic period demonstrates the need of combining both methods to decipher in details the topographic evolution of a region.
