**Abstract.** The aim is to evaluate the use of a satellite infrared (IR) technique for estimating rainfall over the eastern Mediterranean. The Convective-Stratiform Technique (CST), calibrated by coincident, physically retrieved rain rates from the Tropical Rainfall Measuring Mission (TRMM) Precipitation Radar (PR), is applied over the Eastern Mediterranean for four rain events during the six month period of October 2004 to March 2005. Estimates from this technique are verified over a rain gauge network for different time scales. Results show that PR observations can be applied to improve IR-based techniques significantly in the conditions of a regional scale area by selecting adequate calibration areas and periods. They reveal, however, the limitations of infrared remote sensing techniques, originally developed for tropical areas, when applied to precipitation retrievals in mid-latitudes.

## 1 Introduction

The Convective-Stratiform Technique (CST) is a satellite infrared (IR) technique designed to estimate precipitation of the scale of individual thunderstorms. The original application (Adler and Negri, 1988) was over southern Florida, and the technique was calibrated by the output from a 1-D model. With the launch of the Tropical Rainfall Measuring Mission (TRMM) in November 1997, high quality, high-resolution, instantaneous microwave based estimates became available from the (passive) TRMM Microwave Radiometer (TMI) and the (active) TRMM Precipitation Radar (PR). Negri et al. (2002, 2003) used TMI and PR derived rain rates to recalibrate the CST over northern South America and the

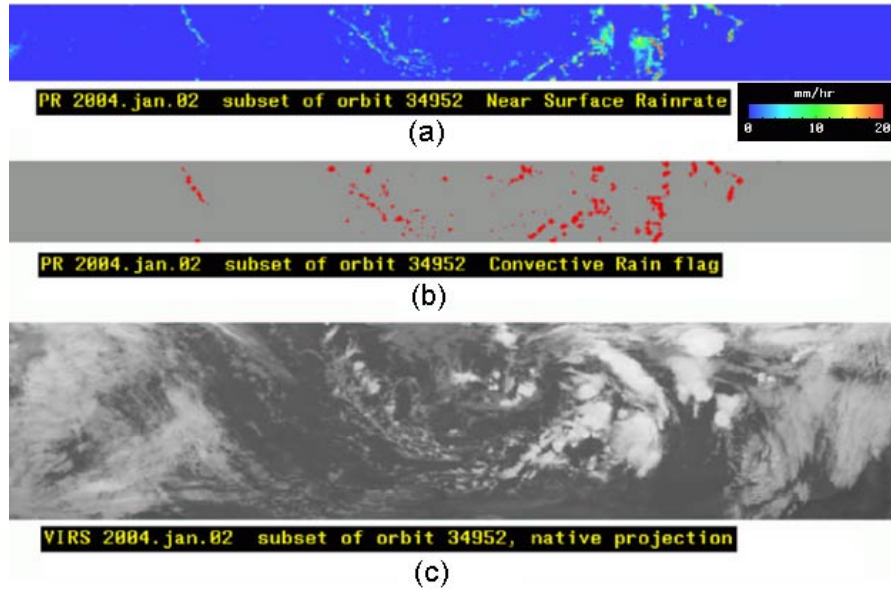

globe, respectively, and then apply the recalibrated technique in studying the diurnal variability of rainfall.

In this study we present work-in-progress to recalibrate the CST for the Mediterranean region using coincident physically retrieved rain rates from the TRMM PR and its application in studying rain events of different intensity over this area.

## 2 Data and methodology

The present method used to recalibrate the CST is similar to the one published in Negri et al. (2002) except it is applied to Visible/Infrared Scanner (VIRS) and extended to Meteosat-7 data. The original CST (Adler and Negri, 1988) locates, in an array of IR data, all local minima in the brightness temperature field. In the original study, digital radar and visible channel imagery was used to remove thin, nonraining cirrus from convective clouds and remaining brightness temperature minima were assumed to be centers of convective rain. A stratiform rain assignment, based on the mode temperature (the temperature that occurs most frequently) of each cloud system, completes the rain estimation.

As an intermediate step, the parameters of the original technique were recalibrated for the Mediterranean region using data from two TRMM instruments: the 2A25 version 5 product from the PR, and the 1B01 version 5 product from the VIRS. We then apply this calibration to Meteosat IR data. The 2A25 data provide near-surface rainrate values at each resolution cell of the PR and distinguish between convective and non-convective precipitation using a flag (Fig. 1a and b). We classified any non-convective precipitation as “stratiform”. The VIRS data include IR measurements in a similar range to Meteosat IR data (Fig. 1c). Since both PR and VIRS are aboard the same satellite the data sets match in temporal and spatial coverage. Processing accounted for the difference

**Fig. 1.** Three TRMM data subsets taken from a single orbit along the satellite track (native projection): (a) PR near-surface rainrate field; (b) PR convective rain flag; (c) VIRS IR data. Note that PR swath is narrower than VIRS swath.

**Fig. 2.** (a) Probability function of convection based on temperature and deviation from background (slope); probability ranges from 0.0 to 1.0; constant value contours are shown. (b) Relationship between temperature and rainrate for convective  $T_{\min}$ s.

in resolution of the data (5 km at nadir for PR, 2.4 km for VIRS), and VIRS data was only used from the area covered by the narrower PR swath. Only data falling within the range of longitude 10 W–30 E, latitude 30 N–38 N from a rainy season (October 2003 through March 2004) were used regardless of the precipitation content. More than 1000 TRMM orbits from this time period had coverage within this area.

The goal of the recalibration is to determine parameters so that the CST will be able to reproduce efficiently the total rain volume, total rain area, and the PR-observed divi-

sion between convective and stratiform rain for the Mediterranean region. We adjust the CST on a statistical basis, over the 6-month calibration period, without explicit constraints on instantaneous rain estimates. The recalibration takes the following form:

a. *Determination of Convective Cores.*

This is based on the identification of points of local temperature minimum ( $T_{\min}$ ) on VIRS IR data and the computation of the deviation of the  $T_{\min}$  from the background temperature (deviation from background), defined as the average temperature of the eight surrounding pixels. Using the corresponding PR-retrieved rain rate and type, each  $T_{\min}$ , within the Mediterranean area of the TRMM orbits was categorized as either convective or nonconvective. Then a function was derived which determines the probability of convective rain for a given  $T_{\min}$  and deviation from background. This function was obtained by applying an optimization method to the database of  $T_{\min}$  occurrences. The resulting function accepts a  $T_{\min}$ 's values of temperature and deviation from background, and returns the likelihood that the  $T_{\min}$  is associated with convective precipitation. The resulting function accepts values of  $T_{\min}$  and deviation from background as inputs, and returns the likelihood of  $T_{\min}$  to be associated with convective precipitation. We realize there may be differences between seasons. In this experiment we chose to ignore the seasonal variations. The probability function is expressed as a value between 0.0 and 1.0 and is illustrated in Fig. 2a.

b. *Convective Rain Area.*

The next task in the calibration is to determine the average area covered by a convective occurrence, i.e. the

number of VIRS pixels to be labelled with a convective flag and rainrate in the neighborhood of each convective  $T_{\min}$ . This is based on the computation of the simple ratio between the total convective area in the 6 months of PR overpasses and the corresponding number of convective  $T_{\min}$ s sensed by VIRS. The result is 15 VIRS pixels are affected within the area of a convective  $T_{\min}$ .

c. *Convective Rain Rate.*

The convective rain rate assigned to each  $T_{\min}$  is a function of temperature. This function can be actually represented by a smoothed look-up-table, in which each  $T_{\min}$  is mapped to the average of near-surface rain rate values found in its neighbourhood in PR data. The graphical representation of final look-up table is shown in Fig. 2b.

d. *Stratiform Rain Threshold.*

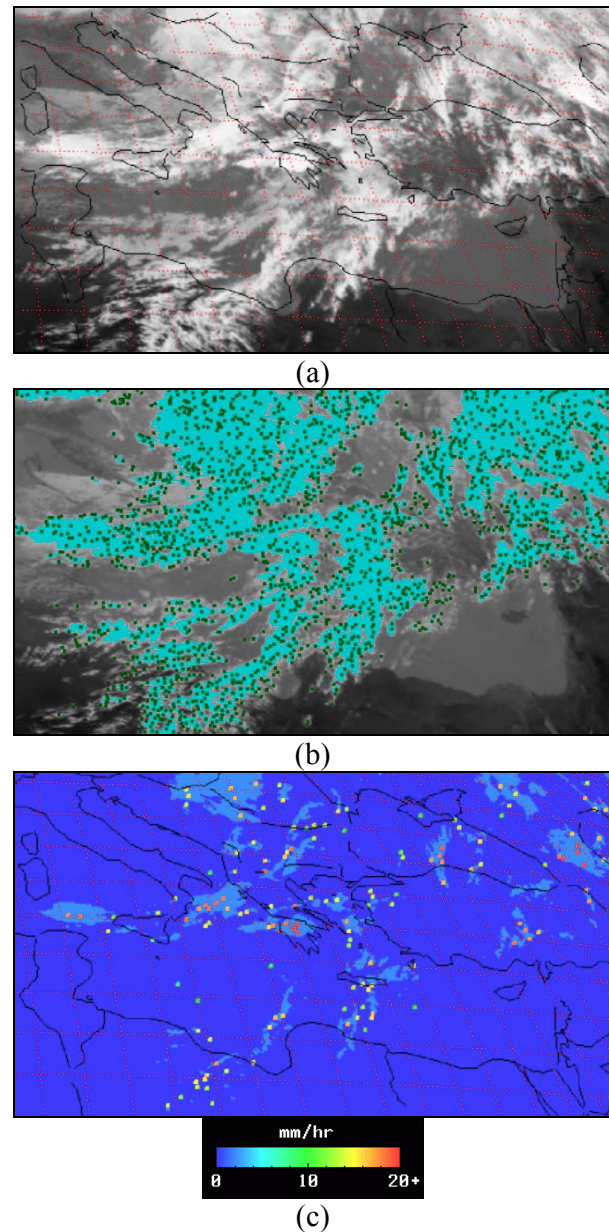

To associate VIRS pixels with stratiform rain, a threshold on brightness temperature was determined from a three-step cumulative-area matching approach: i) the percentage of PR pixels (2.4%) with rain was determined from the measurements over the studied region; ii) then the cumulative frequency of brightness temperature for the 97 million VIRS pixels in the studied region was computed; iii) finally the entry of the cumulative frequency with a percentile of 2.4%; i.e. the aforementioned PR percentile, was found at 233 K and used as a temperature threshold.

e. *Stratiform Rain Rate.*

We set the stratiform rain rate equal to the mean stratiform rain rate of the PR estimates for the training data set, which was computed to be 1.6 mm/hr. Since the total stratiform rain area from CST is equal to that of PR (integrated over the 6-month calibration period), this constant rain makes the total stratiform rain volume from CST to equal that of the PR alone.

f. *Modification for Meteosat-7.*

The calibration described above determined the parameters for CST using VIRS data. In order to take into account the differences in sensor resolution and calibration, two adjustments were made to the CST. First, functions were derived, which when applied to Meteosat brightness temperature and deviation from background values, modify their distributions to more closely match distributions found in VIRS data. This was accomplished by identifying several pairs of VIRS orbits/Meteosat scenes over the Mediterranean region within 3 min from each others and with significant cloud systems. Frequencies of brightness temperature and deviation from background of those “training swaths” were used to build some “histogram-matching” functions. Those functions shift brightness temperature values derived from Meteosat IR data so that the resulting histograms more closely matched those of the VIRS IR data. Finally these correction functions are applied before the convective probability test is done.

**Fig. 3.** (a) Meteosat-7 IR subimage over the Mediterranean on 8 October, 2003, at 11:30 UTC; (b) all  $T_{\min}$ s identified in the subimage (both convective and non-convective) are shown with small green dots, and cloud patches with temperatures between 150 and 263 K are shown in cyan; (c) the resulting CST rainrate estimation with small convective areas in different colors (where  $T_{\min}$ s were judged to be convective) and larger stratiform areas shown in cyan.

The fraction of convective pixels over total pixels was computed, and then multiplied by the total number of Meteosat pixels in the training swaths, to yield the target number of convective pixels expected from CST operating on that portion of Meteosat data. CST was then applied to the Meteosat data to determine the number of convective  $T_{\min}$ s. Finally, the total count of expected convective pixels was divided by the number of convective  $T_{\min}$ s, yielding the number of pixels per  $T_{\min}$ .

**Table 1.** Statistics of rain retrievals from calibrated and original CST for all four examined periods over each rain gauge station. Precipitation totals are accumulated over different time scales (6, 12, and 24 hourly intervals).

(a) Calibrated algorithm								
	Pairs	Mean gauges (mm)	Mean satellite (mm)	$r$	Bias (mm)	MAD (mm)	RMSD (mm)	PDF

	Pairs	Mean gauges (mm)	Mean satellite (mm)	$r$	Bias (mm)	MAD (mm)	RMSD (mm)	PDF
6-hourly	13342	1.5	1.5	0.19	0.0	2.2	7.7	2.8
12-hourly	8284	3.3	3.0	0.23	-0.3	4.3	11.8	3.8
24-hourly	3865	6.0	5.5	0.27	-0.5	7.2	16.4	5.4
(b) Original algorithm								
	Pairs	Mean gauges (mm)	Mean satellite (mm)	$r$	Bias (mm)	MAD (mm)	RMSD (mm)	PDF
6-hourly	48	1.5	1.5	0.59	0.1	0.8	1.2	0.7
12-hourly	24	3.3	3.0	0.51	-0.3	1.5	2.3	0.5
24-hourly	12	6.1	5.6	0.60	-0.5	2.8	3.9	0.4

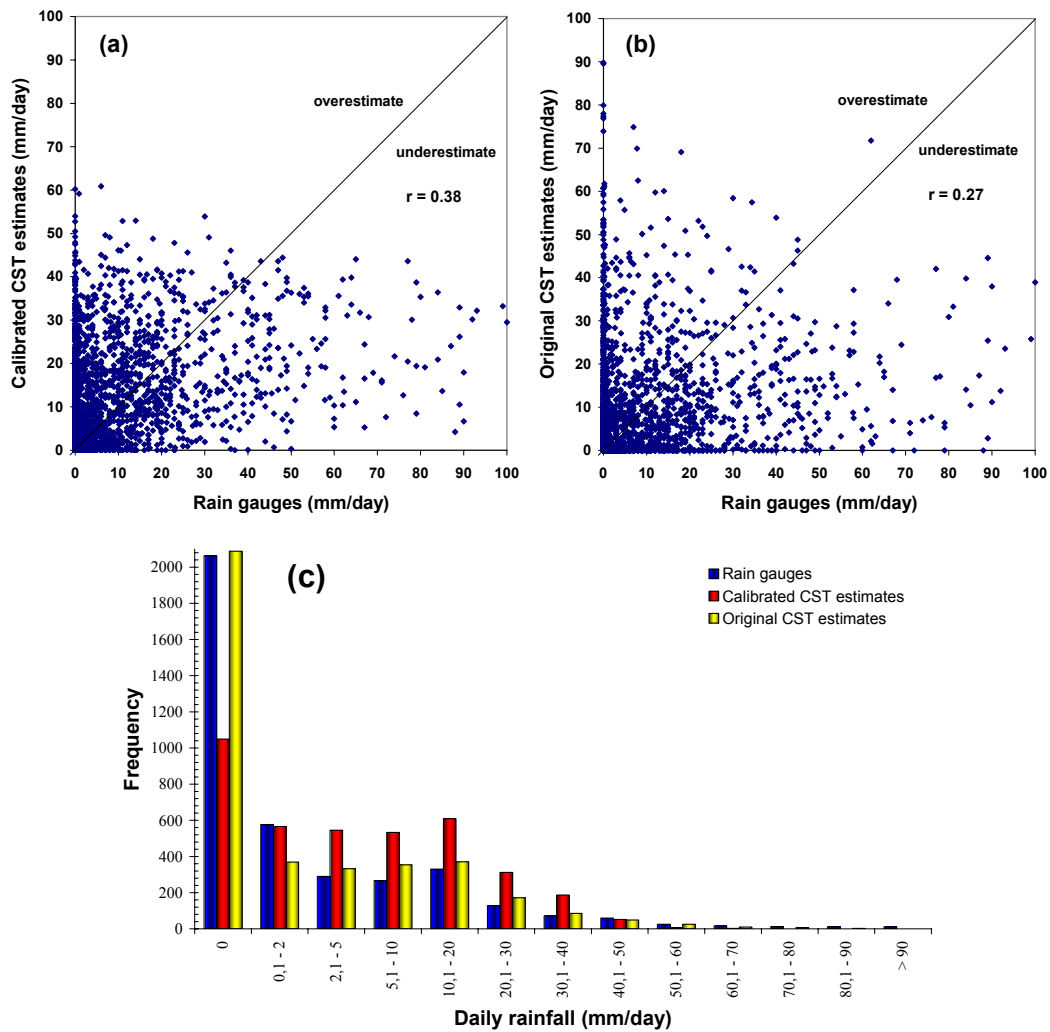

The second modification of CST for use with Meteosat data is the adjustment of the size of convective area (i.e. number of Meteosat pixels) assigned to each convective  $T_{\min}$ . The CST algorithm is applied to the VIRS training swaths. The fraction of number of convective pixels over the total number of pixels was computed, and then multiplied by the total number of Meteosat pixels in the training swaths, to yield the target number of convective pixels expected from CST operating on that portion of Meteosat data. CST was then applied to the Meteosat data to determine the number of convective  $T_{\min}$ s. Finally, the total count of expected convective pixels was divided by the number of convective  $T_{\min}$ s, yielding the number of pixels per  $T_{\min}$ s.

In summary, the recalibrated CST, dubbed as CST/Met-7, finds local IR minima, decides if they are convective features, then assigns a rain area and rain rate based on the PR calibration parameters. A stratiform rain area is then defined, and a lower rain rate is assigned to those cloud pixels colder than the stratiform IR threshold and not previously assigned convective rain. An example of the instantaneous application of this technique is shown in Fig. 3. The main differences of

the calibrated CST with the original technique is the higher temperature threshold used for the identification of stratiform regions and the determination of a larger number of convective cores.

The CST/Met-7 algorithm is applied along with the original CST to half-hourly Meteosat IR data for four rain events of varying intensities resulted by the passage of a frontal depression system over eastern Mediterranean: 29 October–2 November 2004, 13–14 November 2004, 18–20 December 2004 and 26–27 December 2004. Results from both algorithms are intercompared and verified against gauge measurements. Six-hourly precipitation totals recorded by a network of 150 to 260 synoptic stations were employed as ground truth data to verify the precipitation estimates. This number of pluviometric stations was the maximum available and provided by the European Center for Medium Weather Forecast (ECMWF). Quality tests have been performed to these data to detect potential outliers.

For the total and for each one of these periods the following comparisons were made on the basis of 6, 12 and 24-h precipitation totals:

**Fig. 4.** (a) Calibrated CST and (b) Original CST daily rain accumulation as function of rain gauge measurements for the four studied periods (3865 pairs). (c) Frequencies of daily rain accumulation as measured from the rain gauges and as determined from the original and calibrated CST estimates.

1. Twelve-hourly accumulated precipitation for each of the pluviometric station processed, versus the rainfall retrieved from satellite data for the corresponding pixel location. For each station the total precipitation was calculated as the average value of 3 by 3 Meteosat pixels (representing an area of  $300 \pm 9 \text{ km}^2$  depending on geographic position), centered over each pixel corresponding to the station.
2. Average regional rain gauge precipitation as function of average regional satellite precipitation during 6, 12 and 24-h intervals. The mean regional precipitation measured by rain gauges is calculated by applying a simple arithmetic average of rain accumulation reported by the network of rain gauges during a given time interval. The corresponding average regional satellite precipitation corresponds to the arithmetic average of rain accumulation retrieved within 3 by 3 Meteosat pixels centered at the location of each ground station.

**Fig. 5.** Mean regional daily precipitation for the four examined periods.

Several measures of the closeness of the estimates to the observed values are the correlation coefficient ( $r$ ), the mean square difference (RMSD), the bias, the mean absolute difference (MAD) and the percent difference (PDF).

**Fig. 6.** (a) Surface map with 4-hPa interval at 00:00 UTC on 14 November 2004; daily accumulated precipitation derived from (b) ground observations, (c) calibrated and (d) original CST projected in a regular latitude-longitude mesh. Statistics between ground measurements and satellite estimates on a single station basis are also presented.

### 3 Results

#### 3.1 Quantitative validation

In order to validate both rainfall retrieval algorithms against gauge measurements, we first intercompared the accumulated precipitation measured by each of the pluviometric stations with the corresponding satellite retrieved rain depths. The intercomparison was implemented in terms of precipitation accumulated over different time scales (6, 12 and 24 hourly intervals) and estimated for the four periods as a whole and for each period separately.

Scatter diagrams and frequency histograms for the four periods as a whole are given in Fig. 4 with the associated statistics provided in Table 1. This type of comparison shows rather low correlation coefficients (0.23–0.38) and high errors for the calibrated technique (Table 1a). The positive values of bias errors (0.6–2.3 mm) indicate a systematic overestimation of the precipitation values. The technique performance is gradually improved when estimated

precipitation are averaged over larger time intervals (from 6 to 24 h). The CST/Met-7 overestimates weak rain rates (<30 mm/day) whereas, conversely, underestimates intense precipitation (>60 mm/day) (Fig. 4a, c). Since, however, weak precipitation prevails in the dataset the overall bias becomes positive. The poor correlation is also reflected in the uneven and widespread pattern of the distribution of points in the scatter plot (Fig. 4a). Although the calibrated CST induced a significant improvement in the correlation coefficients compared to those of the original technique, most errors are slightly deteriorated (Table 1). The overestimation of weak rain rates by the original CST is less intense resulting in a small negative bias; the pattern of the scatter plot, however, is less widespread indicating a better correlation (Fig. 4b).

As a second step in this study, we determined the correspondence between the average regional precipitation measured by rain gauges in the whole area of study with the corresponding average estimated from satellite data, according to the methodology described in the previous paragraph. This type of comparison provides high correlation coefficients for

Fig. 7. As in Fig. 6 but for 27 December 2004.

the calibrated CST (0.79 to 0.86) – distinctly higher than in the case of comparison on a single station basis - and a bias error that indicates an overestimation of the precipitation (Table 2). Rain retrievals of the original CST correlate less efficiently with rain gauge data ( $r$  from 0.51 to 0.60); errors, however, are similar to those of the calibrated technique with the exception of the bias errors which takes very low values. The comparison between the average regional daily precipitation recorded by gauges and the corresponding value estimated by both satellite techniques is presented in Fig. 5. Both techniques show the same general pattern, with limited quantitative variations among them. Although the calibrated CST correlates better with the situ data, its tendency for overestimating precipitation is evident. The most evident limit of the CST is that the discrimination between convective and stratiform clouds is still unsatisfactory in mid-latitudes where cold thick cirrus clouds dominate in frontal cloud bands, a feature that is intrinsic in all the IR techniques.

### 3.2 Qualitative validation

The calibrated CST is next qualitatively investigated in the context of whether the spatial distribution of rainfall can be accurately determined. To achieve this we chose to present two cases of convective systems over eastern Mediterranean associated with different rainfall patterns. The gauge daily precipitation data and the corresponding estimates from the two satellite techniques (original and calibrated) along with surface weather maps are presented for both cases in Figs. 6 and 7. Comparison statistics (observations with satellite estimates) on a single station basis are also presented.

On 14 November 2004 a persistent low pressure centre was positioned east of Sicily at 00:00 UTC (Fig. 6a) associated with a cut-of-low at the 500 hPa (not shown). During the next hours the system slowly moved NE towards Adriatic Sea. The release of instability ahead of the system was supported by favourable dynamics resulting from the convergence of the inflow of unstable warm and moist low-level air in conjunction with the diffluent flow at the 500-hPa level. As a result intense precipitation occurred in the northern part of the Balkans peninsula (Fig. 6b). In this case both

techniques, original and calibrated, provide unacceptable results with very low correlation coefficients ( $r=0.19$  and  $0.26$ ) and large errors. The technique erroneously assigns convective precipitation in areas (e.g. Rumania) where cold thick cirrus clouds of frontal origin produce stratiform rain.

In the second case of 27 December 2004, an occluded frontal depression was located over northern Italy (Fig. 7a). The low-pressure system remained stationary and filled during the same day. Several mesoscale convective systems were triggered in northern Italy and northwestern Balkans by low-level forcing for ascent along the associated fronts in combination with considerable forcing associated with an upper level cut-of-low (not shown). An inspection of the rainfall maps reveals that both techniques exhibit a spatial rainfall distribution – mainly in the north-eastern part of the area – which is in general agreement with the rainfall pattern obtained using the rain gauge network (Figs. 7b to c). The calibrated CST technique performs better ( $r=0.56$ ) with only a slight underestimation of precipitation (bias=1.3 mm). Locations and magnitudes of the local convective maxima coincide adequately with those of the rain gauge network over the north-western part of the area. The technique, however, erroneously locates a large number of convective cores in the cloud band related to the warm front in the south-eastern Mediterranean Sea. The performance of CST is worsened – though not significantly – when the original technique is implemented ( $r=0.47$ ) presenting a general underestimation tendency (bias=-5.3 mm) evident mainly for weak precipitation estimates, which might be attributed to the lower temperature threshold used for the stratiform area definition in combination to a more stringent screening of the convective cores.

#### 4 Conclusions

The well-known infrared satellite technique CST was calibrated using PR data for the area of Mediterranean and applied to four convective systems to test its performance for reproducing rainfall at mid-latitudes. The comparisons between satellite and rain gauge measurements performed on a single station basis provide rather low correlation coefficients and large errors. The calibrated CST overestimates weak rain rates whereas, conversely, underestimates intense precipitation. The technique performance is gradually improved when estimated precipitation are averaged over larger time intervals (from 6 to 24 h). In order to obtain a more satisfactory reproduction of the rainfall data, a regional average is necessary. A pixel-by-pixel comparison between calibrated CST retrievals and PR observations from TRMM orbits, different from those used in the calibration procedure, would provide a more comprehensive picture of the method's performance and a further development of this work could be to this direction.

In general, the validations clearly show that the performance of the CST is improved when its rain parameters are adjusted to the geoclimatic conditions of the Mediterranean region. This improvement, however, is restricted by the inherent shortcoming of infrared techniques – originally developed for convective cloud systems over the tropics – in discriminating convection in the frontal clouds of mid-latitudes.
