Abstract. Greenhouse gas (GHG) fluxes from a seminatural, extensively sheep-grazed drained moorland and intensively sheep-grazed fertilised grassland in South East (SE) Scotland were compared over 4 yr (2007–2010). Nitrous oxide (N₂O) and methane (CH₄) fluxes were measured by static chambers, respiration from soil plus ground vegetation by a flow-through chamber, and the net ecosystem exchange (NEE) of carbon dioxide (CO₂) by eddy-covariance. All GHG fluxes displayed high temporal and interannual variability. Temperature, radiation, water table height and precipitation could explain a significant percentage of seasonal and interannual variations. Greenhouse gas fluxes were dominated by the net ecosystem exchange of CO₂ at both sites. Net ecosystem exchange of CO₂ and respiration was much larger on the productive fertilised grassland (−1567 and 7157 g CO_{2eq} m^{−2} yr^{−1}, respectively) than on the seminatural moorland (−267 and 2554 g CO_{2eq} m^{−2} yr^{−1}, respectively). Large ruminant CH₄ (147 g CO_{2eq} m^{−2} yr^{−1}) and soil N₂O (384 g CO_{2eq} m^{−2} yr^{−1}) losses from the grazed grassland counteracted the CO₂ uptake by 34 %, whereas the small N₂O (0.8 g CO_{2eq} m^{−2} yr^{−1}) and CH₄ (7 g CO_{2eq} m^{−2} yr^{−1}) emissions from the moorland only impacted the NEE flux by 3 %. The 4-yr average GHG budget for the grazed grassland was −1034 g CO_{2eq} m^{−2} yr^{−1} and −260 g CO_{2eq} m^{−2} yr^{−1} for the moorland.

1 Introduction

European governments are required to reduce their greenhouse gas (GHG) emissions by 80 % by 2050. Anthropogenic emissions are recorded annually through UNFCCC (United Nations Framework Convention on Climate Change) and CORINAIR (Core Inventory of Air Emissions in Europe) activities. This is done mostly by simple, but crude, IPCC Tier 1 emission factor approaches, which cannot accurately reflect regional variability and monitor mitigation. To improve the current reporting structure, countries have started to (i) develop and implement more complex Tier 2 reporting systems for some of the emission sectors and (ii) monitor GHG concentrations and fluxes at the landscape-scale together with improving top-down modelling. Successful Tier 2 emission factors need to focus on easily measurable or documented variables (i.e. rainfall, temperature), and landscape scale measurements/top-down models would benefit from including emissions from seminatural/natural ecosystems. This paper addresses these requirements by comparing 4 yr of GHG flux measurements from nearby intensively grazed grassland and extensively grazed moorland in a temperate maritime climate and assesses the drivers responsible for spatial and temporal variability.

2 Methods

2.1 Site description

Auchencorth Moss (AMo) is a low-lying acid moorland (pH 4.3, in H₂O) dominated by grasses and is approximately 17 km south-west (SW) of Edinburgh, Scotland (Table 1) (Drewer et al., 2010). The moorland, which is not fertilised, was drained about 100 yr ago and again in the 1960s to improve the land for extensive grazing. The peat depth is now mostly 0.5 m, but in places up to 2 m deep. The moss is extensively grazed by sheep at a very low stocking density of < 0.2 LSU ha⁻¹, which equates to circa 1 ewe ha⁻¹, accompanied by one to two lambs between April and September (1 LSU (livestock unit) = 1 animal of 600 kg live weight, therefore 1 ewe = 0.1 LSU and 1 lamb = 0.04 LSU).

In contrast, two adjacent fields at Easter Bush (EBu), 7 km north-west (NW) of AMo, have been intensively managed for livestock grazing for over 20 yr. The grass is grown on an imperfectly drained Macmerry soil of the Rowanhill soil association (eutric cambisol, FAO classification) with a pH (in H₂O) of 5.1 and a clay fraction of 20 % to 26 % (Table 1). Although the fields were drained over 50 yr ago, the drainage system no longer operates properly and large puddles of standing water are a regular occurrence during prolonged periods of rain. The fields have not been ploughed in the last 20 yr, and were only cut on three occasions – once in 2002, 2003 and 2004. Grazing occurs all year round, and animals always have access to the entire field, but livestock is occasionally taken off the field for periods of one day to several weeks. Annual livestock numbers were calculated from farmers and our own records. Between 2002 and 2006 the average stocking density was 0.7 LSU ha⁻¹, and consisted of beef cattle (30 %) and ewes + lambs (70 %). Lambs are only present between April and September. To maintain the high stocking densities, the grassland received predominantly granules of mineral N fertiliser, either as ammonium nitrate or a NPK compound fertiliser between March and August. The average annual N fertilisation rate between 2002 and 2010 was 245 kg N ha⁻¹ yr⁻¹. Since 2002 cattle slurry was only applied in September 2004 (69 kg N ha⁻¹ yr⁻¹) and March 2005 (158 kg N ha⁻¹ yr⁻¹).

During the 2007 to 2010 study period, fields were only stocked with sheep at an average annual stocking density of 0.77 LSU ha⁻¹ (Table 1). Animal numbers ranged from 0 to 170 ewes (0 to 17 LSU ha⁻¹) and 0 to 260 lambs (0 to 10 LSU ha⁻¹). Between spring 2007 and summer 2010, N fertiliser was applied on 16 occasions. The average application rate was 58 (range 35 to 92) kg N ha⁻¹. There were three applications in 2007 and 2010, four in 2009 and six in 2008 (Table 1). Mostly ammonium nitrate was applied, but on three occasions (August 2008, March and May 2009) urea was used and once a NPK compound fertiliser (June 2009).

Both sites are long-term field sites run by the Centre for Ecology and Hydrology (CEH), where we have studied car-

bon and nitrogen fluxes and pools as part of a range of national and European programmes, including Graminae (Sutton et al., 2001), GreenGrass (Soussana et al., 2007), NitroEurope (Skiba et al., 2009) and CarboEurope (Schulze et al., 2010).

2.2 Soil greenhouse gas flux measurements

Methane and nitrous oxide fluxes were measured by static chambers. Chambers were manufactured from opaque polypropylene pipes (0.4 m in diameter) cut to lengths of 0.2 m and fitted with a 0.05-m-wide flange at the outward facing end (Clayton et al., 1994). The pipe was inserted into the soil at approx. 0.03 to 0.07 m depth, and the chamber volume was approximately 17 L. The measurement protocol was slightly different at the two sites.

At AMo, nine chambers were installed within a 25 m radius of each other and within the main fetch of the CO₂ eddy-covariance tower. They remained in position over the 4-yr study period and covered the most dominant vegetation types on the Moss: three chambers each on (1) hummocks dominated by *Deschampsia* and/or *Eriophorum*, (2) hummocks of *Juncus* and (3) hollows dominated by mosses. To measure fluxes a flexible, transparent, dome-shaped polyethylene lid was placed onto the chamber for approximately 60 min (MacDonald et al., 1996). Air samples (200 mL) were withdrawn via a three-way tap fitted at the side of the chamber, just after chamber closure and then approximately 30 and 60 min later (later referred to as t_0 , t_{30} , t_{60}). To mix the chamber air, the syringe was flushed three times before collection into 500 mL Tedlar[®] bags. During summer it was necessary to fit extension collars onto chambers containing *Juncus*; as a result, the volume of air enclosed in each chamber was then approx. 30 L. Measuring the volume of a chamber enclosing hummock vegetation was not easy due to uneven hummock shapes and hidden airspaces within the hummock. Instead of just measuring the chamber height, as done at EBu, we filled the chambers with a known SF₆ concentration (4.8 ppb), stirred the air by fan and collected chamber air after 5 min incubation. The volume was calculated from the magnitude of dilution of SF₆ (Dinsmore, 2008).

At EBu, eight chambers were inserted: four within the eddy-covariance footprint of the prevailing SW wind direction and another four in the NW direction (Jones et al., 2011). Chambers were moved every fortnight to allow free grazing. For flux measurements chambers were sealed with aluminium lids fitted with a central port for sample collection. At the beginning of the incubation period, ambient air samples were taken from about 0.5 m above the soil surface next to the chambers (t_0). After about 60 min incubation (t_{60}), 200 mL samples were withdrawn from inside the chambers into Tedlar[®] bags. Linearity tests, taking samples every 15 min over 2 h, were carried out several times during the study period and demonstrated linearity of up to 120 min with an average $r^2 = 0.96$ for N₂O.

^c annual total (total for January–March + October–December; April–September, i.e. cold; warm period),

^d annual average (average for January–March + October–December; April–September).

Samples were analysed for N₂O and CH₄ within one week of collection. In the laboratory, samples were transferred to glass vials and were analyzed using a Hewlett Packard 5890 series II gas chromatograph (Agilent Technologies, Stockport, UK), fitted with an electron capture detector for N₂O and a flame ionisation detector for CH₄. Fluxes were calculated from the difference of gas concentration from the start (t_0) and average concentration increase at t_{30} and t_{60} for AMo samples and the concentration increase at t_{60} for EBU samples. Concentration differences were converted to gas densities assuming standard temperature and pressure conditions, multiplied by the chamber volume and divided by the chamber area and time of incubation. The minimum detectable flux was 3 µg N₂O m⁻² h⁻¹ and 6 µg CH₄ m⁻² h⁻¹.

Respiration from soil including the ground-covering vegetation (grass at EBU and mosses and small herbs at AMo) was measured close to all static chambers at AMo and EBU using a PP-Systems (Hitchin, UK) SCR-1 respiration chamber (0.1 m diameter) attached to an EGM-4 infrared gas analyser (Dinsmore et al., 2009). The chamber was placed onto the ground for 1–2 min periods, during which chamber air was re-circulated between chamber and EGM-4. Fluxes were calculated from the linear increase in concentration, taking into account the soil temperature at the time of measurement. The ground at AMo was too soft to create a proper seal between soil and chamber. Therefore, during measurements the chamber was attached to small plastic collars which were inserted 0.05 m into the peat before the start of the 4-yr study period.

Measurements were usually made when N_2O and CH_4 fluxes were measured.

The frequency of soil GHG flux measurements was different at the two locations. At EBU, outwith fertilisation periods, fluxes were measured weekly during the growing period and fortnightly in winter. Intensive measurements scaling down from daily to weekly were made immediately after N fertiliser applications. Between January 2007 and December 2010, we measured N_2O , CH_4 and respiration on 248, 239 and 222 dates, respectively. At AMo, fluxes were measured approximately every two weeks during the growing season and every four weeks in winter, in total on 78 (N_2O and CH_4) and 49 (respiration) dates.

2.3 Net ecosystem exchange of carbon dioxide

The net ecosystem exchange (NEE) of CO_2 was measured by eddy-covariance at both locations, using a fast-response closed-path CO_2 and H_2O analyser (Li-COR 7000 IRGA, LI-COR Lincoln, USA) operating at 10 Hz and an ultrasonic anemometer (Gill WindMaster Pro, Lymington, UK) operating at 20 Hz. The sample inlet was fixed just below the ultrasonic anemometer at a height of 3.6 m at AMo and at 2.5 m at EBU. The LI-COR instruments were situated in mains-powered research cabins 20 m (AMo) and 10 m (EBU) away from the towers. Air samples were drawn into the analysers via 6 mm (out-diameter) non-reactive tubing. The three-dimensional wind vector components, sonic temperature, CO_2 and H_2O concentrations were logged using an in-house LabViewTM data acquisition program. The data were filtered offline. The following data were excluded from the analysis: CO_2 molar fractions not in the range of 350 ppm to 500 ppm, and hourly data (a) with standard deviations of mean vertical wind velocities $> 1 \text{ m s}^{-1}$, (b) with total sample numbers $< 30\,000$ and (c) not meeting the criteria of the stationarity test described in Foken and Wichura (1996) and, Foken et al. (2004). Data during periods of low turbulence ($< 0.2 \text{ m s}^{-1}$), unrepresentative wind directions and malfunctions of the analysers were filtered out. The annual data coverage, expressed as a percentage of total annual hourly data before filtering, ranged from 76 % to 85 % and after filtering from 57 % to 77 %. Eddy-covariance CO_2 fluxes were calculated following CarboEurope protocols (Reichstein et al., 2005). The protocols prescribed how to deal with block averaging, coordinate rotation, lag-time calculation, density corrections and corrections for the systematic high-frequency loss. Gaps were filled using the online tool developed by M. Reichstein (<http://www.bgc-jena.mpg.de/~MDIwork/eddyproc/upload.php>), and CO_2 fluxes were calculated for 30 min periods.

2.4 Environmental measurements

Both study locations were supersites in the NitroEurope project, which means that fluxes and pools of carbon and ni-

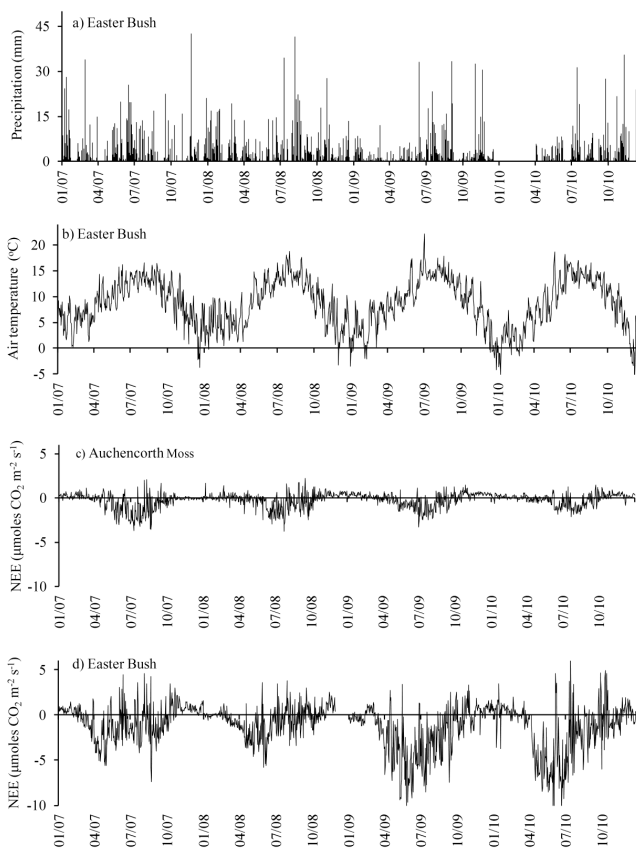

Fig. 1. Daily average air temperature (a) and daily cumulative precipitation at Easter Bush (b). Counterpart data for Auchencorth Moss are not shown as the pattern is almost identical. Daily net ecosystem exchange of CO_2 (NEE) calculated from 30 min averages at Auchencorth Moss (c) and Easter Bush (d).

trogen compounds and meteorological data were measured intensively following a common measurement protocol outlined in Skiba et al. (2009). The measured parameters that caused significant influence on the GHG fluxes discussed in this paper were air temperature, soil temperature, soil heat flux, total solar radiation, photosynthetically active radiation (PAR), net radiation, rainfall, soil moisture and water table height. Average air temperature and cumulative rainfall (using a tipping bucket) were recorded every 30 min from the meteorological stations at both sites. The volumetric soil moisture content at 0.1 m depth was measured using a Theta probe (Delta-T Devices Ltd., Cambridge, UK). In addition water table height was recorded from dip wells (0.04 m diameter) inserted adjacent to each flux chamber at AMo. The moisture and water table measurements were made whenever N_2O and CH_4 fluxes were measured.

Table 2. Annual soil greenhouse gas (GHG) and NEE fluxes ($\text{g CO}_2\text{eq m}^{-2} \text{yr}^{-1}$) from the intensively grazed grassland “Easter Bush” and the extensively grazed moorland “Auchencorth Moss”.

^a Annual fluxes of soil GHG were calculated from monthly averages of eight chamber measurements at Easter Bush and nine chamber measurements at Auchencorth Moss.

^b Standard deviation is the average variation across the chambers.

^c Number of observations is the total number of measurement dates in each year.

^d There are no records of actual sheep numbers; we assumed < 1 ewe ha^{-1} ; CH₄ emissions are $< 0.004 \text{ g CO}_2\text{eq m}^{-2} \text{yr}^{-1}$.

^e Respiration from soil plus small vegetation enclosed by the chamber.

^f Annual fluxes were calculated from gap-filled daily averages of 30 min data.

^g GHG budgets for EBU included CH₄ emissions from ruminant fermentation.

2.5 Statistical methods

Minitab version 16 was used to identify significant correlations between greenhouse gases and climate and soil variables.

3 Results

Rainfall and temperature patterns are very similar at both sites and therefore are only shown for EBU in Fig. 1a and b. AMo is on average 1.2°C colder than EBU and precipitation is 17 % larger, although the inter-annual variability is

larger than the differences between sites (Table 1). The driest year was 2009, with monthly rainfall in February, April and October less than 26 mm at EBU and in February and April less than 31 mm at AMo. In 2007 and 2008 very similar cumulative rainfall was measured between April and September (warm period) and January and March plus October and December (the cold period) at both sites. But in 2009 and 2010 cumulative warm period rainfall was 1.5-fold larger than in the cold period at EBU. At AMo warm period rainfall was 1.2- and 2.1-fold larger in 2009 and 2010, respectively. Neither site receives a lot of snow; and snow accumulation > 50 mm is rare, except in 2010, when snow

disrupted precipitation measurements from 1 January to the beginning of March 2010 followed by no precipitation until beginning of April. Snowfall was estimated from the ratio of precipitation and discharge, recorded at the small burn on AMo not far from the flux measurement site. The warm period average temperatures were almost the same for the 4 yr, $11.9 \pm 0.24^\circ\text{C}$ at EBU and $10.5 \pm 0.24^\circ\text{C}$ at AMo. However, cold period temperatures changed, with highest averages in 2007 (6.4 and 5.29°C in 2007) and lowest in 2010 (4.3 and 2.9 at EBU and AMo, respectively).

Average fluxes of CO_2 respiration and NEE over the 4 yr were three and six times larger at EBU than at AMo, respectively, and soil CH_4 fluxes were five times smaller at EBU than at AMo. Nitrous oxide fluxes were around zero at AMo and two orders of magnitude larger at EBU (Table 2). Spatial variability between the nine flux chambers at AMo and the eight chambers at EBU was very high. Standard deviations calculated as a percentage of the flux for each measurement date at AMo and EBU, respectively, were on average 7 % and 31 % for respiration, 62 % and 121 % for N_2O and 372 % and 372 % for CH_4 flux. Note that for CH_4 the same high variability of 372 % was measured at both sites. Temporal variations, which were also very large for CH_4 , N_2O , NEE and ecosystem respiration are described in detail below.

3.1 Methane fluxes

At AMo CH_4 fluxes ranged from -38 to $+604 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ between January 2007 and December 2010 and the average flux was $+37 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ (Fig. 2a). Methane fluxes correlated significantly with water table height ($p < 0.05$, Fig. 3) and soil temperature at a depth of 0.4 m ($p < 0.05$), but not with soil temperatures at 0.1 or 0.2 m depth, air temperature or cumulative precipitation that fell on the day and 6 days before flux measurements were made. A net CH_4 uptake dominated when the water table was below 0.2 m; then the average flux was $-8 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ with a range from -38 to $+18 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$. When the water table was closer to the surface (< 0.2 m depth), CH_4 emissions prevailed; the average flux was $51 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ with a range of -6 to $+604 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$. Methane fluxes $> +100 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ were only measured when the soil temperature at 0.4 m depth was at and above 10°C , except on one occasion when at 5°C a flux of $+161 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$ was measured.

At the grazed grassland EBU, the average CH_4 flux was 4.5 (range -44 to 113) $\mu\text{g m}^{-2} \text{ h}^{-1}$ (Fig. 2b). On more than 50 % of the measurement dates, fluxes were either negative or smaller than $5 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$. Larger fluxes occurred sporadically, often only in one of the eight chambers. Monthly average CH_4 fluxes correlated with the average daily soil heat flux ($p < 0.05$).

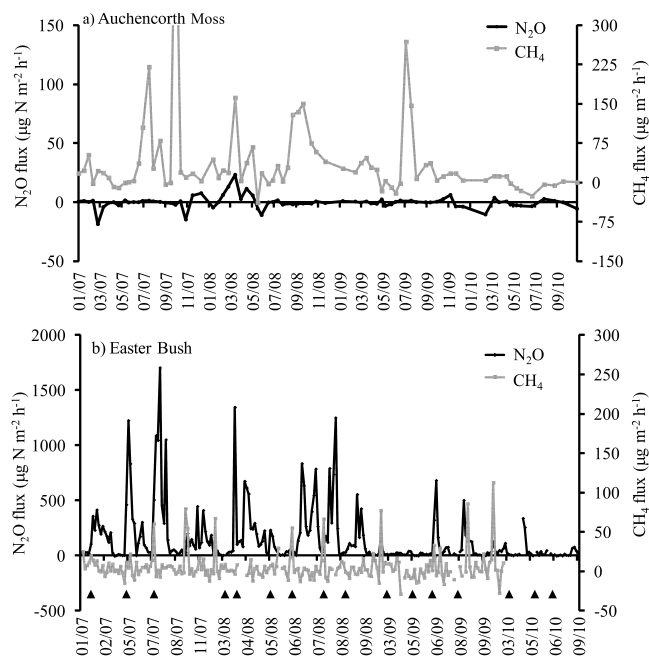

Fig. 2. Variations of CH_4 and N_2O fluxes from the unmanaged, extensively grazed moorland Auchencorth Moss (a) and the N-fertilised, intensively grazed grassland Easter Bush (b). Data are averages from nine chamber measurements at Auchencorth Moss and eight at Easter Bush. Note the different scales for Auchencorth Moss and Easter Bush and for N_2O and CH_4 . X-axes (mm/yy) are scaled by number of measurement, rather than date. Black triangles indicate when N fertiliser was applied at Easter Bush. The “off-scale” CH_4 flux in October 2007 at Auchencorth Moss was $604 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$.

3.2 Nitrous oxide fluxes

At AMo, the average N_2O flux was $-0.14 \mu\text{g N}_2\text{O-N m}^{-2} \text{ h}^{-1}$ (range -19 to $+23 \mu\text{g N}_2\text{O-N m}^{-2} \text{ h}^{-1}$) (Fig. 2a). Correlations between N_2O flux and water table height, air and soil temperature, heat flux or precipitation were not statistically significant.

Over the 4-yr study period, EBU N_2O fluxes ranged from -5 to $1703 \mu\text{g N}_2\text{O-N m}^{-2} \text{ h}^{-1}$ (mean 146, $n = 248$). Mineral N fertiliser applications stimulated N_2O emissions, and most of the large emission peaks seen in Fig. 2b were measured during the first 2 to 25 days after application. Sometimes the fertiliser response was immediate (< 1 day, March, May and July 2007, April and May 2008, and June 2009), and on others there was a delay of 5 (June 2008), 9 (August 2008), 14 (March 2008) and 20 days (March 2010). The fertilisation events in March and May 2009, May and June 2010, did not stimulate measured N_2O emissions significantly. To further investigate these differences, we divided the data set into two groups: (i) average fluxes over the three weeks after fertilisation and (ii) average three-week fluxes for all other dates. N_2O fluxes averaged over

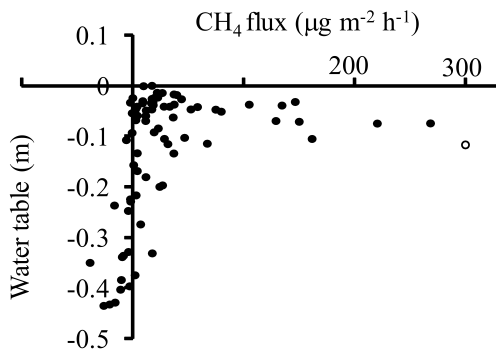

Fig. 3. The influence of water table height on CH₄ fluxes at Auchencorth Moss observed between 2007 and 2010 (data are monthly averages). The “off-scale” CH₄ flux in October 2007 was 604 µg CH₄ m⁻² h⁻¹ and defined by an open circle.

the three-week period after fertilisation were much larger than fluxes averaged over three-week periods not affected by fertilisation (period (i): 205 ± 195 µg N₂O-N m⁻² h⁻¹, range 9.5 to 700, *n* = 16; period (ii): 51 ± 65 µg N₂O-N m⁻² h⁻¹, range -3.4 to 255, *n* = 36). In fertilisation periods (period (i)) N₂O fluxes correlated with the total rainfall that fell within these three weeks. An improved significant correlation (*p* < 0.001) was obtained when the rainfall of the week prior fertilisation was added to the rainfall that fell in period (i) (Fig. 4). Due to different fertiliser application rates (35 to 92 kg N ha⁻¹), N₂O data in Fig. 4 were expressed as percentage of N applied. Smallest emission factors were calculated when the cumulative rainfall was < 55 mm. This was the case for all fertilisation periods in 2010, March and May 2009 and May 2008 fertilisations (Fig. 4). In the three-week fertilisation period (i) N₂O fluxes tended to increase with soil moisture and air temperature, but these trends were not significant. In three-week periods not affected by fertiliser (period ii), N₂O fluxes did not correlate with the cumulative precipitation; however, there was a significant correlation with air temperature (*P* < 0.001).

3.3 Soil and ground cover respiration of carbon dioxide

Respiration measured at AMo and EBU is the sum of soil respiration and that from any vegetation enclosed by the flux chamber. AMo respiration rates ranged from 81 to 694 mg CO₂ m⁻² h⁻¹ at AMo (average 285 mg CO₂ m⁻² h⁻¹), but were around 3-fold larger at EBU (average 1003 mg CO₂ m⁻² h⁻¹, range 98 to 3126 mg CO₂ m⁻² h⁻¹). At both sites monthly ground respiration rates correlated significantly (*p* < 0.001) with air temperature, total solar radiation, net radiation, PAR and NEE (Fig. 5) and with soil heat flux (*p* < 0.01). At AMo, respiration also increased significantly (*p* < 0.001) with increasing daily average soil temperature measured at 10, 20 and 40 cm depth and decreased significantly (*p* < 0.001) with increasing daily average water table height. At EBU respiration rates

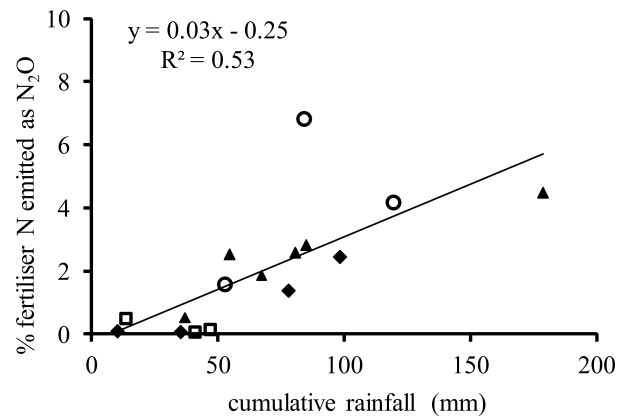

Fig. 4. The role of rainfall in determining N₂O emission rates after N fertilisation. Data are average N₂O fluxes measured in the three weeks after fertilisation (expressed as the percentage of fertiliser N applied) and the cumulative rainfall in the week before plus three weeks after fertiliser application. Different symbol types represent emission factors in 2007 (circle), 2008 (triangle), 2009 (diamond), and 2010 (square).

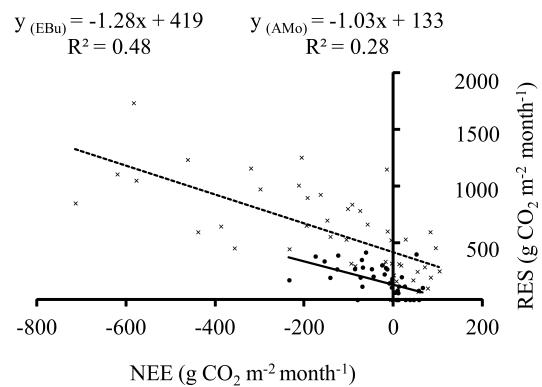

Fig. 5. Relationship between CO₂ respiration (RES), measured by chambers enclosing soil and some of the short vegetation, and net ecosystem exchange of CO₂ (NEE), measured by eddy covariance at Easter Bush (crosses and dotted trend line) and Auchencorth Moss (black circles and black trend line). Data are monthly sums for 2007 to 2010.

tended to decrease with increasing soil moisture, but this correlation was not significant.

3.4 Net ecosystem exchange of carbon dioxide

Net ecosystem exchange of CO₂ followed seasonal cycles (Fig. 1c, d), with CO₂ uptake dominating the flux between April and September at both sites. In the cold period (January–March and October–December) CO₂ was emitted at very small rates (Fig. 1c, d; Fig. 6) with the exception of the cold period in 2009 at Easter Bush when there was a very small net uptake of CO₂ (-17.9 g CO₂ m⁻² 0.5 yr⁻¹). Warm period NEE uptake rates were almost two times larger

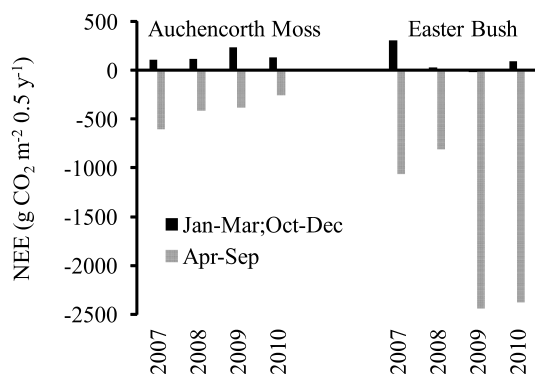

Fig. 6. Cumulative net ecosystem exchange of CO₂ (NEE) for the cold period (January–March and October–December) and the warm period (April–September) at Auchencorth Moss and Easter Bush.

at EBU than at AMo in 2007 and 2008; but six and nine times larger in 2009 and 2010, respectively. Annual fluxes ranged from -125 in 2010 to -498 g CO₂ m⁻² yr⁻¹ in 2007 at AMo and from -758 in 2007 to -2264 in 2010 g CO₂ m⁻² yr⁻¹ at EBU (Table 2).

The NEE of CO₂ correlated significantly ($p < 0.001$) with air temperature, PAR, net radiation and total solar radiation. At AMo NEE increased with decreasing water table height ($p < 0.01$), but a significant relationship between NEE and volumetric soil moisture content at EBU was not observed.

4 Discussion

The comparison of the intensively grazed grassland (EBU) with the extensively grazed seminatural moorland (AMo) was conducted to evaluate the effect of land-use and ecosystem on the seasonal and inter-annual patterns of GHG fluxes. At both sites GHG fluxes were dominated by CO₂ exchange.

4.1 Methane and nitrous oxide fluxes

Methane fluxes at AMo were small compared to those observed in northern peatlands, due to the shallow peat layer and the old drainage system. For example, a recent analysis of CH₄ flux measurements made across different soil types and land-uses in the UK showed that AMo CH₄ fluxes (37 μg m⁻² h⁻¹) were at the top end of the range of CH₄ fluxes reported for mineral soils (17 to 40 μg m⁻² h⁻¹), rather than peatlands (17 to 1580 μg m⁻² h⁻¹) (Levy et al., 2012). The largest CH₄ fluxes in that analysis were recorded from the deep peats in the flow country (Loch More) (peat depth = 4 m), but also from a lowland raised bog, Whim Bog within 2 km of AMo (peat depth = 6 m) (Levy et al., 2012; Carter et al., 2012). Methane fluxes at Loch More and Whim Bog were at least 50 times larger than those at AMo, and were similar to those measured in northern Finland (Drewer et al., 2010; Lohila et al., 2011). This can be explained by the

differences in peat depth, which is a key determinant of CH₄ fluxes, as discussed by Levy et al. (2012).

An interesting observation is that water table and temperature affected CH₄ and N₂O fluxes in the same manner but only significantly for CH₄ (Fig. 3). Both gases were absorbed when the water table was below 0.28 m, and emissions only occurred when the water table was within a few cm of the surface (above 0.07 m). Saturated soils provide the anaerobic conditions required for both methanogenesis and denitrification to operate (Dise et al., 1993; Bakken et al., 2012). In a neutral to slightly acid soil, such as EBU, these conditions would facilitate denitrification to proceed to N₂ and one would expect a decline in N₂O production under water logged conditions. This could not be confirmed, as we did not measure denitrification to N₂ at either site. However, in acid soils such as AMo, N₂O tends to be the end product of denitrification (Bakken et al., 2012).

Soil CH₄ fluxes from the intensively grazed grassland EBU on mineral soil hovered around zero, with small uptake and small emission rates. The occasional larger emissions observed may be due to sheep dropping providing the carbon source and increased anaerobicity during its decomposition to promote methanogenesis.

Nitrous oxide fluxes at Easter Bush showed the typical large spatial and temporal variability common to fertilised grazed grasslands (Jones et al., 2007; Klumpp et al., 2011). In addition to the fertiliser-induced emission peaks, uneven soil compaction and deposition of excreta/urine increased soil heterogeneity even further. Average annual N₂O fluxes in 2007 and 2008 (Table 2) were similar to those measured from the grazed grass clover field in Ireland (542 g CO₂eq m⁻² yr⁻¹, Leahy et al., 2004). However, 2009 and 2010 average annual fluxes were much smaller than the Irish measurements, due to lack of rainfall during the fertilisation period (Fig. 4, Table 2). Fertiliser-induced emission rates are not a uniform fraction of the N applied, as assumed by the Tier 1 IPCC methodology (IPCC, 2006), but depend on rainfall at the time of fertilisation, rate and type of fertiliser, soil and crop type (Cardenas et al., 2010; Ranucci et al., 2011; Klumpp et al., 2011; Flechard et al., 2007). Easter Bush N₂O emissions calculated as a fraction of mineral N input were always larger than the IPCC Tier 1 emission factor; they were 6.5 %, 3.3 %, 1.4 % and 1.4 % in 2007, 2008, 2009, 2010, respectively. Mineral fertiliser-induced N₂O emissions are usually short-lived, and background conditions tend to be established within one to three weeks (Fig. 3 and i.e. Bouwman, 1996). The length of the fertiliser-induced peaks depends on the precipitation amount before and during fertilisation. For EBU, cumulative precipitation one week before plus three weeks after fertilisation correlated with the average N₂O flux during the three weeks after fertilisation better ($r^2 = 0.53$, Fig. 4) than when only considering precipitation during the three-week period after fertilisation ($r^2 = 0.34$). This simple relationship between N₂O flux and precipitation is good news for developing Tier 2 emission factors, and

should be tested for different soil types, crops and climate zones. Fertiliser-induced N_2O emissions from grasslands are not always larger than the IPCC default value. For example, emission factors ranged from 0.3 % to 0.9 % from fertilised semi-natural grassland in France (Klumpp et al., 2011). In a previous study of GHG fluxes from European grasslands, emission factors ranged from 0.01 % to 3.6 % (Flechar et al., 2007). Their sites covered several climate zones and grassland management types, and explaining variation at this scale required a multilinear regression equation based on changes in soil temperature, soil moisture and rainfall.

4.2 Carbon dioxide fluxes: respiration and net ecosystem exchange

The respiration rates reported here are the sum of heterotrophic soil respiration and autotrophic respiration of short vegetation: mosses and small herbs and grasses at AMo and a continuous grass sward at EBU. At EBU respiration measurements included all vegetation present, but at AMo the dominant tall grasses, sedges and heathers could not be included due to the small size of the respiration chamber. Respiration rates increased with increasing air temperature, as also reported by Raich and Schlesinger (1992), but decreased with increasing water table height at AMo and soil moisture at EBU. Jones et al. (2006) reported a bimodal response of soil respiration rates to soil moisture content on a nearby cut grass field on similar soil. When the soil moisture content was below 0.3 m^{-3} , respiration rates increased with increasing moisture; above this rate, soil respiration rates decreased as soils became wetter. The EBU soil moisture contents were usually above 0.3 m^{-3} . Mineral N fertilisation events did not affect soil respiration rates at EBU, and this agrees with Raich and Schlesinger (1992). The synthesis of Schulze et al. (2010) of carbon flux measurements across Europe (CarboEurope IP) included heterotrophic respiration values for the major land cover types. Heterotrophic soil respiration rates from all CarboEurope grasslands were three times larger than from their peatlands. We calculated very similar values with EBU respiration rates being 2.8 times larger than those at AMo. Respiration rates were five to nineteen times larger than the net ecosystem exchange of CO_2 (Table 2), and were not a trivial component of the carbon balance, as also noted by Parkin et al. (2005).

NEE and respiration fluxes for the 2007 to 2010 study period were almost three and six times larger, respectively from the fast growing N fertilised grass sward at EBU compared to the slow growing vegetation on the nutrient-poor moorland AMo (Table 2). Similarly, in 2003 and 2004 EBU NEE fluxes were six times larger than fluxes from grazed semi-natural grasslands in France (Laqueuille) and Hungary (Bugac) (Soussanna et al., 2007). The French and Hungarian flux rates of the Soussanna study were of similar magnitude ($255 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$) to those of this paper's AMo data ($267 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$). Easter Bush average annual NEE

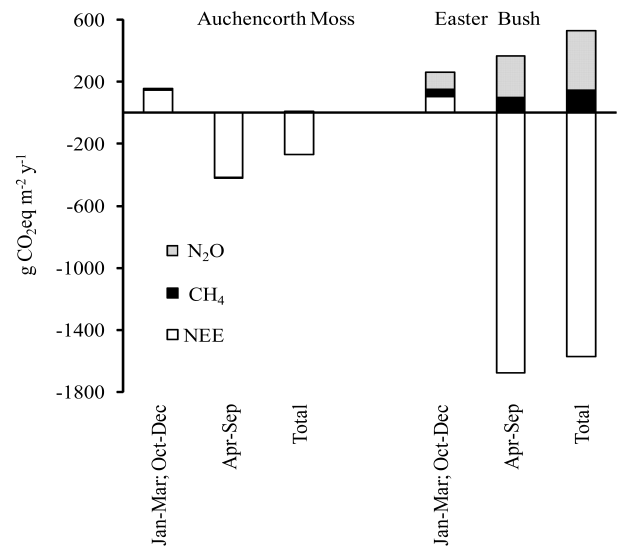

Fig. 7. Greenhouse gas budgets for the semi-natural moorland Auchencorth Moss and the intensively grazed grassland Easter Bush. Data are averages over 4 yr (Total) and split into the period when NEE CO_2 was small or positive (January–March and October–December) and the net ecosystem exchange of CO_2 (NEE) uptake period (April–September). At Auchencorth Moss N_2O fluxes are too small to be visible and the small CH_4 fluxes are only visible as a slightly thicker black line.

fluxes in 2007 and 2008 ($771 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$) were smaller and in 2009 and 2010 ($2363 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$) larger compared to NEE fluxes measured from two Irish grasslands: a grazed grass clover sward ($1074 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$; Soussanna et al., 2007) and a grazed grassland (99 % *Lolium*) ($945 \text{ g CO}_2 \text{ m}^{-2} \text{ yr}^{-1}$; Leahy et al., 2004).

Substantial differences in CO_2 uptake rates were observed during the growing seasons of 2007/2008 and 2009/2010 (Table 2). There is no reason to believe that a systematic bias was introduced between the years 2008 and 2009 as the eddy-covariance measurement system was neither modified nor moved and the analysis routine remained the same. However, environmental and management conditions were slightly different in 2009 and 2010 compared to 2007 and 2008. Total annual rainfall, and that in the warm and cold periods, was lower in 2009 and 2010 compared to 2007 and 2008 (Table 1), but rainfall distribution and number of days with precipitation $< 5 \text{ mm}$ during the growing period (April to September) did not change. Air temperature patterns did not differ significantly, but there was a rise in total solar and net radiation (both by 11 %), PAR (16 %) and a 17-fold increase in soil heat flux. Most importantly sheep stocking densities declined over the years and fell to 25 % and 40 % of their 2007 levels for the April to September periods, which correspond approximately to the annual growing season. It is likely that the changes in NEE observed in 2009 and 2010 were caused by the partial removal of a source of CO_2 (the

sheep) rather than a significant change in uptake or the introduction of a methodological bias.

4.3 Greenhouse gas budgets

Greenhouse gas budgets were calculated using the 100-yr horizon global warming potential of 25 for CH₄ and 298 for N₂O (IPCC, 2007) (Fig. 7). We only included on-field biological production and consumption processes including livestock CH₄ emissions from fermentation. Dengel et al. (2012) measured CH₄ emissions by eddy covariance from the herd at EBU between March and October 2010 and calculated a CH₄ emission factor of 7.4 kg CH₄ sheep⁻¹ yr⁻¹. This measured emission factor is very similar to the IPCC default emission factor of 8 kg CH₄ sheep⁻¹ yr⁻¹. Using the measured emission factor, we calculated that sheep contributed a further 147 g CO_{2eq} m⁻² yr⁻¹ to the average annual GHG budget at EBU and less than 0.01 g CO_{2eq} m⁻² yr⁻¹ at AMO.

NEE of CO₂ provided the largest term in the annual GHG budgets at Auchencorth Moss and Easter Bush (Table 2). At AMO CH₄ and N₂O emissions counteracted the NEE sink strength by 2.8 % and 0.3 %, respectively, and the average 4-yr GHG budget thus was -260 g CO_{2eq} m⁻² yr⁻¹. Inter-annual variations (Table 2) were mainly caused by variations in NEE during the growing period, April to September (Fig. 6). In contrast, fertiliser use and sheep grazing significantly impacted the NEE sink at EBU. Fertiliser-induced N₂O emissions reduced the NEE sink strength by 25 % and ruminant CH₄ emissions by 10 %. The 4-yr-average GHG budget was -1034 g CO_{2eq} m⁻² yr⁻¹, and thus almost four times larger than at AMO. Inter-annual variations were mainly influenced by variations in NEE during the growing period and variations in N₂O due to variations in precipitation at times of fertiliser application. In 2007 and 2008 large N₂O emissions, large sheep populations, hence large ruminant CH₄ fluxes, negated all or most of the CO₂ uptake. Similar observations were made by Leahy et al. (2004).

5 Conclusions

The GHG budget of a drained acid moorland (Auchencorth Moss) was found to be dominated by net ecosystem exchange of CO₂; CH₄ and N₂O fluxes were insignificant by comparison and were only emitted when the water table was close to the surface. For an intensively grazed fertilised grassland (Easter Bush), CO₂, CH₄ and N₂O contributed significantly to the overall GHG balance. Precipitation before and during fertilisation periods correlated with N₂O emissions. Frequent rainfall events, as commonly experienced in NW Europe, together with a high ruminant stocking density can significantly reduce the GHG sink or turn the sink into a source, as seen here for 2007 at Easter Bush. High productivity facilitated by fertilisation resulted in much larger CO₂ uptake rates on the grassland during the growing season than on the

acid moorland. However, this positive effect of CO₂ uptake was greatly reduced by large CH₄ and N₂O emissions.
