Abstract. Local and global bifurcation structure of the forced Lorenz model in the $r-F$ plane is investigated. The forced Lorenz model is a conceptual model for understanding the influence of the slowly varying boundary forcing like Sea Surface Temperature (SST) on the Indian summer monsoon rainfall variability. Shift in the probability density function between the two branches of the Lorenz attractor as a function of SST forcing is calculated. It is found that the one-dimensional return map (cusp map) splits into two cusps on introduction of forcing.

1 Introduction

Rainfall over India varies both in space and time during the Summer monsoon season and the large-scale rainfall oscillates aperiodically between active spells with good rainfall and weak spells with little rainfall. Typically the transition time between active and weak spells is shorter than the residence time (few weeks) of the spells themselves. Ramamurthy (1969) and Sikka and Gadgil (1980) conducted an exhaustive analysis of the daily rainfall over India and related the active/break periods to location of monsoon trough. Although rainfall is one of the most highly variable quantities, both in observations and in model simulations, seasonal mean rainfall anomalies are largely determined by the sea surface temperature (SST) (Shukla, 1998). The influence of the slowly varying boundary forcing like SST is to bias the system towards more active/break regimes thus altering the shape of the probability density function.

Because of the interaction between atmosphere and ocean, the SST of the Indian and Pacific Oceans may influence the variability of the Indian monsoon and in turn, the monsoon winds and rainfall may affect the variability of the SST of the referred oceans. This mutual interaction introduces the possibility that the monsoon and the oceans form a coupled

climatic system (Webster and Yang, 1992). However, the Indian monsoon rainfall is understood to have a stronger relation with the Pacific Ocean SST than with the Indian Ocean SST.

The lower boundary conditions like SST are less chaotic and therefore can lend partial predictability to the atmosphere. Charney and Shukla (1981) proposed that the seasonal monsoon rainfall over India although being one of the most highly variable quantities, has potential predictability, because it is forced by the slowly varying boundary conditions such as sea surface temperature (SST), soil moisture, sea ice and snow. There are several studies, both observational and modelling indicating that the interannual variability of Indian summer monsoon (JJAS) rainfall is linked to the SST variation in Pacific (Rasmusson and Carpenter, 1983; Mooley and Parthasarathy, 1983; Ju and Slingo, 1995; Soman and Slingo, 1997). The SST has a strong influence on atmospheric dynamics, while it itself remains coherent over large spatial scales. It varies slowly on time-scales of individual weather events, but it is not constant from year to year. In particular, it is known that year-to-year variations in tropical Pacific SST associated with the El Niño/Southern oscillation event have a strong influence on the inter-annual variations in the monsoon.

The monsoon region has a dominant intraseasonal fluctuation with periodicity of 30–50 days (Sikka and Gadgil, 1980; Yasunari, 1980; Krishnamurthy and Sybramaniyam, 1982). Large-scale rainfall over the Indian region is associated with the so-called “Inter-tropical convergence zone” (ITCZ), a region where lower tropospheric winds are convergent. For Indian longitudes, ITCZ may be located over the heated continent, leading to active monsoon phase, or over the equatorial Indian Ocean, leading to break phase.

The Lorenz model (Lorenz, 1963) has been widely used as a conceptual model for predictability studies in meteorology (Palmer, 1993a, 1993b, 1994, 1998; Corti et al., 1999; Sparrow 1982; Tsonis, 1992; Evans et al., 2004; Yadav et al., 2005).

It has been shown by Sikka and Gadgil (1980) that the probability distribution function of the ITCZ is bimodal. To be specific, one may assume that the positive x - y regime in the Lorenz attractor corresponds to the oceanic ITCZ with reduced monsoon rainfall, and that the negative x - y regime corresponds to the continental ITCZ with the enhanced monsoon rainfall.

Motivated by the above observations, Palmer (1994) introduced constant “forcing” terms in the Lorenz (1963) equations to put forward a paradigmatic model for discussing long-range monsoon predictability. In this model, the “forcing” terms correspond to the tropical Pacific SST anomaly. The two branches of the forced Lorenz attractor correspond to the two regimes of active and weak spells of the monsoon.

In the absence of forcing, both the branches are equally likely. When forcing is introduced, the probability of the state lying in one of the branches is greater than that in the other branch. Palmer (1994) has hypothesised that slowly varying boundary conditions change only the nature of the intraseasonal variability. He suggested that Summer monsoon evolves nonperiodically between the regimes of active and the break phases. The seasonal mean rainfall is determined by the bimodal probability distribution function (PDF) of rainfall, depending on the frequency and length of active and break periods. The spatial patterns of the interannual variability of the monsoon rainfall, for example, should correspond to those of intraseasonal active and break periods. In an evaluation of NCEP-NCAR reanalysis circulation data, Goswami and Ajaya Mohan (2001) lend support to Palmer’s hypothesis by identifying a mode of variability common to both intraseasonal and interannual time scales and an asymmetric bimodal PDF of active and break conditions.

The forced Lorenz model has been the subject of various studies (Pal, 1996; Pal and Shah, 1999; Mehta et al., 2003; Mittal et al., 2003).

In recent years bifurcation analysis has proven to be an important tool for mathematical analysis and better understanding of the internal dynamics and physics of low order ocean atmospheric models. There are several parameters in the atmosphere and ocean which, when changing beyond a critical value, lead to entire changes of the nature of the system. The need therefore is to identify such parameters and to see how they are affecting the atmosphere when they pass beyond a critical value.

Regular and chaotic behaviour in the Lorenz-84 model, which is a low order general circulation model of the atmosphere (Lorenz, 1984, 1987, 1990) has been studied extensively using bifurcation theory by Masoller et al. (1992) and Sicardi Schifino and Masoller (1996). Masoller et al. (1995) have investigated the dynamics of the Lorenz-84 model of general circulation of the atmosphere by full characterisation of chaotic strange attractors found. A comprehensive bifurcation and predictability analysis of the Lorenz-84 model has been done by Shil’nikov, Nicolis and Nicolis (1995). Roebber (1995) has investigated the dynamical behaviour of the climate system using a low order coupled atmosphere-ocean general circulation model, in order to gain some qualitative

understanding of how nonlinear interactions between the individual system components may affect the climate. Van Veen (2001) has done a detailed study of the baroclinic flow and the Lorenz-84 model.

These studies motivated us to present a mathematical analysis of the forced Lorenz model. We have done the analysis first by varying the forcing along two particular lines in the $F_x - F_y$ plane and then by also varying r along with the forcing F . We have investigated the local and global bifurcation structure of the forced Lorenz model in the $r - F$ plane, where F parameterises a particular line in the $F_x - F_y$ plane. We also study the shift in the probability density function between the two branches of the Lorenz attractor as the forcing (anomalous SST) is changed. We found that by introducing the forcing term, the one-dimensional return map (cusp map) produced by the maximum z values splits into two cusps.

2 Bifurcation analysis of the forced Lorenz model

The system of equations for the forced Lorenz model is:

$$\begin{aligned} \frac{dx}{dt} &= -ax + ay + cF_x \\ \frac{dy}{dt} &= -xz + rx - y + cF_y \\ \frac{dz}{dt} &= xy - bz + cF_z, \end{aligned} \quad (1)$$

where $a=10$, $b=8/3$ and $r=28$.

The $(x, y, z) \rightarrow (-x, -y, z)$ symmetry of the original Lorenz equations (Lorenz, 1963) is lost in the forced Lorenz system.

The transformation $z = z' + (\frac{c}{b}) F_z$; $r = r' + (\frac{c}{b}) F_z$ clearly tells us that the forcing F_z is equivalent to a shift in the parameter r . Therefore, without loss of generality we study the system

$$\begin{aligned} \frac{dx}{dt} &= -ax + ay + F_x \\ \frac{dy}{dt} &= -xz + rx - y + F_y \\ \frac{dz}{dt} &= xy - bz. \end{aligned} \quad (2)$$

To make the analysis simpler we study here two particularly simple cases:

Case I: $F_x = aF$, $F_y = -F$ and case II: $F_x = aF$, $F_y = -rF$.

In case I, if $F^2 < 4b(1-r)$ there is only one fixed point $O(0, -F, 0)$. For $F^2 > 4b(1-r)$ there are two more fixed points $P_{\pm}(x_{\pm}, y_{\pm}, r-1)$, where

$$\begin{aligned} x_{\pm} &= \frac{1}{2} \left\{ F \pm \sqrt{\{F^2 + 4b(r-1)\}} \right\} \\ \text{and} \\ y_{\pm} &= \frac{1}{2} \left\{ -F \pm \sqrt{\{F^2 + 4b(r-1)\}} \right\}. \end{aligned} \quad (3)$$

Fig. 1. Fixed points P_+ and P_- for $a=10$, $b=8/3$, $r=28$ (a) $F=0$, $P_+=(8.4853, 8.4853, 27)$ and $P_-=(-8.4853, -8.4853, 27)$; (b) case I, $F_x=aF$, $F_y=-F$, $P_+=(8, 9, 27)$ and $P_-=(-9, -8, 27)$; and (c) case II, $F_x=aF$, $F_y=-rF$, $P_+=(8.4853, 8.6353, 27.4773)$ and $P_-=(-8.4853, -8.3353, 26.5227)$.

The fixed points P_+/P_- represent a state of continuous rainfall/complete absence of rainfall. They are shown in Fig. 1a for no forcing i.e. $F=0$, in Fig. 1b for the case I with $F=-1$, and in Fig. 1c for case II with $F=-0.15$.

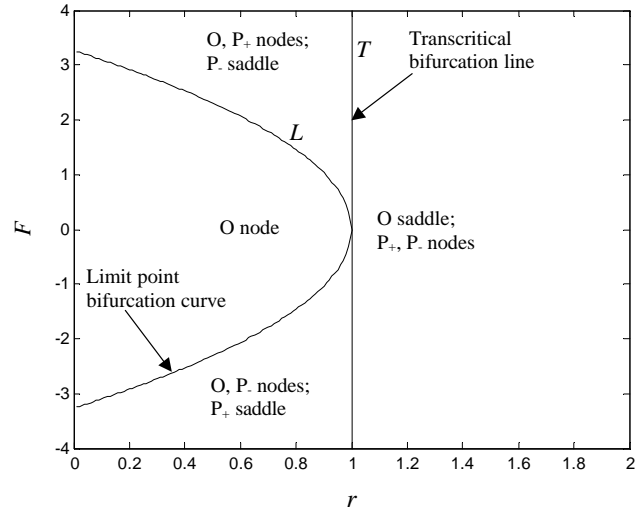

Fig. 2. Bifurcation structure of the forced Lorenz Model in case I, i.e. $F_x=aF$, $F_y=-F$ around $r=1$.

For the case I, the eigenvalues of the linear tangent model matrix at the fixed point O are:

$$-b \text{ and } \left\{ -(a+1) \pm \sqrt{(a+1)^2 - 4a(1-r)} \right\} / 2.$$

For $r < 1$, all the eigenvalues are negative and O is a stable node. One of the eigenvalues is positive for $r > 1$. Hence, for $r > 1$, O is an unstable fixed point. The characteristic equations at the fixed point P_{\pm} are:

$$\lambda^3 + (a+b+1)\lambda^2 + (ab+b+x_{\pm}^2)\lambda + a(x_{\pm}^2 + x_{\pm}y_{\pm}) = 0. \quad (4)$$

Figure 2 shows two curves in the $r-F$ plane (i) L given by $F^2=4b(1-r)$ and (ii) T given by $r=1$. For parameter points to the left of L , there is only one fixed point O . For the region to the right of L , there are two more fixed points P_+ and P_- . Immediately to the right of T , both these fixed points are stable nodes, whereas in the region between L and T , one is a stable node whereas the other is a saddle point. In this region, for $F > 0$, P_+ is a stable node, whereas P_- is a saddle point. For $F < 0$, it is the other way round. We notice that L represents a limit point bifurcation (Thompson and Stewart, 2002), where a node – saddle pair is born. For $F > 0$ ($F < 0$), as T is crossed from left to right, O and P_- (P_+) collide and exchange their stability. Thus, T represents a transcritical bifurcation (Thompson and Stewart, 2002). The curves L and T touch at the point $r=1$, $F=0$. For the unforced Lorenz model, this is a point of pitchfork bifurcation (Thompson and Stewart, 2002). For the two parameter bifurcation considered here this point may be regarded as a codimension 2 bifurcation point (Kuznetsov, 1998) obtained by the touching of the limit point bifurcation and the transcritical bifurcation curves.

For $F=0$, if $a > (b+1)$, as r is increased beyond $r_c = \left(\frac{a(a+b+3)}{a-b-1} \right)$, the equilibrium points P_{\pm} lose their stability via a Hopf bifurcation.

Fig. 3. Plot of F_c vs. r for fixed point P_+ (P_-) in case I, i.e. $F_x = aF$, $F_y = -F$ [P_+ (P_-) is locally stable if $F > F_c$ ($F < -F_c$)].

We define F_c such that if $F > F_c$, P_+ is stable, whereas if $F < -F_c$, P_- is stable.

In Fig. 3, F_c is plotted as a function of r , taking the standard values $a=10$ and $b=8/3$, where $F_c = (a-b-1)(r-r_c) \left(\frac{b}{(b+1)\{a(r-r_s)\}} \right)^{1/2}$ and $r_s = r_c - \left(\frac{b+1}{a} \right) (r_c - 1)$. It is seen that for $r > r_c$, the equilibrium point P_+ (P_-), which was unstable in the absence of forcing, can be made stable by a sufficiently large positive (negative) forcing parameter F . For $r_s < r < r_c$, P_+ (P_-), which is stable in the absence of forcing, can be made unstable by a negative (positive) forcing parameter F of sufficiently large magnitude. For $1 < r < r_s$, the equilibrium points P_{\pm} are stable for all values of the forcing parameter F .

In case II, for $r < 1$, there is only one fixed point at O ($F, 0, 0$). For $r > 1$ there are two more fixed points $P_{\pm}(x_{\pm}, y_{\pm}, z_{\pm})$, where

$$x_{\pm} = \pm\sqrt{\{b(r-1)\}}, y_{\pm} = \pm\sqrt{\{b(r-1)\}} - F$$

and

$$z_{\pm} = (r-1) - \left(\pm F \sqrt{\left\{ \frac{(r-1)}{b} \right\}} \right). \tag{5}$$

The characteristic equation at the fixed point O is given by

$$\lambda^3 + (a+b+1)\lambda^2 + (ab+a+b-ar+F^2)\lambda + ab(1-r) + aF^2 = 0. \tag{6}$$

The equilibrium point O becomes stable, if $F > F_c$ or $F < -F_c$, where

$$F_c^2 = \begin{cases} b(r-1) & , \text{ for } 1 < r < r' \\ \max [a(r-r'), b(r-1)] & , \text{ for } r' < r < r'' \\ \max [a(r-r'), b(r-1)] & , \\ \left(\frac{a(a+1)(r-r'')}{(b+1)} \right) & , \text{ for } r > r'' \end{cases} \tag{7}$$

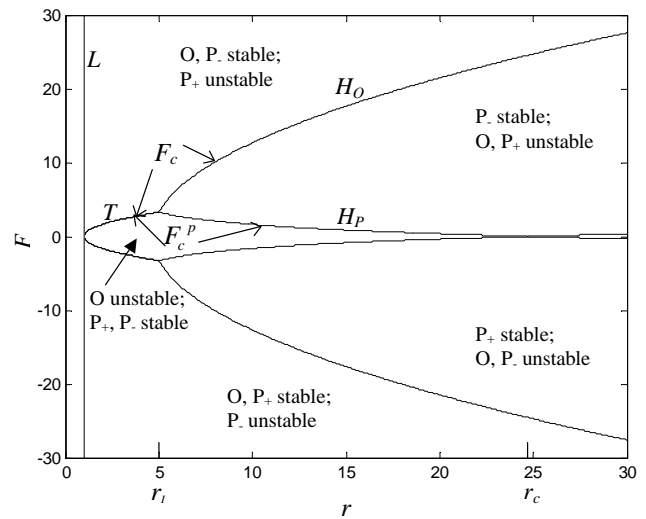

Fig. 4. Bifurcation structure of the forced Lorenz Model in case II, i.e. $F_x = aF$, $F_y = -rF$ around $r=r_I$. Here, O is locally stable if $F > F_c$ or $F < -F_c$ and P_+ (P_-) is locally stable if $F < F_c^p$ ($F > -F_c^p$).

where $r' = \left[1 + \left(\frac{b(a+1)}{a} \right) \right]$ and $r'' = \left[1 + \left(\frac{b(a+b+1)}{a} \right) \right]$.

The fixed point O in case II becomes stable for sufficiently large values of the forcing parameter magnitude unlike the case I where the fixed point O remains unstable for $r > 1$.

The characteristic equations at fixed point P_{\pm} of case II are:

$$\lambda^3 + (a+b+1)\lambda^2 + \left\{ ab+b+a(1-r+z_{\pm})+x_{\pm}^2 \right\} \lambda + a \left\{ b(1-r+z_{\pm})+x_{\pm}^2+x_{\pm}y_{\pm} \right\} = 0. \tag{8}$$

Necessary and sufficient condition for all roots of the Eq. (8) to have negative real parts is: $|F| < F_c^p$, where F_c^p is given by

$$F_c^p = \min \left[\left(\frac{b^{3/2}(a+r)}{a(r-1)^{1/2}} \right), [b(r-1)]^{1/2}, \left(\frac{b^{3/2}}{a} \right) \left(\frac{r_c-r}{(r-1)^{1/2}} \right) \left(\frac{a-b-1}{a-b+1} \right) \right]. \tag{9}$$

The condition (9) reduces to $F < F_c^p$ at P_+ , and to $F > -F_c^p$ at P_- .

Figure 4 shows a plot of F_c from Eq. (7) and F_c^p from Eq. (9) as a function of r , taking the standard values $a=10$ and $b=8/3$ along with their mirror images $-F_c$ and $-F_c^p$. We notice that the curve T is common to both F_c and F_c^p . For $F > 0$, as one crosses the line L ($r=1$) from left to right, the point O remains a stable node, whereas a saddle node pair P_+, P_- is born. Thus L is a line of limit point bifurcation. On crossing the curve T , O and P_+ collide and exchange stability. Thus curve T is a codimension 1 transcritical bifurcation curve at which one of the eigenvalues vanishes. Curves H_O and H_P are co-dimension 1 Hopf bifurcations at which a pair of pure imaginary eigenvalues exists for the fixed points

Fig. 5. Bifurcation structure of the forced Lorenz Model in case I, i.e. $F_x = aF$, $F_y = -F$.

Fig. 6. Bifurcation structure of the forced Lorenz Model in case II, i.e. $F_x = aF$, $F_y = -rF$.

O and P_+ (or P_-), respectively. The point of intersection of these curves at $r_I = \frac{a(1+b)}{(a-b)}$ is a codimension 2 bifurcation point (Kuznetsov, 1998).

It is seen that for $r > r_c$, the equilibrium point P_+ (P_-), which was unstable in the absence of forcing, can be made stable by a sufficiently large negative (positive) forcing parameter. For $1 < r < r_c$, P_+ (P_-), which is stable in the absence of forcing, can be made unstable by a positive (negative) forcing parameter of sufficiently large magnitude.

It is naturally of interest to know whether there is a parameter range of F for which there is a co-existence of a strange attractor and a stable fixed point in the forced Lorenz model similar to the Lorenz model when the parameter r has values in the interval $24.06 < r < 24.74$ (Sparrow, 1982). To answer this question we surmise that when a strange attractor co-exists with one or more stable fixed points, the unstable manifold of the fixed point O belongs to the basin of the strange attractor (Alfsen and Froyland, 1985). For a given set of parameter values, if the orbit of a point close to the unstable fixed point on the unstable manifold does not converge to P_+ or P_- in 2×10^5 time steps, we assume that it is attracted to the strange attractor, where we have used a time step of 0.01. In this way, the parameter space $r-F$ is divided into distinct regions as shown in Fig. 5 for case I.

These regions are distinguished by the following properties:

Region S.A.: There exists a strange attractor. None of the fixed points is locally stable (For large values of r , stable periodic orbits are expected to exist, but this has not been investigated).

Region I: There exists a strange attractor. The fixed point P_+ is locally stable. The unstable manifold of O belongs to the basin of attraction of the strange attractor.

Region II: There exists a strange attractor. The fixed point P_- is locally stable. The unstable manifold of O belongs to

the basin of attraction of the strange attractor.

Region III: There exists a strange attractor. Both the fixed points P_+ and P_- are locally stable. The unstable manifold of O belongs to the basin of attraction of the strange attractor.

Region IV: The fixed point P_+ is stable. The unstable manifold of O belongs to the basin of attraction of P_+ .

Region V: The fixed point P_- is stable. The unstable manifold of O belongs to the basin of attraction of P_- .

Region VI: The fixed points P_+ and P_- are locally stable. An orbit starting at a point O^- (O^+), which is slightly left (right) of O on the unstable manifold of O , will converge to P_+ (P_-).

Region VII: The fixed points P_+ and P_- are locally stable. The unstable manifold of O belongs to the basin of attraction of P_+ .

Region VIII: The fixed points P_+ and P_- are locally stable. The unstable manifold of O belongs to the basin of attraction of P_- .

Region IX: The fixed point P_+ and P_- are locally stable. An orbit starting at a point O^- (O^+), which is slightly left (right) of O on the unstable manifold of O , will converge to P_- (P_+).

As one enters region VI from the left, one encounters a homoclinic orbit to the saddle point O . As the saddle quantity (Kuznetsov, 1998) at this bifurcation is positive, by Shil'nikov theorem, this homoclinic orbit bifurcates into a unique saddle limit cycle in region VI. The size of this limit cycle diminishes and eventually vanishes as one approaches the F_c ($-F_c$) curve at which P_+ (P_-) becomes locally unstable. Prior to that in region III, there is a co-existence of the strange attractor and the stable fixed points P_+ , P_- . The attractor basins of these are delimited in phase space by the saddle limit cycles, which are a continuation of those created at homoclinic bifurcation. This region may show hysteretic behaviour. As one moves from left to right in this region if

Fig. 7. The zoomed portion of the box region in Fig. 6 for case II, i.e. $F_x = aF$, $F_y = -rF$.

Fig. 8. Plot of p_+ vs. forcing parameter F for case I, i.e. $F_x = aF$, $F_y = -F$.

the system lands at a fixed point, which loses its stability on encountering the right hand boundary of region III then the system may land on the strange attractor if the unstable manifold of the fixed point collides with the strange attractor. On returning back to region III from right to left the system will remain on the strange attractor.

The bifurcation diagram for case II has also been obtained using the same process and is shown in Fig. 6. The zoomed portion of the box region in Fig. 6 is shown in Fig. 7. The regions shown in this figure are distinguished by the following properties:

Region S.A.: Same as in case I.

Region I–V: Same as is case I.

Region VI: The fixed points P_+ and P_- are locally stable. The unstable manifold of O belongs to the basin of attraction of P_+ .

Fig. 9. Plot of p_+ vs. forcing parameter F for case II, i.e. $F_x = aF$, $F_y = -rF$.

Region VII: The fixed points P_+ and P_- are locally stable. The unstable manifold of O belongs to the basin of attraction of P_- .

Region VIII: The fixed points P_+ and P_- are locally stable. An orbit starting at a point O^- (O^+) which is slightly left (right) of O on the unstable manifold of O , will converge to P_+ (P_-).

Region IX: The fixed point P_+ and P_- are locally stable. An orbit starting at a point O^- (O^+), which is slightly left (right) of O on the unstable manifold of O , will converge to P_- (P_+).

Palmer (1994) has observed in the forced Lorenz model that the effect of the forcing is not so much to shift the attractor, as to shift the probability distribution function between the two branches of the Lorenz attractor. The probability of finding a point in the $x > 0$ half-space (active spell), i.e. p_+ for the case I is shown in Fig. 8 as a function of forcing parameter F (SST anomaly). Similarly, for case II, the probability of finding a point in the $x > F$ half-space (p_+) as a function of F is shown in Fig. 9. In Fig. 8, the probability of finding a point in the $x > 0$ ($x < 0$) half-space is the probability of occurrence of active (break) spell of the Indian summer monsoon.

For $r=28$ and for different values of the forcing parameter F , we determined the probability of finding a point in $x > 0$ half-space for case I and $x > F$ half space for case II from 10^5 iterations using a time step of 0.01, out of which the first 20 000 points were discarded. For each value of F , initial values were randomly chosen ten times. The probability p_+ was obtained from ensemble average for these ten cases and the error bar from the standard deviation.

We applied the results of our analysis on standard deviation of NINO3 index JJAS seasonal anomaly and the IMR index JJAS seasonal anomaly for 21 years from 1980–2000. NINO3 index is the sea surface temperature anomaly averaged over the area (150° W– 90° W, 5° S– 5° N) in the eastern Pacific (in K) and IMR index is the rainfall anomaly averaged

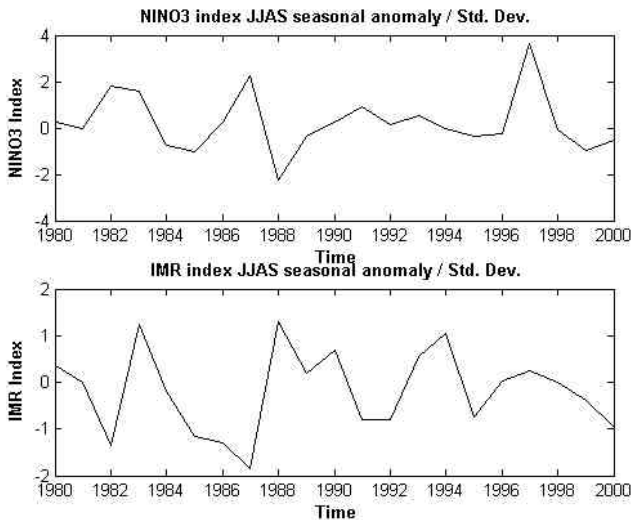

Fig. 10. Standard deviation of NINO3 and IMR index JJAS seasonal anomaly time series for 21 years from 1980–2000.

over all India land points (in mm/day). These time series are shown in Fig. 10.

We assume that the highest value of standardized NINO3 Index (seasonal anomaly/std. deviation), which is 3.65 in 1997, is equivalent to a forcing $F=1.5$ of the case I in forced Lorenz model. In this way, we calculated the value of F for other years by linear scaling. We then calculated the corresponding probability (p_+) for all the years. It has generally been observed that NINO3 index and IMR index are negatively correlated i.e. warmer SSTs in central and eastern parts of equatorial Pacific are associated with lower monsoon rainfall (Angell, 1981; Khandekar and Neralla, 1984; Slingo, 1997). We got a similar correlation between probability and IMR index. The value of the correlation coefficient that we obtained in both the cases is -0.2 .

In an attempt to understand/predict the shift in probability distribution function, we study the effect of forcing on the maxima in z one-dimensional return map (also known as the Lorenz map). It is found that the single cusp obtained in the absence of forcing splits into two cusps on introduction of forcing. The Lorenz maps for $F=0$ and $F=-1$ for case I are shown in Figs. 11a and 11b. Cusp map provides a simpler picture of when the transition from one regime to another of the forced Lorenz model takes place. The $z_{\max}(n+1)$ vs. $z_{\max}(n)$ map is a double valued map, but it is possible to prescribe a heuristic rule by which one can decide which of the two branches is to be chosen. According to this rule, a transition from left hand side of a cusp will be to the same cusp, whereas a transition from the right hand side of a cusp will be to the other cusp. Figure 11b shows how this rule is applied to select the branch at each stage of the iteration. The two cusps correspond to the two regimes. Each point on cusp A (B) corresponds to the regime $x > 0$ ($x < 0$). The point 1 in the figure is on the left branch of cusp A, so for determining its image, cusp A value of the double-valued map will be

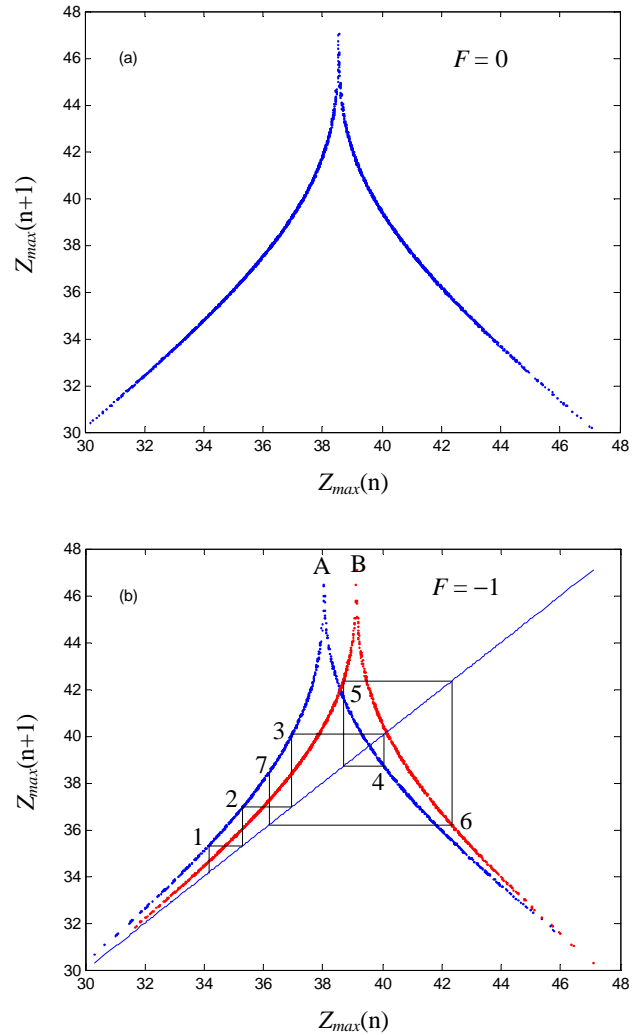

Fig. 11. Lorenz map of the forced Lorenz model without forcing ($F = 0$) and with forcing $F_x = aF$, $F_y = -F$, $F = -1$.

chosen to get the point 2. Subsequent images will be points 3 and 4. Points 4 is on the right branch of cusp A, so a regime transition will take place and the cusp B value of the double-valued map will be chosen giving rise to point 5. Point 5 being on left branch of cusp B its image will be on cusp B. As point 6 is on right branch of cusp B, its image (point 7) is on cusp A.

3 Conclusions

We found that there is no interest in varying F_z , as it is equivalent to a change in the parameter r . We studied the forced Lorenz in detail in the $r-F$ plane for two different cases. First, when the forcing function lies along a particular straight line in the F_x-F_y plane for which $(0, -F, 0)$ is a fixed point (case I) and then, when forcing function lies along another straight line for which $(F, 0, 0)$ is a fixed point (case II). Bifurcation analysis is done here to see the effect of con-

stant sea surface temperature forcing F in the forced Lorenz model. The local and global bifurcation structure in the $r-F$ plane has been studied. We see here that the nature of the system entirely changes as SST forcing is varied beyond a critical value F_c . One of the two symmetric fixed points which lose stability via a sub-critical Hopf bifurcation at a critical value r_c (Sparrow, 1982) becomes stable, if $F > F_c$ and the other becomes stable if $F < -F_c$. It is found that the probability distribution function remains linear for small values of the forcing parameter F and suddenly approaches unity near a critical value of the forcing thus representing a state of continuous rainfall/complete absence of rainfall. The cusp shaped Lorenz map (Sparrow, 1982) splits into double cusp map for small values of the forcing.

Advancement of monsoon trough towards the Bay of Bengal is found to correspond to a dry spell, while its recession towards the foothills of Himalayas denotes a good wet spell (Sikka and Gadgil, 1980). The mathematical model presented here can be of relevance for understanding this phenomenon as well, by treating the forcing function as representing the rate of advancement of monsoon trough towards the Bay of Bengal/foothills of Himalayas.

Though the conceptual forced Lorenz model is too simple to be used directly for the study of monsoon predictability, the bifurcation analysis of the forced Lorenz model presented here may help us understand the influence of slowly varying SST forcing on the Indian summer monsoon rainfall and thus it may provide a better understanding of the dynamics and probability of occurrence of active and break spells of the Indian summer monsoon.

The best defence of potential utility of conceptual models is to remind of the success of Feigenbaum's study of the one-parameter (analog of Reynold's number) family of Logistic Map. It not only gave qualitative insight into period doubling route to chaos, but also gave the concept of quantitative universality.

Acknowledgements. The authors thank M. N. Saha Centre of Space Studies and K. Banerjee Centre of Atmosphere and Ocean Studies, University of Allahabad for supporting this work and extending its facilities. Thanks are also due to the reviewers whose helpful suggestions led to substantial improvement of the paper.
